While approaches to ML-aided everyday diagnostics based on unstructured data have proven rather difficult – exemplified by IBM's Watson Health with the exception of Watson for Genomics [62] – approaches based on structured data such as genomics or transcriptomics data have demonstrated substantial progress in the field. Especially research into disease classification and biomarker identification has profited from ML in recent years.

The investigation of machine learning methods for disease subtype discovery and disease classification is prompted by the heterogeneity in the way in which many diseases manifest in patients, which is also mirrored in individual transcriptomic and genetic profiles. This entails that not all individuals that suffer from the same disease respond adequately to a given treatment. Machine learning techniques have been applied in order to identify subgroups of diseases in different patients to allow a more tailored treatment strategy and to gather insight into the molecular differences of disease specifications.

Already in the very first study that exemplified how high-dimensional gene expression data could be used with machine learning algorithms [2], leukemia has been a prime use case for both class discovery and class prediction and many subsequent studies have dealt with transcriptomic data from hematologic malignancies. Studies using unsupervised machine learning algorithms have identified clinically relevant subtypes and signatures [18–20, 22, 63] that are predictive of disease outcome and severity. The WHO classification of hematologic malignancies distinguishes multiple subtypes of AML that take into account cytogenetic and molecular characteristics [64], however, complete AML diagnosis and risk assessment remains limited within current diagnostic pipelines. A recent study by Arindrarto et al. [65] proposes a comprehensive whole transcriptome sequencing-based pipeline which could be used as a comprehensive platform for

differential AML diagnosis. Furthermore, primary diagnosis of acute myeloid leukemia has been shown to be feasible in a near-automated and low-cost machine learning setting based on transcriptomic data which is also robust concerning the used machine learning algorithm [1].

Disease subclassification has furthermore been performed in various other studies that dissected disease heterogeneity. Random Forest and Support Vector Machines were used to stratify patients suffering from systemic lupus erythematosus [12] and Ebola virus [10], Random Forest and Functional Trees enabled the classification of different states and stages of Multiple Sclerosis [7].

Another research focus that often goes hand in hand with subtype detection and disease classification is the development of biomarker panels. Finding a set of biomarkers specific to a disease allows for a faster diagnosis or a timely prediction of disease progression and therefore makes it easier to establish a fitting treatment plan. SVMs and Random Forest have been used in this regard to identify a set of biomarkers indicative of risk for the development of active tuberculosis [66] as well as for the development of a biomarker panel that identifies pancreatic ductal adenocarcinoma (PDAC), which differentiates the disease from chronic pancreatitis and allows for the distinction between patients with better or worse chances of survival [9]. Besides this, boosted decision trees have been used to identify a set of circulating RNAs for the identification of pregnancies at risk of inducing preeclampsia [67], and PCA-based feature extraction has allowed for the determination of a set of genes indicative of the progression of dengue hemorrhagic fever after infection with the dengue virus [8].

Ethical Considerations, Data Security and Federated Learning

Artificial intelligence, and in particular machine learning, relies on large data sets for training, and gathering them is challenging from an ethical, legal, and technical perspective (Fig. 1b).

In the experiment design phase, the selection of data sources and studies can introduce biases, with racial and sex biases among the more common ones, either through over- or under-representation of populations, age-cohorts, selection of controls, and other factors [68, 69]. In particular for rare diseases with little prevalence, creating a balanced data set can be a challenge and the results often lack statistical power or significance [70].

During the recruitment phase, patient consent needs to be adapted to include ML information and questions [71]. Legal frameworks like GDPR [72] in the EU and HIPAA [73] in the USA restrict the use of patient data and require careful planning of data processing steps [74]. All unnecessary personally identifiable information needs to be stripped from the data and pseudonyms are used. Nonetheless, re-identification and linkage attacks remain possible [75, 76]. Model inversion attacks can be exploited to recover training or patient information from models [77].

Medical data is inherently distributed data and sharing data or patient information is against medical traditions. Data generation and collection happens in physicians' offices, hospitals, or in research centers that often do not have the resources for running their own ML studies and the data sets are typically too small to train reliable models. To overcome this, data can be collected in central clouds [78] and processed there, reducing the technical requirements. However, privacy and data sovereignty concerns makes this often infeasible for patient data. Federated AI approaches [79] have been introduced where the data is kept at the source and the central cloud controls the model parameters distribution and merging. This reduces privacy concerns; however, a central single point of failure still exists. Swarm learning [80] is a decentralized approach that replaces all central components. For each epoch, the swarm elects a leader that performs the parameter merging. Participation in the swarm is controlled by blockchain-based smart contracts to ensure all legal requirements.

The success of artificial intelligence in the clinics depends on the acceptance by physicians and patients. Interpreting the output of ML approaches can be difficult if they act like a black box [81]. Some approaches like KNN or

SVMs allow easy understanding of the deciding factors, but other approaches like ANNs do not offer such easy explanations. Here, explainable AI techniques are needed to expose the underlying mechanisms and to build trust in the suggestions from AI systems.

Outlook

The combination of blood transcriptomics and AI methods has great potential to become an integral part of clinical routine. Blood transcriptomics provides a rich feature space, which is particularly suited for predictions in the context of systemic inflammatory conditions, be they infectious or noninfectious, acute or chronic. If trained correctly, without bias and under strict guidelines concerning data security, AI solutions based on strong feature spaces such as blood transcriptomes could become important supportive systems for the decision-making process by physicians. However, AI algorithms to be applied in such scenarios can all be categorized as weak AI, which leaves the final responsibility for treatment decisions and the patient's well-being with the physician. These AI solutions for primary and differential diagnosis of diseases are at the heart of Systems Medicine, which combines cutting-edge technologies of computer science and biotechnology. Without any doubt, the focus in the development of medical AI-systems should be put on technologies that build on and pursue valuable traditions of medicine such as learning from each other and the importance of patient privacy. In this regard, developments such as Swarm Learning that serve both collective learning and data privacy protection need to be fostered. A fruitful interaction between the medical and computer science communities will be an important prerequisite to achieve these goals.

Abstract

People are generating an enormous amount of social data to describe their health care experiences, and continuously search information about diseases, symptoms, diagnoses, doctors, treatment options, and medicines. This data can be used to extract the “social phenotype”

of diseases, i.e., a *subjective and unfiltered picture of perceptions, health conditions, feelings, and lifestyles* of people affected by a given disease, taking into account the experience lived outside the traditional syndromic care and monitoring structures, the symptoms that are perceived as more limiting, the greater or lesser tolerance to drugs. In this chapter we present an innovative approach based on an Auto-ML pipeline to optimize the classification of relevant messages and threads, and on a cooperative deep learning topic detection model, to characterize the social phenotype of

patients affected by widespread diseases, such as diabetes and hypothyroidism.

Keywords

Social phenotype of diseases · Health blogs · Quality of life assessment · Adverse drug reaction · Topic modeling · Topic clustering · AutoML · Cooperative Neural Networks

Introduction

Despite the progress made in understanding a wide range of diseases, the effectiveness of a treatment depends to a great extent on the communication between doctor and patient [1, 2]. *Patient centeredness* in doctor-patient communication has been advocated in many studies (for example, [1, 2]). Patient centeredness has been defined in [3] as “a move away from a disease focus to personalizing care according to patients concerns and preferences, considering the biological, psychological, and social aspects of illness.”

In medical literature, two methods are commonly used to improve the understanding of problems encountered by patients during a treatment: Quality of Life (QoL) assessments, and specific training programs, called “repairs.”

- Quality of Life assessments [1, 4] are survey studies in which questions are posed to patients using interviews and/or questionnaires.
- Repairs [3, 5] are training programs to improve clinicians’ communication mechanisms and develop a shared understanding of a disease experience.

Both these methods, despite their undisputed effectiveness, have also significant drawbacks. The first problem which is common to both approaches is coverage: questionnaires and training programs can be delivered to a limited number of individuals. Furthermore, repair programs are limited by lack of time and resources, while questions posed in QoL assessments often reflect the care-givers’ view of factors that mostly influence the health status, rather than the patient perspective.

In this chapter we propose to complement the aforementioned approaches with a text-mining methodology to extract from health-related forums and social networks a patient-centered perspective of diseases and treatments. Online patient health data is increasing exponentially. Every day, through social networks, search engines, online forums, web sites, mobile applications, IoT devices, etc., people generate an enormous amount of health information [6]. This digital data includes symptoms, medical experiences, bio data, biometric information, web search queries, personal stories and medical records. They represent the footprints of the patients health status and foster large-scale and low-cost analysis of common diseases [7] for many applications, such as syndromic surveillance [8] and adverse drug reactions [9]. Leveraging social data, it is possible to obtain a subjective and unfiltered picture of perceptions, health conditions, feelings and lifestyles of people affected by a given disease, that we name the *social phenotype* of a disease.

Whether the objective is to assess the quality of life of patients affected by a given disease, or their reactions to drugs, characterizing the social phenotype implies the design of accurate tools to extract and analyze the main topics of discussion in health blogs. Towards this aim, we present a framework based on an Auto-ML pipeline to identify and classify social messages and an innovative technique (*Generative Text Compression with Agglomerative Clustering Summarization*, GTCACS) to identify the main topics of discussions. The distinctive feature of our approach as compared with other topic detection models, is that we are able to organize topics in three dimensions: comorbidities and conditions, emotional states, and symptoms. Clustering patients’ messages along these dimensions may provide useful and large scale information to support doctors in quality of life assessments and therapy analysis.

The chapter is organized as follows: In section “[Related Studies](#)” we summarize related literature. Section “[Methodology](#)” presents our framework to the social phenotype of diseases. Next, we describe all the steps of the proposed workflow in more detail. In section “[Data Gathering](#)” we describe the process of data collection from the

selected web forum. Section “[Data Filtering](#)” presents the techniques implemented to filter significant messages from the collection of patients’ threads, and section “[Topic Modeling](#)” provides details on the approach used for topic modeling. In sections “[Evaluation and Experiments](#)” and “[Data Analytics](#)” we perform a quantitative and qualitative evaluation of the proposed methodology, applied to the case of diabetic and hypothyroid patients. Finally, section “[Conclusion](#)” presents a summary of findings and concluding remarks.

Related Studies

Our work is related to two main areas: social analytics for healthcare, and adverse drug reaction.

Social Analytics for Healthcare

More and more often patients search for information about diseases, symptoms, diagnoses, doctors, treatment options and medicines [6, 7, 10, 11]. A recent study states that in 2017, out of the total American social network users, 26% have discussed health information, and, of those, 30% changed behavior based on this information and 42% discussed their current medical conditions (<http://www.pewinternet.org/fact-sheet/social-media/>). According to [11], users who go online to connect with others with similar health concerns, are especially those who have chronic conditions such as high blood pressure, diabetes, and cancer. Frequently, they also search for support from online communities [12]. The increasing availability of this information presents an interesting opportunity to enhance timeliness and efficiency of care. Greaves et al. [7] describe this growing body of information on the Internet as a “cloud of patient experience.” Several studies have shown that it is possible to detect patterns in data gathered from health forums or social networks, in order to support medical decisions or predictions. There is an ample literature that demonstrates the possibility to analyze different types of discussion forums or

blogs for obtaining useful information. For example, [13] present a survey of qualitative research studies. In [14] the authors published studies on content analysis of online cancer communities, considering both qualitative and quantitative approaches. Quantitative methods, based on text mining and machine learning methods (see [15] for a survey), have been mostly concerned with the use of social networks (especially Twitter) for syndromic surveillance, pharmacovigilance and behavioral medicine, like smoke and diet behaviors (among the others, [8, 9]). In these literature reviews on patients’ blogs analytics, the majority of studies concentrate on classification problems. Fewer articles analyze more in detail users’ messages, for example, [16, 17]. In [17] the authors examined approximately 1000 posts from a public Facebook group on multiple sclerosis, manually labeling the main discussion topics and then using the extracted topic-related terms to extend their analysis to a larger sample. Information and awareness was the most discussed topic, followed by event advertising and petitions, fundraising, and patient support. Finally, in [16], the authors analyzed a database of feedback from patients who received healthcare in hospitals across United Kingdom.

Adverse Drug Reaction (ADR)

Pharmacosurveillance is mostly conducted by clinicians, however, as also reported in a recent survey on ADR [18], patients have the tendency to downgrade the severity of their symptoms, especially when involving depression and other psychological conditions. Social media offer the opportunity to obtain a more detailed and “nuanced” vision of patients and how they react to a therapy, the experience lived outside the traditional syndromic care and monitoring structures, the symptoms that are perceived as more limiting and the greater or lesser tolerance to drugs. A number of methods have been proposed to extract, analyze and classify ADR in social media [19–21]. We refer to [18] for an accurate survey. More recently, many ADR classifiers have leveraged deep machine learning methods in combination with NLP techniques. For example, in [22] the authors propose a LSTM architecture

augmented with a transfer learning approach, in which they make use of a pre-trained sentiment model to improve the quality of ADR classification on social media posts. Word embeddings have been widely used to cope with language inconsistencies, thus improving the rate of detected ADR messages (see [23, 24], among the others). Convolutional Recurrent Neural Networks have been shown in [25] to outperform other methods in the task of classifying ADR sentences in Twitter and in a dataset of MEDLINE case reports.

We note that in both application areas, available studies do not address an in-depth analytics of patients' status, as we do. The social phenotype of a disease does not simply consist in classifying positive or negative feelings about the experience of a disease, or detecting the presence of adverse reactions to drugs. Rather, it implies analyzing the main discussion topics around a disease or therapy, use this information for patient stratification into sub-cohorts, and, for each cohort, evaluate patients' nuanced feelings and reactions.

Methodology

Figure 1 summarizes the workflow to extract, filter and process online patients' messages for extracting the social phenotype. Each step is described in detail in sections “Data Gathering,” “Data Filtering,” “Topic Modeling,” and “Data Analytics.”

1. First of all, appropriate sources of data related to a disease d of interest are identified;
2. Subsequently, useful data are gathered from the selected sources and indexed, to build our collection (section “Data Gathering”);

3. Next, patients' messages related with d are extracted from the collection, using an AutoML classification pipeline to fine-tune the process (section “Data Filtering”);
4. Afterwards, patients' messages are analyzed to detect relevant discussion topics (section “Topic Modeling”), using an innovative technique named Generative Text Compression with Agglomerative Clustering Summarization. Detected topics allow to characterize patients' experience according to different dimensions, such as comorbidities, conditions, symptoms, emotional states;
5. Finally (section “Data Analytics”), topics are analyzed along the detected dimensions and according to specific application objectives, to characterize the social phenotype of d . In this chapter we shortly discuss two applications: quality of life assessment of diabetic patients, and therapy analytics for hypothyroid patients.

Data Gathering

As summarized in section “Related Studies” several studies have collected data on ADR and other biomedical applications using popular social media such as *Twitter*, *Facebook*, *Instagram* and *Reddit*. In these social media, health conditions are reported by the users in a single short message using simpler, naive terms [26], since the intent is to share their worries and feelings with other peers (e.g., “*i feel so lethargic hhh maybe if i like ate better and went and made an appt with a pcp and went back on synthroid i would feel idk better*”). We believe that, in order to gain useful insight into a patient everyday experience of a disease, health forums are a better source of information, since

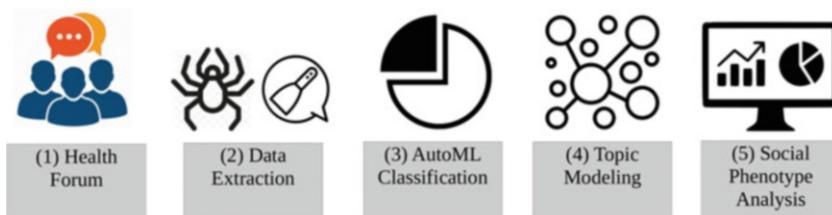

Fig. 1 Process workflow: data sources identification, data gathering, data classification, topics extraction, analysis of the social phenotype of diseases

patients provide more details on their conditions and on the effect of drugs. In health forums, patients engage a conversation with doctors on specific aspects of their health status, to receive advice. Contrary to physical visits, here the conversation is initiated and driven by patients, is centered around their symptoms and worries, and patients feel less intimidated than during a face-to-face medical examination.

Conversation threads are made of several messages and messages are composed by several sentences, written in a (relatively) technical language, since patients strive to use appropriate medical terms with their counterparts doctors. An example of message excerpt involving an ADR is: “*Currently I am taking a eutirox 175 tablet (...). My problem is that for about 4 years and only 6 years after the surgery, I suffer from continuous dizziness (as if I was always in a state of light drunkenness, disorientation, loss of concentration) associated or alternating with muscle pain of the legs (sometimes like the sensation of lactic acid).*”

Although the use of a quasi-technical language may simplify some of the problems often encountered with ungrammatical posts in social media, analyzing health forums is also quite challenging. First, given that threads are often made of several messages and span over different topics and possible comorbidities, identifying relevant messages is far from being trivial. Second, extracting aspect-based features to assess the emotional intensity around a disease experience is more complex in the context of a doctor-patient dialogue than in a short message, since a patient may report issues related to, for example, an adverse drug reaction, in a different phrase or message than the one in which he/she mentions the drug intake.

Data Filtering

After collecting and indexing a suitable number of messages from selected sources, the next step is to filter the information of interest from the collection. In fact, although in health forums threads are often manually classified by the forum curators in

several disease categories (e.g., *thyroid* or *diabetes*), this is not sufficient to identify relevant conversations. The problem is both precision and recall: we observed that often, threads explicitly tagged as related to a disease d were not truly concerned with d , nor with a therapy experience. Conversely, there are threads not tagged as related to d , where patients affected by other diseases mention a comorbidity with d , or mention the intake of d -related medications. Therefore, an accurate classification of health-related threads concerned with a disease d requires a more complex classification phase. To this end, we proceed as follows:

- Step 1: we generate a highly reliable training and test set from a subsample of the collection, by selecting messages with at least 3 highly related keywords identified by a specialist;
- Step 2: we train an optimized classifier using an AutoML pipeline;
- Step 3: we apply the optimized classifier to filter the entire collection, thus obtaining our final dataset of patients’ messages related to d .

In Step 1, based on clinical experience and the online context, we first identify a set of keywords K highly associated with the pathology under study. For example, if $d = \text{thyroid}$, relevant keywords are *euthyrox*, *hashimoto*, *hypothyroid*, *cytomegalovirus*, etc. Usually, about 100–200 keywords can be identified, depending upon the disease and purpose of analysis (e.g.: analyzing the quality of life of d patients, detecting common ADRs, classifying their mental states, and others). To train a classifier, we retrieve from the initial collection all the threads with at least three occurrences in K , and we mark them with the label d (positive examples of threads concerning d). Subsequently, we recover from the entire corpus the threads with not even one occurrence in K , we arbitrarily selected from these threads a sub-sample of messages, and we marked them with the label “other” (negative examples). At the end of this phase, we obtain a highly reliable, although possibly small, labeled set of messages, which constitutes the learning set $L(d)$ of the classifier. As a common practice, $L(d)$

is randomly split into two parts: training set (70%) and test set (30%) (the process can be repeated in k folds, depending upon the dimension of $L(d)$).

In Step 2, we determine the optimal pipeline for the classification task, adopting an automated Machine Learning (Auto-ML [27]) approach based on Sequential Model Based Optimization [28]. An AutoML system is a component that attempts to automate the end-to-end process of a Machine Learning task. It is designed to help machine learning engineers, by automatically searching through the complex space of the learning pipeline and hyperparameter settings, to maximize performance.

Finally, in Step 3 we create the final collection of threads for a disease d using the optimized classification model generated in Step 2. To this end, we consider again all the threads belonging to the entire unfiltered collection, including at least one occurrence of the initial highly related keywords. These messages constitute the “prediction set” P . Subsequently, we generate predictions applying the optimized AutoML classifier on P . Every message $m \in P$ is labeled by the classifier with a probability $p(m)$ of belonging to class d . Since we are more focused on obtaining a highly precise dataset of d -related conversations, rather than a high recall, we consider only those messages in P such that $p(m) \geq 0.9$. This process eventually results in a final collection $C(d)$ of d -related messages.

Topic Modeling

Topic modeling represents a popular technique to learn the thematic structure of large collections of unlabeled documents, without human supervision. It provides a convenient method for dimensionality reduction and exploratory data analysis in vast text bodies. Using contextual evidence, this method can connect words with similar meanings and discover the semantic structure of a collection by examining statistical co-occurrence patterns within a text corpus.

To characterize the therapy and everyday life experience of d patients, we extract the discussion topics that emerge from user messages associated

with the pathology d under study. Toward this aim, we designed a topic detection strategy, Generative Text Compression with Agglomerative Clustering Summarization (*GTCACS*) to identify high-quality discussion topics in the collection.

The proposed *GTCACS* approach is in three steps, detailed below. The *GTCACS* project is available under MIT license and can be downloaded from <https://pypi.org/project/gtcacs/>.

Dimensionality Reduction

Starting from the concept of Energy-based Generative Adversarial Network (EBGAN) suggested by Zhao et al. in [29] and from the architecture proposed by Glover in [30], we developed a model to extract the most significant latent features and learn compressed representations from unlabeled natural language documents in a collection. Generative adversarial networks (GANs) are generative architectures in which two adversarial neural nets, a discriminator and a generator, are trained simultaneously. The discriminator is trained to distinguish real samples of a dataset from fake samples constructed by the generator, while, at the same time, the generator is trained to produce synthetic samples from a random source, in order to train the discriminator to distinguish between the fake generated data and the real data. In the original formulation of GAN (Goodfellow et al. [31]), the discriminator was a probabilistic binary classifier with logistic output, and convergence occurred when the distribution produced by the generator matches the data distribution. More recently, Zhao et al. In [29] propose an innovative model called Energy-based Generative Adversarial Network (EBGAN) that exhibit more stable behavior during training, enabled to implement an extensive variety of Neural Networks architectures and loss functions for the discriminator, and shows higher generative capabilities than regular GANs. In the EBGANs, the generator is trained to produce contrasting samples with minimal energies, while the discriminator represents an energy function (a cost function that maps each point of an input space to a single scalar, which is called “energy”) that is trained to attribute low energies to the “real” data and higher energies to the generated synthetic samples.

Building on the previously illustrated techniques, we propose a model consisting of two neural nets which, instead of acting adversely, are trained simultaneously in a cooperative way. Our model represents a hybrid approach between an EBGAN and a denoising autoencoder and is composed by the followings two networks:

- The generative network learns to produce synthetic documents, with the aim of generating samples that are easily represented by the discriminator and tend to be similar to real data. In our context, a document is represented by a d -related patient's message. The generator has the primary objective of adaptively introducing noise into the training process of the two networks, for regularizing them, and consequently increasing the model's resistance to over-fitting.
- The non-generative network (discriminator) is an auto-encoder. In the first place, it learns how to efficiently compress the input data (both real and synthetic samples) into a lower-dimensional space. Subsequently, it learns how to reconstruct the input data back from the reduced encoded latent space, to a representation that is as close to the original input as possible. As cost function, we adopted the negative value of cosine similarity between the input data and the reconstructed output data.

Let X be a real data sample, $G(Z)$ a synthetic sample generated from a random source Z by the generator, and $D(s)$ the reconstructed sample returned by the discriminator (in our experiments, $G(Z)$ represents a single synthetic message)); then the discriminator loss L_D and the generator loss L_G are formally defined by:

$$L_G(Z) = -\cos_sim\{G(Z), D(G(Z))\} \quad (1)$$

$$\begin{aligned} L_D(G(Z), X) = & -\cos_sim\{G(Z), D(G(Z))\} \\ & - \cos_sim\{X, D(X)\} \end{aligned} \quad (2)$$

The architecture of the model is showed in Fig. 2. Generator and Discriminator were optimized using two separate instances of Adam with a learning rate of 0.005 and a β_1 value of 0.5. The β_1 value was suggested in [32], and, similarly to what reported by the authors, seems to stabilize the training phase in our model. Details on the network structure and hyper-parameters can be found in the previously indicated project link.

Agglomerative Hierarchical Clustering

Once the data samples were reduced to a compressed form containing the essential and most significant features of the text documents, we

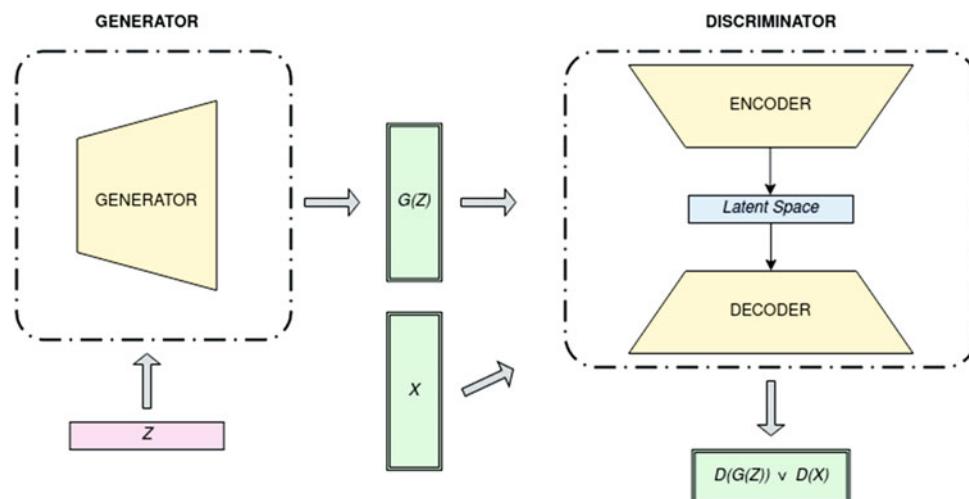

Fig. 2 Architecture of the proposed Cooperative Neural Networks for text compression

proceeded to generate document clusters, based on these representations. We performed various simulations in which we tested several off-the shelf algorithms with different number of clusters, and we evaluated the obtained performance. At the end of this experimental phase, we established to apply agglomerative hierarchical clustering with Ward method [33] as linkage criterion.

Summarization

After determining the groups of highly related documents, we extracted the most representative words for each of these clusters. Specifically, for each subset of documents associated to a single cluster, we extracted the most relevant words for this subset based on a custom weighting scheme. After various empirical tests, for each word w belonging to cluster C , we considered as the relevance score for w in C the ratio between the frequency of the term w within the documents belonging to cluster C and the global frequency of the term w in the whole corpus. In particular, we applied the following formula:

$$\text{relevance_score}(w, C) = \frac{\text{inner_term_frequency}(w, C)}{\sqrt{\text{global_term_frequency}(w)}} \quad (3)$$

Evaluation and Experiments

Dataset and Diseases

For our study, we selected a popular health forum *Medicitalia.it* (presumably the most famous and consulted medical website in Italy) from which to recover conversations related to the selected disease d (<https://www.medicalita.it/consulti/?pagina=1>). It offers medical content, a forum in which users interact with each other and a section dedicated to online medical consultations. This section includes to date more than half a million consultations with answers from at least one doctor. To create a collection of patient-doctor

conversations, we developed a software module for scraping the selected web forum (Note that, due to current *GDPR* regulations on privacy, patient names are not available, nor it is possible to link messages of the same patient in different threads. Furthermore, the text of messages cannot be published.).

To test the proposed framework, we selected 2 diseases and 2 tasks:

- $d1 = \text{diabetes}$, $t1 = \text{quality of life assessment}$
- $d2 = \text{hypothyroidism}$, $t2 = \text{therapy analytics of Levothyroxine}$ (the most common therapy for hypothyroid patients).

We considered diabetic and hypothyroid patients since they are two very common diseases that affect millions of patients around the world. After applying our classification procedure, we obtained 10,388 threads on topics concerning diabetes, and 27,125 thyroid-related threads.

Compared Systems

We compare our GTCACS topic detection techniques with two popular models:

- *Latent Dirichlet Allocation (LDA)* [34]: a generative probabilistic approach for collections of discrete data like text corpora. LDA is a three-level hierarchical Bayesian model, in which each item of a collection is modeled as a finite mixture over an underlying set of topics; while, in turn, each topic is modeled as an infinite mixture over an underlying set of clusters probabilities, that provide an explicit representation of a document.
- *Non-negative Matrix Factorization (NMF)* [35]: a matrix factorization method in which we constrain matrices to be non-negative. NMF represents a tool for analyzing high-dimensional data as it automatically extracts sparse and meaningful features from a series of non-negative data vectors. This technique has an extensive range of uses, from modeling

topics, to dimensionality reduction applications and signal processing.

Evaluation Strategy

To evaluate the quality of the extracted topics, being in an unsupervised context, we adopted the following strategy. Initially, for each extracted topic we considered only the n most relevant words, next we encoded each term in its respective embedding vector, and finally we calculated the quality scores for the obtained clusters based on various evaluation metrics. Word embedding represents a technique where singular words are represented as real-valued dense vectors capable of capturing context of a term in a document, semantic/syntactic similarities and relations with other words. Specifically, we exploited pre-trained word vectors with FastText [36] model for the Italian language (Continuous

Bag Of Words with position weights, size 300 and ngrams characters of length 5).

We selected three metrics widely used for the unsupervised evaluation of clustering and we propose a custom measure, called *quality score*, based on an embedding representation of words in clusters. Below we briefly describe the applied evaluation metrics:

- *quality score (qs)*: In our proposed measure, let $T = \{t_1, t_2, \dots, t_k\}$ be the set of all the k extracted topics, where $t_i = \{v[w_1], v[w_2], \dots, v[w_n]\}$ represents the i -th topic containing the embedding vectors of its top n words; let $centroid(t_i)$ be the vector that represents the multidimensional mean of the word vectors in topic t_i ; let $m \in \mathbb{N}$ and $combinations(S, m)$ be the set that contains all the combinations of size m from the set S , then:

$$\text{quality_score} = \frac{\text{mean}\{\text{intra_topic_sim}(t) | \forall t \in T\}}{\text{mean}\{\text{inter_topics_sim}(t', t'') | \forall (t', t'') \in combinations(T, 2)\}} \quad (4)$$

$$\text{intra_topic_sim}(t) = \text{mean}\{\cos_sim(v[w]', v[w]'') | \forall (v[w]', v[w]'') \in combinations(t, 2)\} \quad (5)$$

$$\text{inter_topics_sim}(t', t'') = \cos_sim(\text{centroid}(t'), \text{centroid}(t'')) \quad (6)$$

- *silhouette score (ss)* [37]: It represents the mean silhouette coefficient of all samples. The silhouette coefficient of the single i -th sample is calculated using the mean intra-cluster distance (a : mean distance between a sample and all other points in the same class) and the mean nearest-cluster distance (b : mean distance

between a sample and all other points in the next nearest cluster).

$$ss_i = \frac{(b - a)}{\max(a, b)}$$

For this measure the best value is 1 and the worst value is -1, while values near 0 indicate overlapping clusters.

- *calinski-harabasz score (chs)* [38]: It is also known as the Variance Ratio Criterion. This

measure is defined as the ratio of between-clusters dispersion (B) and of inter-cluster dispersion (W) for all clusters (dispersion represents the sum of distances squared). Let n the number pf samples and k the number of clusters:

$$chs = \frac{B}{W} \cdot \frac{n - k}{k - 1}$$

A higher Calinski-Harabasz score relates to a model with better defined clusters.

- *davies-bouldin score (dbs)* [39]: It represents the average “similarity” measure between each cluster C_i for $i = 1, \dots, k$ and its most similar cluster C_j . Where, “similarity” is defined as a measure $R_{i,j}$ that represents the ratio between the within-cluster distance (s_i : the average distance between each point of cluster i and the centroid of that cluster) and the between-cluster distance ($d_{i,j}$: the distance between cluster centroids and i and j). For this measure, lower values indicate a better partition, and zero is the lowest possible score.

$$R_{i,j} = \frac{s_i s_j}{d_{i,j}}$$

$$dbs = \frac{1}{k} \sum_{i=1}^k \max_{i \neq j} R_{i,j}$$

Table 1 shows the scores obtained for the thyroid ($d2$) domain. Scores are calculated using the

previously defined metrics for the three compared approaches, varying the selected number of topics and considering the top $n = 100$ words for each topic. In Table 1 bold numbers show the best absolute values for each of the four considered topic validity scores, and varying T . We observe that GTCACS achieves the best performance scores, based on all the selected metrics. Similar results are obtained in the diabetes domain (An extensive study on the social phenotype of diabetes patients has been published in [40].).

Topic Analysis and Subclustering

Starting from the computed scores, and after asking the clinicians to perform a manual analysis on the clusters obtained with GTCACS, we decided to consider $T = 7$ discussion topics in the thyroid domain. With a similar procedure, we selected $T = 14$ topics in the diabetes domain. The list of top 30 words for each topic and each domain can be retrieved from http://iim.di.uniroma1.it/source_spinger.html.

We manually labeled the 14 diabetes topics as follows: *glycemia, hepatology/gastroenterology, gynecology, angiology, cardiovascular complications, neurology, ophthalmology/orthopedics, andrology, endocrinology, symptoms/feelings, dietary issues, clinical tests and drugs, diabetes in general, various problems*. The 7 thyroid-related topics were labelled as

Table 1 Scores obtained in the thyroid domain for the extracted topics (varying T), based on different metrics: qs “quality score,” ss “silhouette score,” chs “calinskiharabasz score,” dbs “davies-bouldin score”

follows: *gynecology, thyroid nodules, cardiovascular complications, pregnancy, clinical tests and drugs, thyroid in general, symptoms/feelings*. As expected, there are similarities in the two sets of topics, while differences are related to the specificity of each disease. Our detected topics are particularly useful to cluster patients messages according to different dimensions and analysis objectives:

1. *Dimension 1: comorbidities.* First, we note that the first nine diabetes topics and the first four hypothyroidism topics are useful to stratify patients according to their reported comorbidities (note that hypo/hyper glycemia is a syndrome, not a disease, and pregnancy is a condition. We are aware that the term “comorbidity” is abused here.). These subsets of topics represent the first detected dimension of our study. Analyzing messages of patients affected by a given disease grouped by their comorbidities and conditions can be greatly helpful for doctors. For example, this message refers to the elder diabetic mother of the message author, with several comorbidities: “*my 78 year old mother suffers from atherosclerotic vasculopathy from arterial hypertension and insulin dependent diabetes mellitus. For some months now she has completely lost her balance and often falls.*”
2. *Dimension 2: symptoms.* The topic “symptoms” includes a variety of physical conditions that would require a better subcategorization for the purpose of therapy analytics. To this end, we repeated the procedure described in section “[Topic Modeling](#)” and found relevant

subclusters of words representing groups of disease-specific symptoms. For example, in the thyroid domain, we found five subclusters of adverse drug reactions to the treatment with Levothyroxine tablets, shown in Table 2 (only top frequency words). Again, this is extremely useful to group patient messages according to their symptoms, to detect adverse drug reactions: e.g.: “*I have autoimmune Hashimoto’s thyroiditis and I regularly take eutirox 75[...]. Since last May I have been accusing various problems that have culminated in the last period with episodes of vomiting, nausea...*”

3. *Dimension 3: emotions.* Finally, with the purpose of evaluating the feelings and emotions of these on-line patients, we further added six clusters of words identifying primary emotions, based on the work in [41, 42], and using the sentiment keywords presented in [43]. An excerpt of these emotion words is shown in Table 3 (10 words) (The complete list is shown in the previously provided link). Grouping messages along this dimension may foster a better understanding of patients’ feelings and quality of life: “*For 6 years I have been taking 75mg eutirox daily (since December 2014 50mg every day) because of thyroid nodules [...] in the last period I feel depressed and as if I was fainting in the heart, I feel like a strong blow in the heart and then the nothing that leaves me with strong shivers of fear.*”

These three dimensions (hereafter D1, D2 and D3), are at the basis of the social phenotype analytics phase, presented in section “[Data Analytics](#).”

Table 2 Subclusters of symptoms for hypothyroid patients (top ranked words)

Symptom	Terms
Cardiovascular disorders	<i>Tachycardia, palpitations, arrhythmia, heart attack, myocardium, heart, cardiac, hypertension, hyper-tense</i>
Nervous system disorders	<i>Headache, tremor, trembling, restless, restlessness, sleepless, insomnia, agitation, agitated, nervousness, nervous, anxiety, anxious</i>
Gastrointestinal disorders	<i>Nausea, diarrhea, vomiting, weight loss, appetite</i>
Systemic disorders	<i>Redness, fever, sweating, hyperhidrosis, flushing</i>
Reproductive system disorders	<i>Menstrual, cycle, menstruation</i>

Table 3 Emotion clusters (first 10 words in alphabetic order), based on the keywords in [43]

Emotion	Terms
Happiness	<i>Cheerful, cheerfulness, complacency, contented, contentment, delighted, enthusiasm, enthusiastic, euphoria, euphoric</i>
Sadness	<i>Afflicted, anguish,anguished, bitterness, bored, boredom, boring, depressed, depression, desolate</i>
Anger	<i>Agitated, agitation, anger, angry, annoyed, exasperated, exasperation, extremely angry, frustrated, frustration</i>
Disgust	<i>Abhorrent, abominable, contempt, degradation, degrading, disgust, disgusted, disgusting, horrendous, horrible</i>
Surprise	<i>Amazed, amazement, appalled, bewildered, confused, confusion, discovery, dismay, disoriented, doubt</i>
Fear	<i>Afraid, agitated, agitation, alarmed, anguish, anguished, anxiety, anxious, apprehension, breading</i>

Data Analytics

Data analytics in healthcare is evolving into a promising field that takes advantage of the increasing daily availability of health information to extract insights for producing better-informed decisions [44]. By discovering associations, understanding patterns and examining trends within patient-related health data, data analytics applications offers the potential to improve the quality of care at more moderate costs and with better outcomes. The misalignment between patients and doctors focuses remains a recognized problem in medical literature. In light of this, the information analyzed in this section is clearly relevant because it is provided anonymously by patients, according to their perceived priorities, rather than in response to specific questions formulated by specialists.

As anticipated in section “[Introduction](#),” in this study we are specifically focused on analyzing in detail the feelings, adverse drug reactions, symptoms, and everyday lifestyle of diabetic and hypothyroid patients.

Towards this objective, we performed various analyses to characterize messages from patients affected by our two considered diseases along the three dimensions identified in section “[Evaluation and Experiments](#).[“](#) This type of analysis is useful to help doctors understand in a more nuanced way the patients’ feelings. Thanks to our proposed methodology, doctors can easily identify specific and statistically relevant subsets of automatically grouped messages (for example, messages of hypothyroid patients with cardiological complications, expressing emotions such as fear or sadness).

Hereafter we provide examples of data analytic that can be carried out using our proposed methodology. For the sake of space, we do not carry out a detailed analysis of both diseases. The interested reader can refer to [40].

We first study the relevance of primary emotions (shown in previous Table 3) within a corpus of d -related messages. For each cluster of words associated with a primary emotion, initially, we calculate the cosine similarities between the centroid of the current sentiment group and all the centroids of the messages; after that, we considered the average of these similarity values as the final mean score associated with the current emotion. Thus, at the end of the procedure, we are able to quantify the *significance* level of emotions for d -patients. As an example, the bar graph of Fig. 3, shows the relevance of primary emotions in hypothyroid patients undergoing standard Levothyroxine therapy. As we can see from this chart, the prevailing emotions are fear and sadness (an example is: “*I have read that tyrosint can cause agitation . . . could this have affected the worsening of symptoms? Since I take it I always feel nervous and agitated, I am afraid that this agitation will ruin my stomach . . . I always drink chamomile and once I tried with Valerian, but I can not calm down!*”).

Next, we can analyze the *correlation strength* between the six primary emotions (D3) and the patients’ sub categories (D1) identified in section “[Topic Analysis and Subclustering](#).[“](#) The result is shown in the heatmap of Fig. 4, always referring to hypothyroid patients. To examine the correlation, in order not to penalize less frequent topics, we adopted the Normalized Pointwise Mutual Information (NPMI) [45] as association measure.

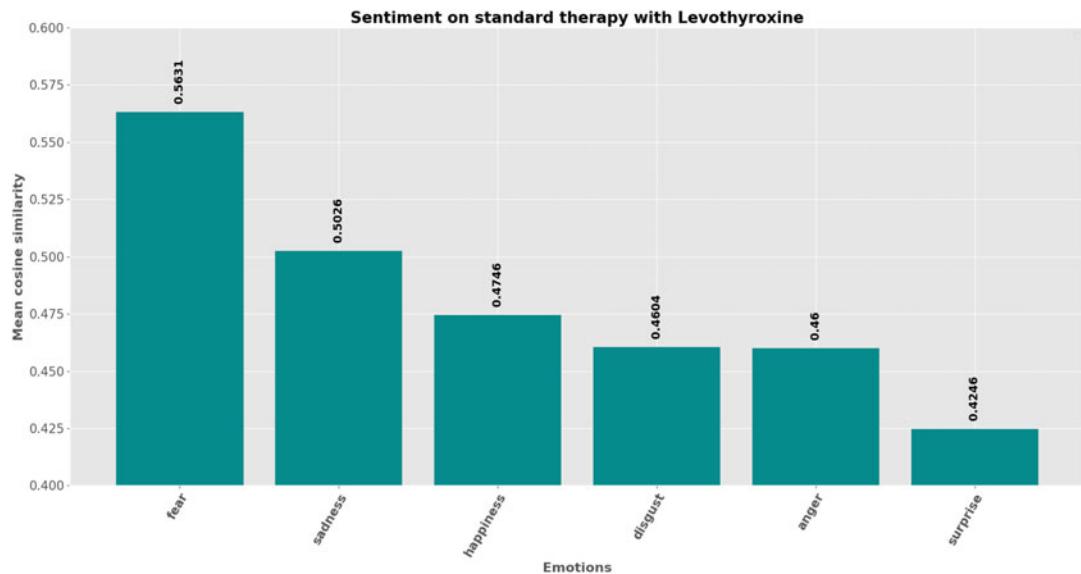

Fig. 3 Relevance of primary emotions (D3) in patients with hypothyroidism subject to standard therapy with Levothyroxine

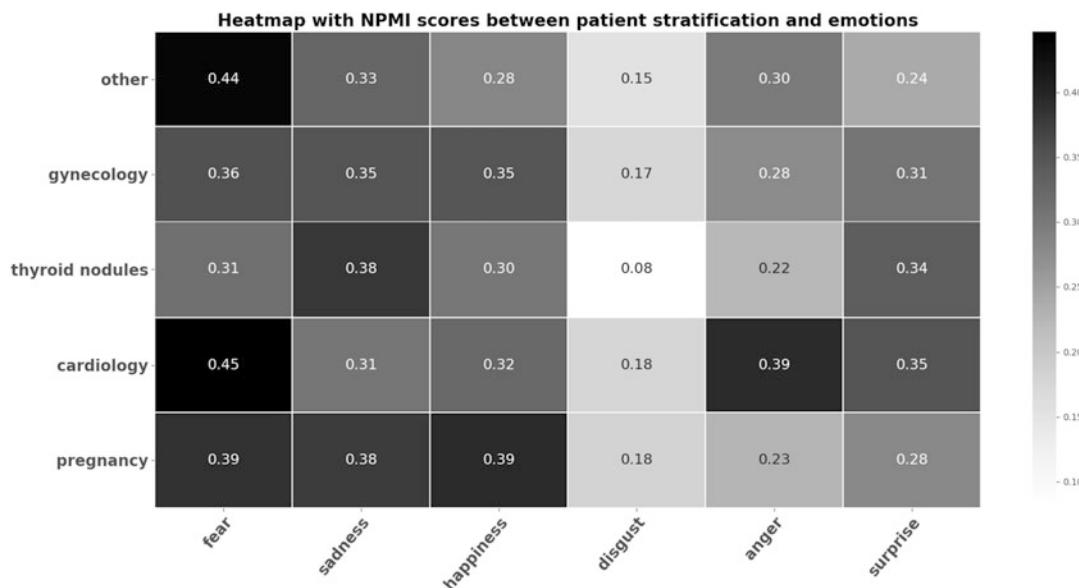

Fig. 4 Correlation between patient stratification (D1) and primary emotions (D3), for hypothyroid patients

Specifically, given two clusters of words $C1$ and $C2$, to calculate the NPMI score between these two groups: in the first place, we considered all the pairs of terms belonging to the Cartesian product between $C1$ and $C2$; next we calculated the NPMI scores for each of the obtained pairs of

words; finally, we selected the ten highest computed scores, and we considered the average of these top ten values as the final NPMI score of the two clusters $C1$ and $C2$. The heatmap shows that the highest NPMI value is between fear (as we already noticed, the most prevalent emotion among

our emotional topics) and the dimension “cardiology.” Not necessarily cardiovascular complications are the most severe, but the data show that they are the ones that patients fear the most.

Next, we can investigate ADRs in a *d*-related corpus of messages. In the hypothyroid/Levothyroxine sub collection, we can use the five symptom clusters (D2) shown in previous Table 2. The bar chart of Fig. 5, calculated as for in Fig. 3, shows that the most relevant groups of complained symptoms for hypothyroid patients appear to be connected to cardiovascular disorders and nervous system problems, such as depression.

Furthermore, we can examine the correlations between the symptom clusters (D2) and the patient stratification (D1). In Table 6 we apply this analysis to diabetic patients. The heatmap of Fig. 6 shows some obvious correlation between comorbidities and symptoms (e.g., ophthalmology/orthopedics and eye problems, or andrology and sexual disorders), but also other interesting correlations, like polyuria symptoms for hepatology/gastroenterology-related comorbidities, and again the widespread relevance of cardiovascular and dietary (polyphagia and weight) problems. An example

of symptoms reported by (the son of) an elder diabetes patient with cardiological comorbidities is: “*My father suffering from diabetes has attacks of angina, now it happens even when at rest. He always has a feeling of heaviness in the stomach and pain in the arm shoulder, that is alleviated with the Cavasini, but then it returns to him often times at night [...] We do not know if his treatment is too heavy for him, for his age, because since he has been doing it he says he feels worse . . .*”

Finally, in Fig. 7, we show the correlations between the symptom clusters (D2) and the primary emotions clusters (D3), again for the case of hypothyroid patients. We observe that patients communicate more openly their emotions when reporting depression (nervous system disorders) and cardiovascular complications.

To summarize the results of our analysis, we can say that psychological and cardiovascular complications represent the types of ADR with the highest association with hypothyroid patients treated with Levothyroxine. This fact reveals how psychological aspect has a key role and reinforces the evidence of dissatisfaction and anxiety of this type of patients. For diabetic patients, the most

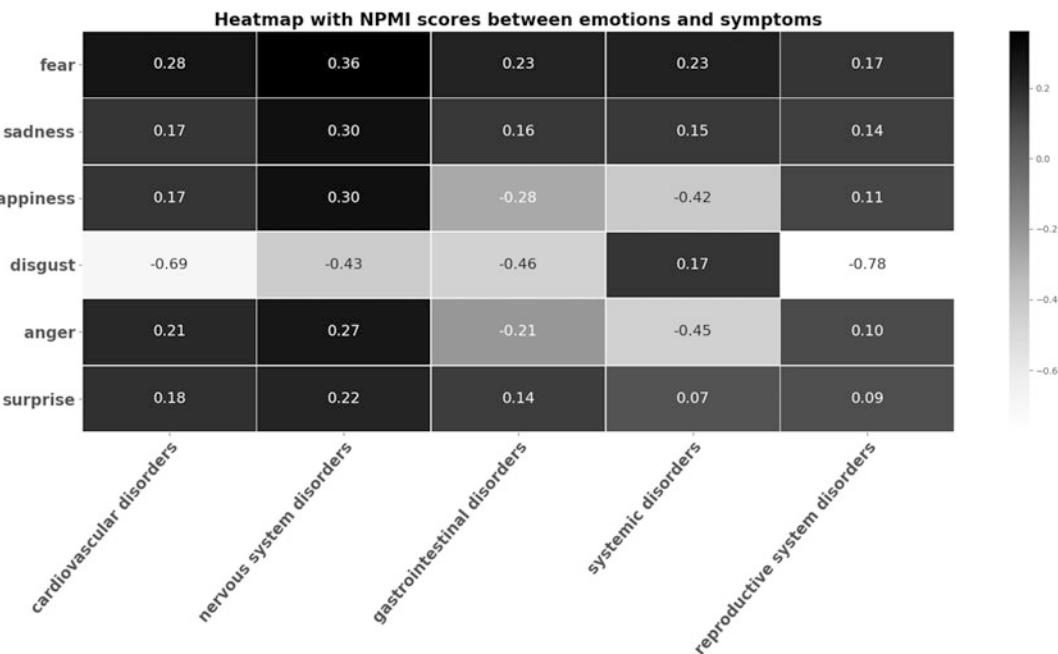

Fig. 7 Correlation between primary emotions (D3) and symptoms (D2) for hypothyroid patients

frequently reported problems concern glycemic complications (more in detail, insulin-related problems) and dietary problems. Although these

problems are not considered by diabetologists as representing a severe limitation of a patient's life (Except for the assumption of insulin, which is

known to be a major cause of discomfort.), at least in comparison with other symptoms affecting eyes, limbs and kidneys [46], our analysis shows that indeed they are reported by the patients in forums as being a major cause of discomfort.

Conclusion

In this chapter we presented a framework for extracting and analyzing the *social phenotype* of a disease, that we define as the systematic detection, analysis and categorization of messages generated by patients affected by a disease. Data on these patients can be collected in the large from health forums, where users more freely present to doctors a subjective and unfiltered picture of their health conditions, lifestyle and emotional status. Fine-grained, large scale categorization of patients' messages is supported by the detection of discussion topics, that we subsequently organized along three dimensions: comorbidities, symptoms, and emotions.

For an effective categorization of patients' messages, we designed a data processing workflow based on:

1. an AutoML pipeline, to accurately classify messages of patients affected by a selected disease;
2. an innovative topic extraction methodology, Generative Text Compression with Agglomerative Clustering Summarization (GTCACS), to identify different dimensions along which patients can be further stratified, in support of therapy analytics.

The framework has been applied to the analysis of the social phenotype of diabetic patients and hypothyroid patients treated with Levothyroxine, extracted from a popular health forum in Italy. We have shown that this type of analysis is useful to help doctors understand in a more nuanced way patients' feelings and types of complained ADRs, which are often overlooked during ordinary patient-doctor communications. Thanks to our proposed therapy analytic framework, doctors can analyze specific and statistically relevant

subsets of automatically grouped messages, rather than inspecting the entire unordered collection.

Abstract

Cardiovascular parameters like blood pressure, heart rate, heart rhythm, and heart rate variability are highly useful in assessing patient health,

disease risk, and response to treatment. However, technological limitations curtail their measurement in many cases. The recent development of transdermal optical imaging (TOI) technology has made it possible to extract high-quality blood flow information from conventional video of a patient's face and then use it to accurately estimate these cardiovascular parameters. TOI technology could thus be implemented on any device capable of capturing and processing video (e.g., any modern smartphone) and thus constitute a comfortable, convenient, and ubiquitous tool for measuring cardiovascular parameters.

TOI builds upon remote photoplethysmography in part by using machine learning to extract robust blood flow information from video of the face. This signal can be used directly to compute heart rate, heart

Supplementary Information: The online version of this chapter (https://doi.org/10.1007/978-3-030-64573-1_250) contains supplementary material, which is available to authorized users.

rhythm, and heart rate variability. Information from signal features containing blood pressure information has been combined with the help of machine learning to accurately estimate systolic and diastolic pressures. Further development of this technology is likely to enable the assessment of additional physiological parameters (e.g., respiration rate, SpO₂), disease risks (e.g., hypertension, diabetes), blood biomarker concentrations (e.g., cholesterol, HbA1c), and even mental health conditions (e.g., depression, anxiety).

With the necessary regulatory approvals and clinical trials, TOI-based tools would enable accurate, convenient, and contactless screening, diagnosis, and monitoring of patient health. They would revolutionize healthcare delivery through better access and efficiency and thus not only reduce costs but also improve health worldwide.

Characterizing the Cardiovascular System: Benefits, Obstacles, and Breakthroughs

Cardiovascular parameters like blood pressure, heart rate, and heart rhythm are some of the most vital measures in clinical health assessment. Heart rate variability (the subtle variation in timing between one heartbeat and the next) provides insight into cardiovascular health and general wellness. Such measures are routinely employed in the medical setting and increasingly at home and elsewhere. While the benefits of comprehensive monitoring are becoming increasingly

apparent, so are the technological barriers preventing cardiovascular monitoring from being used to its full potential.

Blood Pressure Measurement

Hypertension Screening, Diagnosis, and Management

Hypertension (high blood pressure) is a major modifiable risk factor for cardiovascular disease, with a global prevalence of over 30% [1]. There is an immense need to employ blood pressure measurement in screening, diagnosing, and managing hypertensive blood pressures down to target levels. Despite the importance of these activities, hypertension awareness, treatment, and control rates remain less-than-ideal in high-income countries (67%, 56%, and 28%, respectively) and very limited in middle- and low-income countries (38%, 29%, and 8%, respectively) [1, 2].

Awareness is limited by inadequate screening in the clinic [3], and the requirement for special equipment to measure blood pressure is an obstacle to opportunistic self-screening at home. Diagnosis proceeds according to algorithms that most often require home or ambulatory measurements in addition to clinic measurements, and the management of high blood pressure via lifestyle modification or medication calls for regular blood pressure measurement on an ongoing basis at home [4]. The daily home (“out-of-office”) monitoring recommendation is to take two measurements in the morning and two in the evening with a cuff-based oscillometric device. However, such measurements remain uncomfortable, and the need for multiple measurements (to average out naturally occurring oscillations in blood pressure) is time-consuming. Such factors might reduce patients’ willingness to monitor their blood pressure and hinder blood pressure control. Further, comprehensive blood pressure profiles are increasingly valued in characterizing hypertension [5]. However, the bulkiness cuff-based devices make them inconvenient to bring along outside of the home, thus limiting the ability to comprehensively monitor one’s blood pressure over a range of daily activities (e.g., at work).

General Health Assessment

Blood pressure measurement is a primary tool in assessing patient health in the clinic. For instance, high blood pressure could indicate cardiovascular compromise (stroke or myocardial infarction), and low blood pressure could indicate the presence of shock (septic, cardiogenic, anaphylactic). Measurements are conducted by auscultation with a sphygmomanometer or by automated oscillometric devices. A limitation of these cuff-based tools is that they are potentially unsanitary, and they require staff to get close to patients (potentially increasing the likelihood of infectious disease transmission). Further, cuff-based tools cannot be applied remotely in telemedicine consultations, thus precluding a comprehensive health assessment for those without devices at home.

General Health Monitoring

Blood pressure is also monitored continuously and semicontinuously in the clinic. For instance, patients are monitored perioperatively to track depth of anesthesia and both perioperatively and postoperatively for complications (e.g., blood vessel rupture or sepsis) [6]. Continuous monitoring is conducted most accurately (albeit invasively) by arterial line. Noninvasive continuous alternatives include finger-based devices (calibrated by brachial cuff), although such devices are very costly. A frequent alternative to these invasive or costly methods when possible is semi-continuous monitoring via auscultation or oscillometric device. However, their disadvantage is that nurses must occupy more of their time taking measurements. It has been proposed that some patients monitored semicontinuously might be able to spend less time in hospital by self-monitoring at home after minor surgical procedures. However, the logistical hurdle of distributing (and later collecting) cuff-based devices could limit the practicality of this option.

Heart failure patients require regular out-of-office monitoring to ensure that their blood is being pumped adequately [7]. The comprehensiveness of the monitoring required once again raises concerns about the comfort and convenience of cuff-based measurements.

Heart Rate, Heart Rhythm, and Heart Rate Variability

General Assessment and Monitoring

Heart rate is an easily accessible clinical indicator of various conditions that may require further assessment. Abnormally fast heart rates (tachycardia, >100 bpm) could indicate dehydration, infection, or cardiogenic shock. Abnormally slow heart rates (bradycardia, <60 bpm) could indicate depressant effects from medication or that something is wrong with the pacing mechanism of the heart. Heart rate can be crudely assessed by palpation (requiring time and contact with the patient), but in the clinic it is most often measured by various specialized equipment (e.g., pulse oximeter, blood pressure monitor, electrocardiogram (ECG), or auscultation by a trained professional).

Heartbeat rhythm and regularity are also important health indicators. Gross irregularities in inter-beat intervals (e.g., complexes of premature ventricular contractions) constitute arrhythmias that could suggest greater risk of disease or require treatment. Conversely, when it comes to the subtle timing differences between heartbeats (termed “heart rate variability”), more variability implies greater responsiveness to blood pressure and respiratory fluctuations. Higher heart rate variability is prognostically favorable for various cardiovascular diseases [8]. Further, heart rate variability has recently been identified as one of the earliest physiological predictors of sepsis/infection [9]. Frequency analysis of heart rate variability can closely approximate the state of the autonomic nervous system (sympathetic-parasympathetic balance); increased spectral power at low frequencies relative to high frequencies suggests an increase in sympathetic tone [8]. Certain time domain measures of heart rate variability are also informative and are strongly associated with parasympathetic activity [10].

Heart rhythm irregularities can be detected by a trained professional using auscultation, but most often they are assessed by electrocardiography (ECG). Heart rate variability is most often measured by ECG. ECG is highly accurate but requires specialized equipment and the attachment of adhesive probes to the patient’s chest to

attain the highest-quality recordings. This requirement has largely limited such assessments to specialty care (e.g., cardiology, neurology) and made them impractical in large-scale screens, general health assessments, and remote consultations.

Stress Assessment

The appreciation that psychological stress has a major impact on health and general wellness is driving demand for more frequent stress assessment in more people. Psychological stress has been traditionally assessed through questionnaires. However, a growing literature has associated various permutations of heart rate variability with psychological stress, thus creating a quick, efficient, and objective method of stress assessment [11]. However, its potential is limited by the requirement for ECG equipment.

The Need for Technological Breakthrough

It is becoming apparent that more comprehensive monitoring of cardiovascular parameters could have immense benefits but that the inconvenience, discomfort, and inaccessibility of existing tools present obstacles to measurement. A technological breakthrough is needed to enable the creation of a new generation of tools that are more comfortable, more convenient, and more accessible to truly realize the full potential of maximizing health and wellness through the measurement of these parameters.

Transdermal Optical Imaging

Overcoming Measurement Obstacles with Transdermal Optical Imaging Technology

One solution that addresses all of these measurement obstacles is transdermal optical imaging (TOI) technology [12–17], which uses artificial intelligence to accurately measure cardiovascular parameters from video of a patient's face. The technology extracts a continuous pulsatile blood flow signal from video. This signal is rich in physiological information and interrelated

throughout the body [18]. As such, it can be used to estimate parameters like brachial (upper arm) blood pressure [14, 16, 17], heart rate [13], heart rhythm, and heart rate variability/stress [13].

TOI technology has a basis in conventional video and thus can be implemented as software on existing computing devices (e.g., smartphones, tablets, or any other device capable of capturing and processing video), thus transforming them into measurement tools without the need for special equipment. Such tools would be contactless and thus could be used more comfortably than many existing tools. Tools using TOI technology could be conveniently employed anytime and anywhere, with measurements carried out comfortably, safely (e.g., without contact), and efficiently.

Scientific Foundations of Transdermal Optical Imaging

Biomechanics and Video Capture

TOI technology is a novel variant of a more than decade-old technique called remote photoplethysmography [19]. With each beat of the heart, blood is circulated throughout the arterial system and produces a pressure pulse (a small expansion of the arteries) that propagates through the arterial system [20]. As this pulse passes through the superficial arteries of the skin, the arterial expansion compresses microvascular blood toward the surface of the skin. This puts additional blood into range of ambient light that has penetrated the superficial layers of the skin. The additional hemoglobin in this additional quantity of blood absorbs more of this light (according to its absorption spectrum), and consequently less light reemerges from the skin. Melanin in the skin also absorbs light, but its concentration remains constant from moment to moment. These cyclical attenuations of light can be captured by a consumer-grade video camera to reproduce the pressure pulses occurring within the artery. See Fig. 1 for schematic.

Distance from the camera, motion, skin tone, and variable lighting conditions can also affect what the camera captures, and so software

employing TOI technology addresses these issues at the video capture stage. Distance from the camera is approximately controlled by having the user place their head within a head-shaped outline on the graphical user interface, and a software-based face tracker will further warn the user if they are too close or too far away. Motion of the face relative to the camera is similarly tracked with software-based face detection; measurement will not begin, and ongoing measurements will be cancelled if too much motion is detected. Skin tone and variable lighting conditions are accounted for in part by calibrating camera exposure and white balance prior to the measurement. Measurements will not proceed, and ongoing measurements will be cancelled if there is insufficient lighting or too strong of a light gradient from one area of the face to the next. In this way, recording conditions are optimized and standardized.

Extracting Plethysmographic Signal from Video Using Artificial Intelligence

Some of the earliest variants of facial remote photoplethysmography averaged pixel intensity in the green channel and then filtered out noise in this raw signal with software-based digital signal filters [19, 21]. However, it was believed that much of this signal arose from mechanical (ballistocardiographic) movements of the head

(the subtle periodic movement of the head caused by blood pulsing up through the aorta and into the head) rather than color fluctuations caused by arterial pulsation under the skin surface. Principal components analysis (PCA) [22] was used to try to address this issue by identifying components of the signal that oscillated from one moment to the next relative to video data in the red channel (relatively little red light is absorbed by blood hemoglobin, and so it might be used as a baseline against which arterial pressure pulse oscillations can be detected) [23]. Another approach called the chrominance method [24, 25] isolated pulsatile signal in each color channel individually. A limitation of these methods is that they tend to identify periodicity based on the signal frequency with the highest signal power and therefore remain somewhat sensitive to contamination from periodic movements of the head [24]. Others have developed mathematical models to try to account for (and separate) the individual contributions of hemoglobin, melanin, and shadows in the extracted signal based on knowledge about their absorption spectra and camera spectral characteristics [26]. However, this deliberate modeling technique has had only limited success (perhaps due to the difficulty of adequately modeling the complexity of these factors).

TOI technology builds upon these approaches to achieve highly robust signal extraction

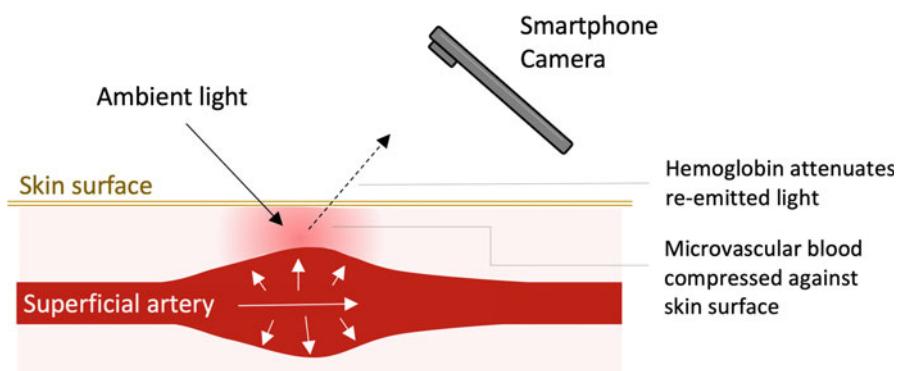

Fig. 1 Biomechanics and video capture for remote photoplethysmography. Pressure pulses created by the left ventricle of the heart arrive at the superficial arteries in the face. Here their expansion compresses microvascular blood toward the skin surface. The increased quantity of hemoglobin near the surface of the skin absorbs more

incident ambient light (the specific wavelengths corresponding to its absorption spectrum), and consequently less of this light reemits from the skin. These subtle attenuations of light are captured by a conventional video camera as subtle skin color fluctuations

[12]. Like other methods, TOI tracks specific regions of the face and extracts information from the red, green, and blue color channels (using multiple colors helps create a more robust signal) (Fig. 2a). But unlike any other approach, TOI uses a computational model trained using advanced machine learning techniques to determine the relation between skin color changes and arterial pressure pulse oscillations from one moment to the next. TOI encodes color information in each pixel as multiple layers (or “bitplanes”) of binary values (0 or 1) for each of the color channel (red, green, and blue), and this serves as input for the computational model. The model (previously trained to predict a continuous arterial pressure) then selects the bitplanes that best represent hemoglobin fluctuations to comprise the signal. This technique results in a high proportion of signal relative to noise (e.g., from variable lighting conditions or skin tone differences). A machine learning approach like this may account for additional complexity that is difficult to model with more deliberate techniques.

TOI further tracks multiple unique regions of interest (ROI) on the face (Fig. 2b). The reason for doing so is that different regions exhibit different spatiotemporal properties relative to ECG, despite all the pulses originating from the heart [12]. This is due to slight anatomical differences in facial vasculature, as well as the differential innervation of specific regions by either sympathetic or parasympathetic vasomotor neurons. For instance, sympathetic activity can strongly constrict subcutaneous blood vessels in the nose and lips and actively dilate vessels elsewhere like the forehead, cheeks, and chin [27]. Parasympathetic activity contributes to vasodilation in the lips and forehead. TOI thus captures rich information about the state of the vasculature and the autonomic nervous system that would be lost if signal from multiple regions of the face was simply averaged together. Finally, differences in temporal dynamics demonstrate that TOI signal is indeed driven by color changes rather than ballistic movements of the head [12].

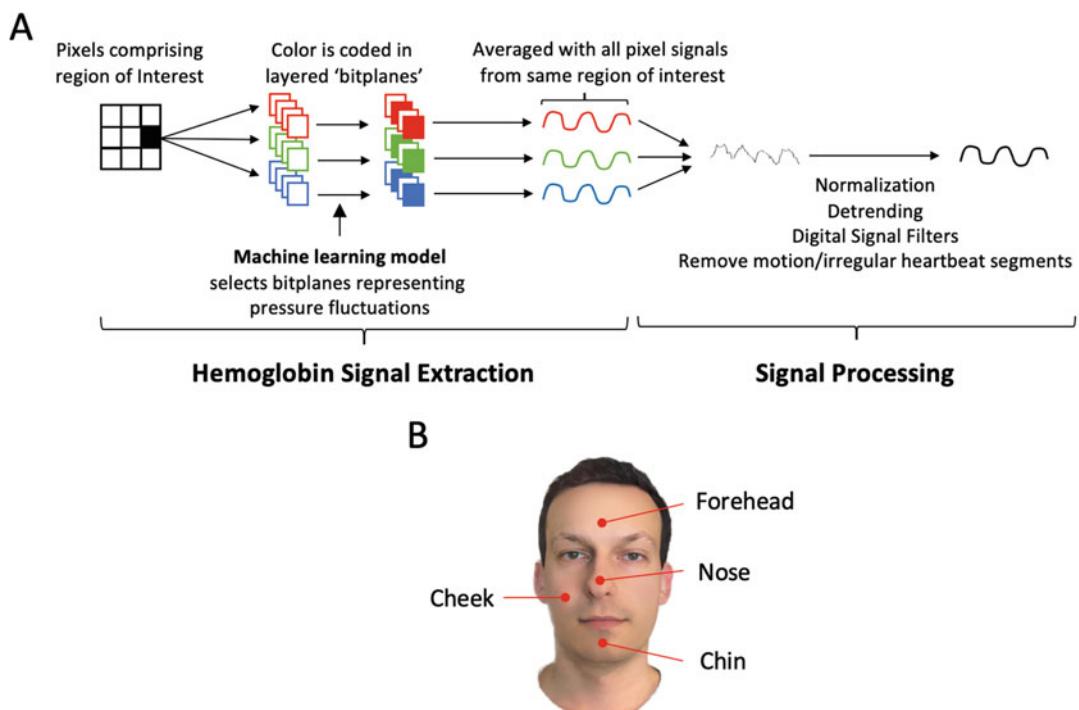

Fig. 2 Schematic of hemoglobin signal extraction and signal processing process (a) and major regions of interest (b)

After extracting raw signal in the red, green, and blue color channels, the signal is combined into a single raw blood flow signal (pressure pulse oscillation) for each ROI according to a special function [14]. During this process, each signal is normalized and detrended to account for variable lighting conditions. Digital signal filters (high, low, band-pass) remove low-frequency physiological oscillations (e.g., Mayer waves) and high-frequency noise. Signal elements suggesting motion and irregular heartbeats are also detected at this stage, and such segments are removed from the signal [17]. The final signal for each discrete region of the face is passed along to a variety of functions that extract information about physiological characteristics [14]. Some raw color information is passed along as well.

Cardiovascular Parameters and Their Relation to Blood Flow Features

Pulse Rate

Pulse rate corresponds to the patient's heart rate and is calculated as the number of pulses that arrive at the facial vasculature (from the heart). Pulses are counted as the number of major peaks within the signal segment and can be expressed as a frequency in hertz or a rate per minute [14].

Pulse Rate Variability

Pulse rate variability corresponds to the patient's heart rate variability, which is a measure of the variability in the intervals between heartbeats. Pulse rate variability measured by TOI closely tracks heart rate variability measured by ECG [13]. Pulse rate variability is calculated by detecting each pulse within the signal segment and then applying one several time domain calculations or frequency analyses that characterize the timing between pulses. For instance, the time domain SDNN measure of heart rate variability is calculated as the standard deviation of the inter-beat intervals. A larger SDNN value indicates more heart rate variability.

Blood Pressure

Systolic and diastolic blood pressures can also be estimated using plethysmographic signal features.

While many such features have been identified (e.g., augmentation index, pulse area) [28], no single feature has yet been found to provide enough information to accurately estimate blood pressure. It has thus been necessary to combine information from a variety of features to yield accurate estimates.

In an example of accurate blood pressure estimation, Luo and colleagues (2019) estimated blood pressure from a comprehensive set of 126 TOI blood flow features and 29 non-blood flow features [14] (Fig. 3). The blood flow features in that study and in a subsequent study by Yang et al. (2020) [17] can be divided into five groups: pulse shape, pulse energy (rates of change in pulse shape), pulse transit time, pulse rate variability, and pulse rate. **Pulse shape** features consisted of distances between various landmarks in the waveform, areas of certain sections within the waveform, or the ratio of one of these measurements with respect to another. Such features were calculated as means, maxima/minima, or measures of spread (e.g., standard deviation) across all pulse waveforms in the signal. **Pulse energy** features captured the rate at which certain pulse shape features emerged in the waveform as a function of time and were calculated as derivatives of pulse shape features. **Pulse transit time** is inversely related to the speed at which the pulse propagates across a fixed distance in the vasculature. It was approximated based on pulse waveform phase differences between two regions of the face. The propagation speed of pressure pulses is largely determined by arterial stiffness, and arterial stiffness is associated with blood pressure [28]. **Pulse rate variability** provides information about the state of the autonomic nervous system (sympathetic-parasympathetic balance), and greater sympathetic tone is associated with blood pressure increases [29]. Finally, **pulse rate** increases typically co-occur with blood pressure increases since both are key mechanisms for increasing cardiac output to meet the demands of the body. Thus, pulse rate contains information about blood pressure to the degree that it is signaling increases in cardiac output.

Non-blood flow ("meta") features included physical characteristics like gender, age, weight, height, race, and skin tone (as per the six-point

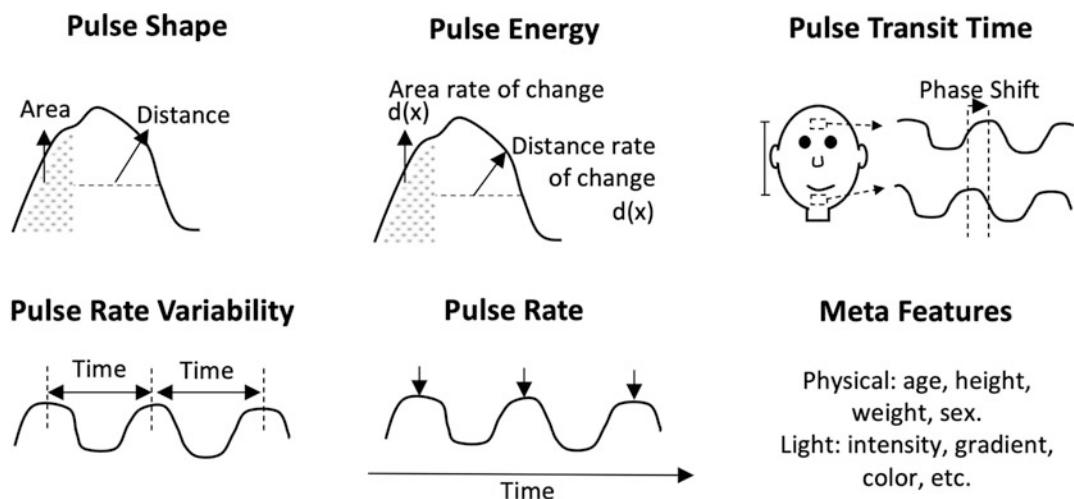

Fig. 3 Feature types used in predicting blood pressure

Fitzpatrick scale), as well as features to help normalize for different lighting conditions (e.g., color information and lighting gradient information).

Predicting Blood Pressure Through the Efficient Combination of Feature Information Using Artificial Intelligence

The Luo [14] and Yang [17] studies extracted features from TOI signal and questionnaires and then input them into a computational model trained to predict either systolic or diastolic brachial blood pressures using advanced machine learning techniques. These models were trained to predict absolute brachial (upper arm) blood pressures and did not require prior calibration with a cuff-based device. Advanced machine learning techniques have thus been used as a method of efficiently combining information from multiple features to accurately predict blood pressure.

Present Advances Using Transdermal Optical Imaging

Accurate Blood Pressure Measurement

In their proof-of-concept study published in *Circulation: Cardiovascular Imaging*, Luo and colleagues demonstrated that combining the predictive power of multiple features makes it possible to accurately estimate blood pressure

[14]. Their blood pressure prediction models trained using advanced machine learning techniques predicted systolic and diastolic blood pressures in a multiracial sample of subjects under controlled conditions when trained and tested on subjects within the normotensive systolic blood pressure range (those with a systolic blood pressure of 100–139 mmHg). Their models predicted with 94.81% accuracy for systolic blood pressure and 95.71% accuracy for diastolic blood pressure. The average measurement error and its standard deviation were 0.39 ± 7.30 mmHg for systolic pressure and -0.20 ± 6.00 mmHg for diastolic pressure, which fall within a generally accepted measurement device limit of 5 ± 8 mmHg [30]. The feature novelty, feature diversity, and large dataset used in this study may have contributed to the high prediction accuracy in this study relative to other remote photoplethysmography approaches to measuring blood pressure.

This system was subsequently incorporated into a smartphone software application called Anura™ (Nuralogix Corporation) that adds additional controls to ensure good measurements under real-world conditions. Specifically, these controls further help account for motion, variable lighting conditions, and skin tone variations through camera calibration (exposure, white balance), measurement constraints (for motion, lighting, and signal quality), and signal normalization techniques [17]. This system is highly robust in

accounting for real-world conditions and informing the user if measurement conditions are inadequate.

In a subsequent study, Yang and colleagues set out to expand the blood pressure prediction range of the models. To do so, they collected new data that included subjects with hypotensive and hypertensive blood pressures and then retrained the blood pressure prediction models on all the data (model performance in a given blood pressure range is largely a function of the quantity of training data in that range). These new models were trained against reference blood pressures measured by a trained observer using the auscultatory technique. As such, they were able to validate these new models in close conformity with internationally accepted blood pressure device validation guidelines published by the Association for the Advancement of Medical Instrumentation (AAMI) [30]. A published study of their preliminary work found that accuracy surpassed AAMI accuracy criteria for both systolic and diastolic blood pressures [17], with an average measurement error \pm error standard deviation of -0.4 ± 6.7 mmHg for systolic blood pressure and 1.2 ± 7.0 mmHg for diastolic blood pressure (both were below the 5 ± 8 mmHg limit). This suggests that Anura is a viable blood pressure measurement tool for a range of blood pressures. A limitation of this work was that it was conducted entirely on Chinese patients, and it is yet unclear how this performance will translate to other races. The process of Anura blood pressure prediction is described in Fig. 4.

Accurate Heart Rate and Heart Rate Variability Measurement

Wei and colleagues (2018) validated heart rate and heart rate variability measured by TOI (as pulse rate and pulse rate variability) against heart rate and heart rate variability measured by the clinical gold standard ECG [13]. They quantified heart rate as pulses per minute and heart rate variability with the SD1/SD2 ratio. SD1 tracks “short-term” variability and SD2 tracks “long-term” variability; higher values of SD1/SD2 imply increased sympathetic activity [31]. Pulse rate measured by TOI was perfectly correlated with heart rate measured by ECG (Pearson $r = 1.0$) [13]. Pulse

rate variability measured by TOI was highly correlated with heart rate variability measured by ECG (Pearson $r = 0.89$). TOI technology therefore captures all heartbeats and accurately captures the subtle variation in timing between them.

Sympathetic nervous system activity as reflected by increases in heart rate variability measures like SD1/SD2 ratio is associated with mental stress [32], and so it is apparent that TOI can also successfully track mental stress. The study results further imply that TOI can also capture gross rhythm abnormalities, although this has not yet been directly investigated.

These TOI-based measures have already been implemented as software-based tools. For instance, the Anura™ smartphone app (Nuralogix Corporation) measures heart rate, heart rate variability (SDNN), and mental stress (a proprietary stress score from 1 to 5 based on heart rate variability) and counts the number of irregularly spaced heartbeats (e.g., heartbeats suggestive of premature ventricular contractions) during its 30-s measurement.

Trends in Medicine and the Potential Impact of TOI

Growing Challenges for Healthcare Delivery

Population aging is expected to bring a rise in the prevalence of age-related chronic diseases (e.g., cardiovascular diseases), and this in turn will increase the need for comprehensive screening, diagnostic and monitoring approaches [33]. Such approaches help mitigate the health burden of disease, but they are highly resource-intensive when they are carried out in the clinic or long-term care home setting where they require time from primary care physicians and other staff. Growing primary care physician shortages in many jurisdictions will limit the ability to deliver this type of care. Concurrently, patients are demanding a more “patient-centered” approach to their care that is more convenient and gives them more control and involvement in their care. Issues with accessibility might further limit the ability to deliver high-quality and efficient care, particularly when it comes to remote communities

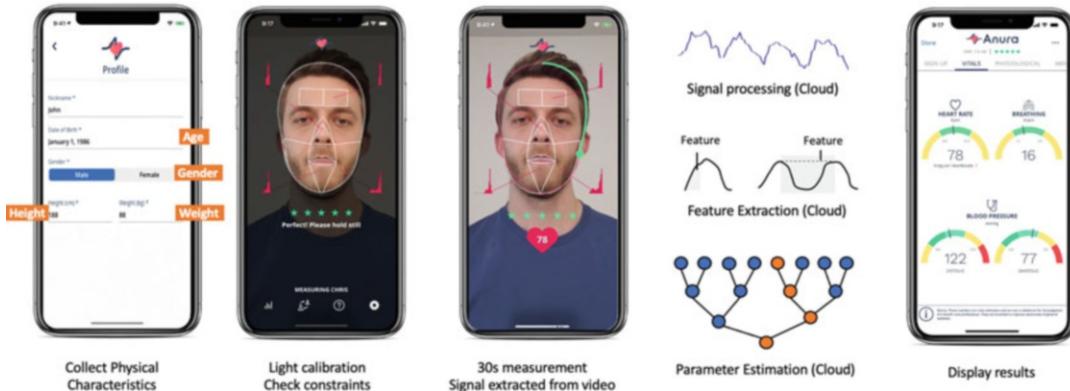

Fig. 4 Process of transdermal optical imaging in prediction of blood pressure with the Anura™ smartphone app (Nuralogix Corporation). Physical characteristics are collected on the profile screen during sign-up. Entering measurement mode triggers exposure and white balance calibration. Distance, motion, and lighting constraints are checked to ensure that conditions are adequate before beginning the measurement. A star-based signal quality system rates the lighting conditions (five stars indicate

and providing care safely during times of elevated infectious disease risk (e.g., when restrictions are in place for COVID-19).

Improving Healthcare Quality and Efficiency with Patient-Centered Health Monitoring

A shift from health monitoring in the clinic to self-monitoring at home would facilitate comprehensive monitoring of cardiovascular parameters like blood pressure and heart rate at reduced cost. Comprehensive monitoring maintains health and reduces costs associated with illness [34]. For instance, facilitating hypertension awareness and control greatly reduces the risk of cardiovascular diseases. Further, remote health monitoring in heart failure patients is credited with reducing costly hospital readmissions in heart failure patients by more than half through identifying complications early [35]. A shift away from clinic-based monitoring would improve convenience (via fewer trips to the clinic) and allow many with chronic diseases to remain in their own homes and in the community for longer before requiring care at a long-term care home [36]. Payers are realizing massive cost savings with such models and are increasingly

ideal conditions and will result in the most accurate measurements). The measurement will then begin and proceed for 30s. Blood flow signal is extracted from video during this time. Signal is then uploaded to the cloud for further processing and feature extraction. Machine learning-based models in the cloud estimate parameters. Finally, these parameters are downloaded to the phone and displayed to the user

incentivizing them in favor of costly long-term care arrangements [37, 38]. In fact, it is estimated that remote health monitoring will reduce chronic disease management costs by 10–20% or more. Finally, patients have shown a willingness to engage in patient-centered remote monitoring solutions for both health and wellness. Technological innovations in remote home monitoring will continue to be a major enabler for self-monitoring at home [33].

Improving Healthcare Accessibility with Telemedicine

Telemedicine is beginning to address issues of accessibility and convenience in medicine by assessing, diagnosing, monitoring, and communicating with patients remotely, most typically through video conferencing technology. Its use has been growing as a way to increase convenience (through fewer trips to the doctor) and provide high-quality care to remote communities. Most recently during the COVID-19 pandemic it has been used as a substitute for in-person visits to mitigate the risk of spreading infection. While the proliferation of ubiquitous high-speed internet and computing devices has enabled this technology, its application has thus far been limited by the

lack of access to standard cardiovascular parameters (e.g., blood pressure, heart rhythm) that are commonplace in the clinic but most often cannot be measured at home. For telemedicine to reach its full potential, it will be necessary for measurement tools to match the ubiquity of video conferencing tools.

TOI-Based Tools Could Transform Personalized Self-Monitoring and Telemedicine

TOI technology has unique characteristics that would enable the creation of tools that address obstacles to measuring cardiovascular parameters at the patient level, as well as address wider challenges in healthcare delivery. Contactless measurement of blood pressure, heart rate, heart rhythm, heart rate variability, and stress via TOI would be much more comfortable than inflatable cuffs, ECG leads, or even wearables, for instance. Since TOI acquires pressure pulse information continuously, it can average out slowly oscillating physiological waves (e.g., Mayer waves) and determine blood pressure not only more precisely but in one quick measurement instead of the three long measurements required with cuff-based devices. Importantly, TOI technology could be implemented on any device capable of capturing and processing video. Such devices are already ubiquitous (e.g., smartphones, tablets, computers). Since the hardware required to run TOI is already everywhere (e.g., at home, at work, and on a video call with a doctor), measuring cardiovascular characteristics using TOI is highly convenient and does not require purchasing or carrying around extra equipment like wearables or often bulky cuff-based devices.

These improvements in comfort, convenience, and access to measurements have the potential to address challenges in healthcare delivery by facilitating patient-centered health monitoring and telemedicine (Fig. 3). TOI-based tools could facilitate a patient-centered approach and improve healthcare quality by making physiological measurements more accessible, more convenient, and more resource efficient. For instance, in the general public unaware of their blood pressure status,

unprecedented access to clinical-grade blood pressure measurement right on one's mobile phone could facilitate the detection of abnormal blood pressure and help drive much-needed increases in hypertension awareness. Diagnosed hypertensives could benefit from increased comfort and convenience over traditional cuff-based devices in monitoring response to therapy. Facilitating regular measurements any time and any place (e.g., even outside the home) could provide greater awareness of high blood pressure triggers throughout the day and help drive increases in hypertension control (via lifestyle changes or medication). This would help address the massive health and financial burden of cardiovascular disease. More comfortable and convenient measurement tools are liable to drive further uptake of remote monitoring programs and thus reduce costs at the healthcare delivery level. TOI technology within telemedicine could enable the measurement of cardiovascular parameters that were previously not possible to measure over video calls unless the patient had specialized equipment at home. Such an advancement would drastically increase the utility of video consultations. A summary of TOI-based functionality is shown in Fig. 5.

Future Uses and Challenges for TOI

Given the tight interrelation between the cardiovascular system and other physiological parameters, plethysmographic signal acquired via TOI can further estimate additional parameters to varying degrees of accuracy. For instance, the expansion and contraction of the diaphragm during respiration exerts significant pressure modulations on the cardiovascular system and enables the quantification of respiration rate. The Anura smartphone app (Nuralogix Corporation) estimates respiration rate from plethysmographic signal, as do some clinical-grade pulse oximetry tools. Other health parameters convey information through the vascular system and might also be measured. They include blood oxygen saturation (by quantifying differences in the absorption spectra of oxygenated versus deoxygenated

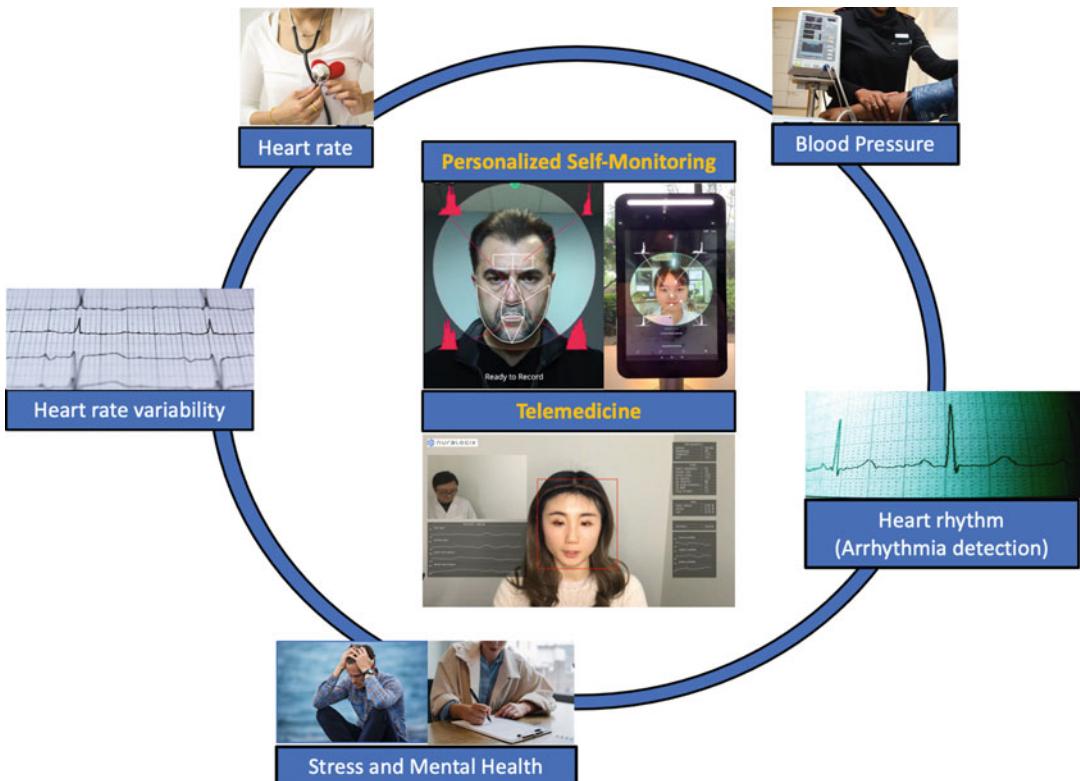

Fig. 5 TOI-based functionality in personalized self-monitoring and telemedicine applications. TOI has enabled the quick, comfortable, and convenient measurement of

parameters like heart rate, heart rate variability, stress, blood pressure, and heart rhythm using already ubiquitous hardware like the smartphone

hemoglobin), blood biomarkers (e.g., hemoglobin concentration, cholesterol level, and even hemoglobin A1c [39]), disease risks (e.g., hypertension, diabetes mellitus, obesity), and even mental health conditions (e.g., depression and anxiety via the effects of autonomic activity on blood flow).

Employing TOI-based measurement tools in the clinic will require medical device approval from appropriate regulatory bodies (e.g., the Food and Drug Administration in the United States). These agencies commonly cite specific validation standards for blood pressure and heart rate monitoring equipment. However, such standards are technology-specific and currently there are no specific standards for remote photoplethysmography devices.

The most closely related blood pressure device standard from the Association for the Advancement of Medical Instrumentation (AAMI) [30]

provides guidelines for validating cuff-based automated blood pressure devices against a gold standard reference device (e.g., auscultation by a trained observer). Despite technological differences, many features of this standard are likely to be translatable to TOI, including testing conditions, subject distribution requirements (for sex, age, and blood pressures), validation procedure, and accuracy requirements. A major accuracy criterion is that the mean error and error standard deviation between the systolic and diastolic blood pressures of reference and test devices fall below 5 mmHg and 8 mmHg, respectively. The technological differences between image-based devices like TOI and cuff-based devices may necessitate consideration of additional factors during validation like skin tone, lighting conditions, and motion, as such factors could conceivably impact measurements in an image-based system. Regulators have also recognized validation standards for

heart rate measurement devices. For instance, the accuracy requirement for heart rate measured by a pulse oximeter is an error of less than 10% or ± 5 beats per minute (whichever is greater) [40]. Once again, there are no guidelines specific for remote video-based technology like TOI, and so manufacturers will need to seek specific guidance from regulators on the validation approach to be used.

Finally, given the pivotal role of blood pressure and heart rate measurement in various clinical applications, it will be crucial to assess how TOI-based tools compare with existing standard techniques in terms of practical effectiveness. For instance, pragmatic trials might investigate how well measurements agree with existing standard methods and the impact of this on diagnostic or treatment decisions. With the necessary regulatory approvals and clinical trials, TOI-based tools will be able to provide accurate, convenient, and contactless screening, diagnosis, and monitoring of patient health. As a result, these tools will have the potential to revolutionize healthcare delivery by enhancing access and efficiency, which in turn will not only reduce healthcare costs but also improve the health of people all over the world.

Abstract

Since 2013, deep learning systems, a form of artificial intelligence (AI), outperformed humans in image, voice, and text recognition, video games, and many other tasks. In medicine, AI has outperformed humans in dermatology, ophthalmology, and several areas of diagnostic medicine. Since the first publication of aging clocks based on methylation data in 2013 by Horvath and Hannum, AI techniques were used to predict human age, mortality, and health status using blood biochemistry in 2016 and later using transcriptomics, proteomics, imaging, microbiome, methylation, activity, and even psychological survey data. Today, these deep aging clocks (DACs) are being used by the research physicians to evaluate the effectiveness of longevity interventions, clinical trial enrollment and monitoring, risk profiling, biological target identification, and personalized medicine. The advent of data type-specific and multi-omics DACs allowed for the nascent field of aging clock-driven preventive and regenerative medicine, referred to as longevity medicine, to emerge.

Introduction

Over the past decade, we witnessed unprecedented advances in the field of biogerontology and the massive convergence of biotechnology, information technology, AI, and medicine. The birth of longevity medicine, which integrates the latest advances in many of these fields of science and technology, is not surprising but rather embraced by progressive clinicians, scientists, and patients. Longevity medicine is advanced personalized preventative medicine powered by deep biomarkers of aging. This domain is extremely novel – aging clocks were first published in 2013 by Steven Horvath et al. [1] and deep aging clocks first published in 2016 by Alex Zhavoronkov et al. [2]. Nevertheless, it became one of the most important areas of

precision medicine. What started with a symbiotic effort of mathematics and biochemistry evolved to an artificial neural network approach – deep learning. The method is used to develop deep age predictors with the potential to accelerate research and clinical translation of causal relationships in nonlinear systems. Applying the clocks in the clinic may allow clinicians to determine the efficacy and efficiency of interventions and prognostic and preventative measures. A tailored longevity medicine education is incumbent in order to train clinical experts in longevity medicine, who will play a crucial role, since the universal process of aging renders every human a patient of longevity medicine, therefore preventing the multimorbidity characterized by old age, including physical and/or mental limitations. Drug therapy poses a further problem of multimorbidity. This is because older people often take many different medicines, and this can also increase the number of undesirable side effects (Fig. 1).

Longevity medicine is suited for advances in machine learning for numerous reasons. Longevity is affected by a large number of intrinsic factors such as genetics and epigenetics [3] and by extrinsic factors such as medical history, diet, exercise, socioeconomic determinants of health, and geolocation [4, 5]. Additionally, the effects of these exposures summate over the course of a lifetime affecting, among other factors, development or progression of age-related disease. Collating this data on biomarkers and drug candidates using a trial-by-trial basis conducted on sufficiently large patient or participant cohorts over long-term follow-up is resource-intensive and unpragmatic. For such heterogeneous and complex data, machine learning is a well-suited candidate both to identify suitable biomarkers in advance of physical trials and to do so with higher accuracy than traditional statistical analysis.

A quintessential tense of a machine learning algorithm is endpoint selection. Actual age and clinical outcomes such as the development or progression of age-related disease provide a

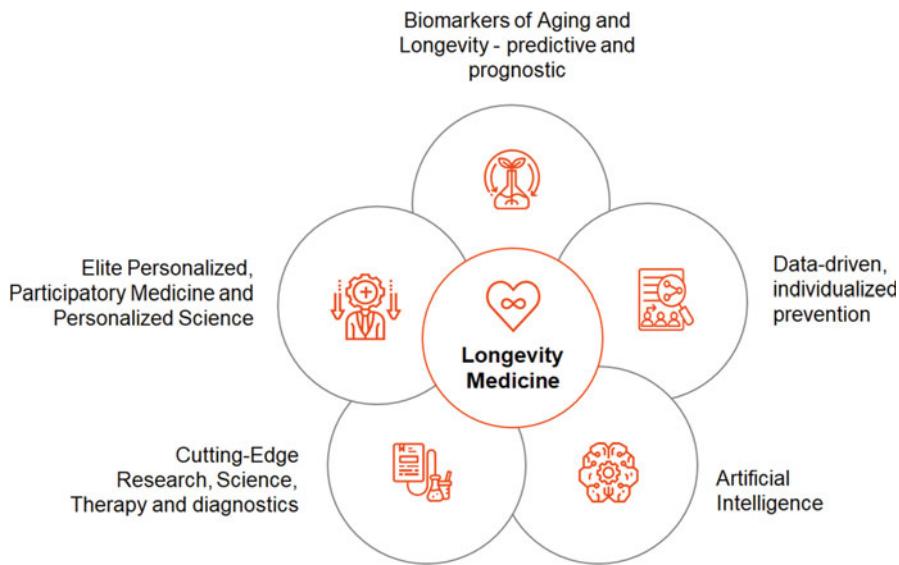

Fig. 1 The technologies enabling the field of longevity medicine

limited view of one's age status. Biological age, which more closely explains age status in the context of one's physiology, is a measure that focuses on progression through aging instead of actual age. Surrogate biomarkers of biological age, termed deep aging clocks, have been shown to estimate disease mortality [6], discern the age of developmental tissue [7], and estimate time remaining before onset of age-related pathologies [8]. The utility of these tools is often based on multi-omics or panomics databases with extensive measures generated on trillions of data points. The interpretation and analysis of these datasets requires advanced techniques for which machine learning may be better suited over traditional methods.

It is often difficult to train an accurate model based on a single dataset as this makes the model prone to bias and it may not have the desired complexity given the project aims. Additionally, databases are generated interinstitutionally with different protocols and specifications across potentially diverse biological features, which makes some of them prone to having gaps in data provision, necessitating the imputation of missing or unknown values. Access to multiple

datasets will negate these effects, but this is practically near impossible due to inherent issues of confidentiality and governance surrounding sensitive medical data. Therefore, techniques like federated learning [9] that train unified models across multiple databases without sharing the data sources would overcome some of the strong barriers around patient confidentiality. This may also bridge together wisdom gained from the academic and medical fields with wisdom generated from data collected in the private sector, which is traditionally difficult due to large conflicts of interest.

The Advent of Deep Aging Clocks

Many biological characters have demonstrated broad correlations with chronological age, including telomere attrition and racemization of amino acids in proteins [10]. The primary progenitor, however, in the advent of aging clocks is what would become known as the “epigenetic clock.” In 2013, Steve Horvath et al. established significant correlations between CpG methyl groups and chronological age, suggesting that this deep aging

clock demonstrated the cumulative effect of an epigenetic maintenance system [1]. This has led to significantly increased attention in the fields of longevity, biogerontology, biomarkers of aging, and the role of machine learning in consolidating these data into precise and coherent models.

What was not well established were geroprotective interventions that could reduce the rate of aging in the novel epigenetic clock and whether these could translate to the actual lengthening of both healthspan and lifespans. Hence, research proliferated utilizing hematological biomarkers indicative of morbidity and mortality putatively involved with aging. This would include a hematological, biochemical clock developed by Putin et al. [2]. Through the use of deep neural networks (DNN), the group were able to train AI to produce a robust model utilizing 41 factors that could predict one's chronological age with impressive accuracy ($R^2 = 0.82$, MAE = 5.5). The benefit of employing DNN architecture in model generation in this instance was that it was able to recursively remodel and account for non-linear associations among features. Importantly, they established for their model the five most important markers for predicting human chronological age: albumin, glucose, alkaline phosphatase, urea, and erythrocytes. What was particularly useful for this deep aging clock was that interventions that could ameliorate the biomarkers used in the model were already well established, and hence, some of the first truly geroprotective interventions were identified.

Indeed, the advent of deep biomarkers of aging has led researchers to target different loci in human and animal biology. For example, researchers as early as 2015 were investigating the role of gene expression through relative quantitative changes in mRNA presence for particular genes and correspondent proteins [11]. Using a cohort of 14,983 individuals, they identified 1497 genes that are differentially expressed with chronological age and used this to develop a clock with a 7.8-year MAE. Importantly, they established that individuals for whom transcriptional differentiations departed above the model's slope exhibited biological features associated with aging, notably, blood pressure, cholesterol levels,

fasting glucose, and body mass index. They also established that their gene panel was enriched for the presence of potentially functional CpG-methylation sites in enhancer and insulator regions that associate with both chronological age and gene expression levels, therefore discovering a mechanism by which the epigenetic clock (DNAm age) could behave as an actor in the development of morbidities with age.

Another transcriptome aging clock was produced in 2018 by Mamoshina et al. [12]. In this instance, they employed the use of DNNs to predict chronological age from 545 gene expression profiles in skeletal muscle of healthy individuals. Among currently published transcriptomic clocks, this clock is the most accurate, demonstrating an MAE of 6.24 years, which may indicate that transcriptomic age prediction requires more complex machine learning techniques than those commonly used in DNAm clocks [13].

Federated Learning for Biomarker Discovery and Development

One's longevity is dependent on a large number of covariates such as dietary habits, exercise levels, and socioeconomic determinants of health. As a result, unbiased long-term trials are used to identify or repurpose new or existing agents that contribute toward greater longevity. For example, the Targeting Aging with Metformin (TAME) trial [14] investigates the use of metformin to delay development or progression of age-related chronic disease in 3000 participants aged between 65 and 79 for 6 years. Aging is chronic and develops in conjunction with long-term environmental exposures. Thus, it may be a further 10 or more years posttrial for the clinical endpoints to appear in participants before the impact toward longevity can be fully evaluated.

The long time-to-event in trials may come at high cost for longevity drug discovery. Machine learning (ML) algorithms may be employed to generate advanced accurate predictions into the efficacy of interventions, particularly for repurposing existing medicines. Data on existing medicines is collected in electronic health records

and the generation of research repositories. This applies especially for commonly prescribed medicines such as metformin.

ML is well suited to the complex variability of human studies and is already being applied for fields such as drug target discovery and protein folding, but a limitation into their application is often a shortage of usable data [15]. Large panomics databases are generated to provide ample numbers of data points for medical research, such as the UK BioBank [16] comprising 500,000 participants. Despite the large number of participants, when variables of interest are selected such as a given disease and when covariates such as ethnicity are stratified, the usable numbers of participants may be insufficient to train an accurate machine learning algorithm. Furthermore, curated datasets may also have biases stemmed from processes such as participant acquisition. To address these limitations, it may be tempting to consolidate different datasets in order to have a sufficiently sized dataset including all variables of interest generated from a variety of sources to counter bias that would be present in a single dataset.

Medical data is highly sensitive and there are many regulations over how it is used [17]. Anonymization by removing personally identifiable information is generally insufficient to surpass this barrier making it practically difficult to combine medical datasets. Another reason why medical data is unstandardized is that generating shared datasets is time intensive and may be costly.

Federated learning [9] is a ML algorithmic methodology which was created for collaborative model generation where the learned wisdom is shared but the data is not shared between repositories. This means that a single model can be generated without breaking data governance over a large number of datasets. Federated learning by design consists of using a central server to distribute nodes for each database source behind the owner institution's firewall. The local nodes train the model and return it to the central server for aggregation and redistribution to the local nodes. Split learning, a type of federated learning, uses a peer to peer design, where there is no

central server and the individual nodes share their trained models, aggregate them locally, and redistribute them with each other. These protocols for both designs are repeated until the training is completed [18]. Federated learning performs faster than split learning as the clients generate models in parallel, but split learning has improved privacy as the architecture is split between the clients and the server but is more computationally intensive on each local node [19].

In addition to federated learning, other methods can be employed either as alternatives when federated learning is unavailable or to help validate a federated learning model. The bias and variability of single nonfederated models trained on small datasets can be compensated against using traditional statistical methods. ML models on small data can have a tendency to overfit training data and may not interpret unknown data accurately, but using models such as logistic regression on expert selected features and selectively removing outliers may improve the efficacy of the model. This methodology may be further optimized by running multiple models and generating a weighted average [20].

Longevity Physicians: Emerging Specialists and the Need of a Tailored Education

With the progress in geroscience and biogerontology, as well as in AI-based diagnostic and therapeutic tools, longevity medicine as a field has been increasingly in demand by educated patients. For longevity medicine to become an organic expertise area or, preferably, a specialty, just as oncology or cardiology, it needs to be practiced. This in turn implies a solid education of physicians, allowing them to not only acquire the necessary fundamentals, such as hallmarks of aging, but also to rapidly internalize and apply related research outcomes and tools.

Furthermore, as to develop and adequately practice longevity medicine, an ongoing continuous learning is required, encompassing the likewise rapidly evolving areas of precision, prevention, and functional medicine. Ultimately,

educating physicians in longevity medicine is one of the most challenging endeavors, requiring a structured, meticulous approach of interdisciplinary educators. Overall, physicians' continued education is still inadequate to meet the challenges and opportunities of longevity medicine.

Current medical training does not include AI, not to mention machine or deep learning [21]. The AI-enforced tools for early diagnostics and prevention of communicable and non-communicable (NCD) diseases are thus unpopular among the majority of physicians [2, 22, 23]. The so-called millennials are increasingly exposed to innovative solutions in medicine and to active patients' inquiries. Facing a lack of structured, physician-oriented, conceptualized curricula, this new generation, with a tremendous potential for global healthy longevity, is deserting and often diffusing away from the field. At the same time, a growing interest in longevity medicine is observed among related fields including biotechnologists, biologists, geroscientists, as well as among the general public, pharmacologic companies, and target industry groups. Interestingly, the latter two demonstrate an extremely high interest in growing a longevity physician community, while specific approaches to incentivize specific educational approaches (building of certified courses, curricula, accreditations) require significant resources. As long as academia will not sufficiently support such endeavors, the educational initiatives remain grandly scattered, in a form of individual or lecture series given by mostly nonclinical experts. In addition, despite the benefits longevity-focused medicine has to offer, currently, only its fragmentary aspects are available within the certification system: lifestyle, holistic, integrative medicine, or geriatrics. Extremely time-limited clinicians rarely can accommodate extracurricular educational activities in their schedules. Currently, we mostly face reactive medicine, managing diseases rather than mitigating risks toward pathogenesis. Since most healthcare systems are fragmented, specialists are often dispersed and comprehensive patient care is suboptimal. Most importantly, there is extremely limited access to

the practitioners who have self-initiated their education into longevity sciences, follow the rapid development of various diagnostic and monitoring solutions, and implement these from the longevity standpoint.

The paradigm of longevity and healthy aging as the top priority will greatly impact the primary, secondary, and tertiary prevention rates; it is essential that doctors have the access to well-structured and practitioner-friendly course contents. Development of such courses is only possible through interdisciplinary efforts that would generate contents and contexts teaching both the fundamentals and ways of how they can be implemented in the clinical practice.

Education is the foundation for longevity health findings to be implemented in the daily practice for patients and in preventative settings. It decimates the knowledge gap between physicians and nonclinical longevity experts (bio-/gerontologists, AI and computer scientists, etc.) and reduces stigmatization of longevity medicine being falsely dismissed as a highly anecdotal movement toward life prolongation. In contrast, longevity medicine is a highly scientific approach toward the extension of a healthy and productive lifespan, with an AI-based precision approach using measurable markers of aging.

An accurate physicians' education in longevity medicine must aim to clearly demonstrate current medical practice, which evaluates and optimizes the parameters of patients within the reference range for their corresponding age groups from truly personalized medicine based on large data. Even if an age group is selected based on a variety of further variables, such an approach is at most a personalized one, but not a precise or individual one. Longevity medicine brings together the best practices from various biomedical disciplines and AI to evaluate the patient's biological age throughout his/her course of life in order to reduce the gap between the current and the parameters of maximum physical performance (based on a calculated ideal biological age). A longevity physician is thus required to be able to not only apply measurements of aging clocks but also to then (with AI assistance) identify ways to reduce the gap between the current and the optimal biological age. These ways include, at the moment,

noninvasive lifestyle modifications (e.g., physical activity, intermittent fasting, circadian rhythm readjustment) or geroprotective supplements and anecdotal invasive methods. It is apparent that these approaches will require ongoing data collection in order to customize and improve protocols, as well as individual AI-supported recommendations (Fig. 2).

Only in the year 2020, a global interdisciplinary team developed the first official Longevity Medicine for Physicians course, covering topics of biogerontology, machine learning, biostatistics, differential diagnosis, programming, molecular biology, immunology, geroprotective interventions, drug design, healthcare organization, and others, as well as providing an overview of clinical applications of recent advances in aging research, skills to evaluate the validity of biomarkers of aging and other biological age testing systems, and knowledge of the available longevity therapies to tackle diseases that are mostly based on senescence-related processes in the organisms. It additionally bridges discrepancies in awareness and information on advances in research while bringing practicable examples of implementation into clinical practice. The unprecedented increase in the percentage of people over 65 years of age and corresponding increase in the illness, social, and economic burden associated

with aging require us to advance our understanding of the aging process and how to tackle those processes and provide the care needed. This and similar initiatives will ultimately lead to major benefications in healthcare systems as paramount, effective management of diseases, since progress in longevity and biogerontology research will likely increase the healthy productive lifespan and the number of years of government support in old age. It is therefore incumbent to educate physicians about the most recent parameters that can be applied to established models of prevention of diseases by tackling and applying biogerontology advancements. As such, they will be linked to economic growth via biomedical progress rate, the rate of clinical adoption, and the rate of change in retirement age.

Aging is a complex multifactorial process leading to loss of function, causing multiple NCDs, rendering prone toward CDs and premature mortality [24, 25]. There are many theories explaining the origin of the overall process [26, 27] and cause and effect relationships between different processes and systems, including aging of the immune system [28], inflammation [29–32], fibrosis [33, 34], mineralization of connective tissue [35], cellular senescence [36], wear and tear, and many others. In addition, many genetic and epigenetic changes implicated in aging and

AI-Guided Longevity Medicine

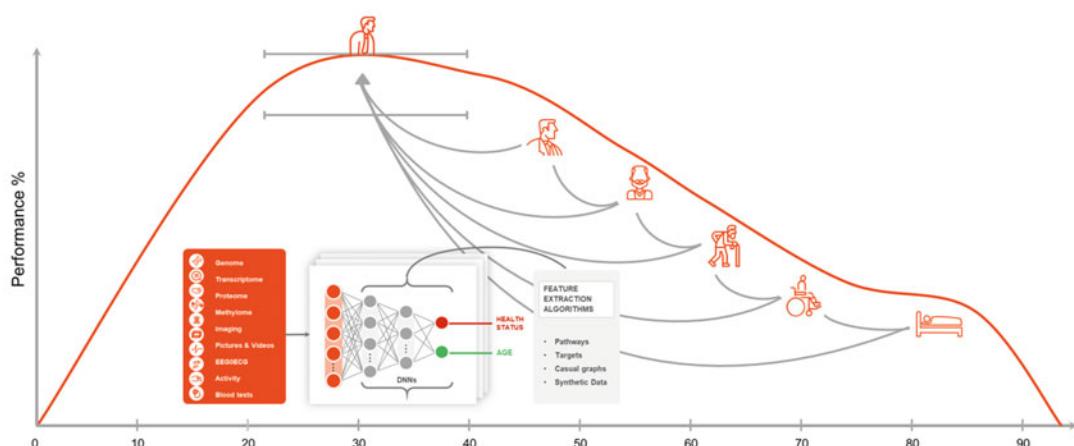

Fig. 2 How human performance changes with age. Panomics technologies integrated with deep neural networks can interpret this and identify geroprotective pathways

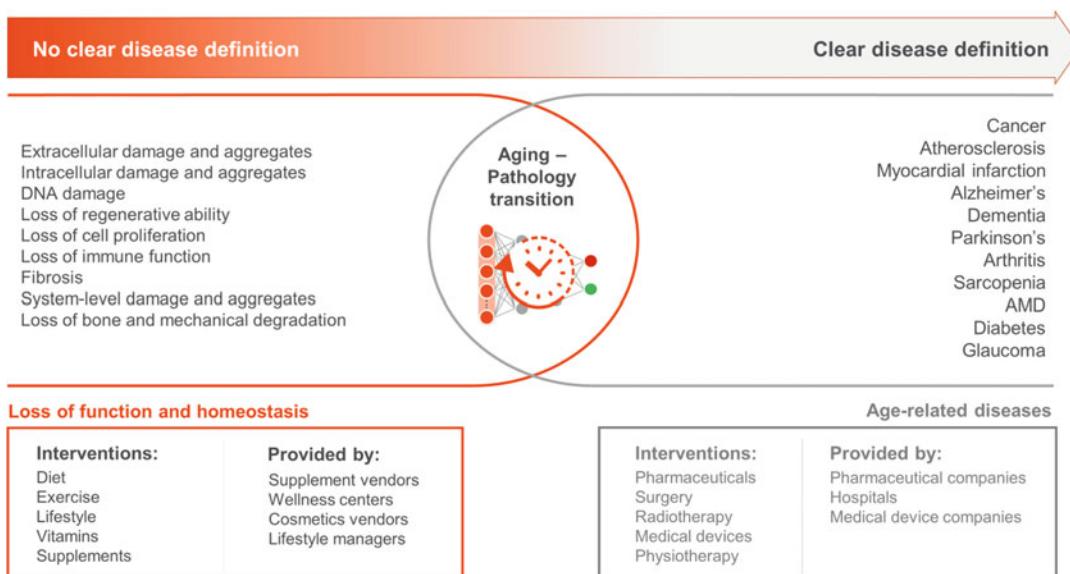

Fig. 3 Cellular processes with no clear disease definition contribute to aging and pathology over time and are affected by environmental factors such as diet. These can then lead to age-related disease

longevity are associated with aging in model organisms [37, 38]. Even though their role and action in human aging are uncertain, many of these changes are also associated with non-communicable diseases [37–43]. Recent discoveries showing that mechanisms involved in cancer are strongly associated with the aging process have led to multiple proposals to prevent cancer and other age-related diseases using drugs that increase lifespan in model organisms [44, 45]. AI and machine learning in the course are an inseparable aspect of modern medicine, especially tackling the prevention of global burden diseases. AI is expected to have a major impact in healthcare, where it can be used for the development of effective personalized medicine based on the interpretation of large medical databases gathered over the years by companies and healthcare providers [22, 46–49] (Fig. 3).

Healthy Versus Wealthy Longevity: Longevity Medicine and Public Health

The debate around longevity medicine allowed a valid but easily refutable argument that it might lead to an increase in health inequity. There are abundant reasons to counter-resonate. Firstly,

novel technologies and interventions are developing rapidly in a competitive ecosystem. We have seen a decline in, e.g., genetic testing pricing or CT/MRI imaging. With this trend, the longevity medicine might actually be one of the most affordable domains in terms of diagnostics and follow-up, as well as regarding geroprotective supplements or even specific invasive interventions, such as plasmapheresis. Secondly, most of the hallmarks of aging can be co-influenced by lifestyle modifications (exercise, nutrition, supplements, caloric restriction, intermittent fasting, cognitive activities, etc.), led by inexpensive app-based solutions, such as DACs and CGM [2, 22]. Such management toward risk prevention and short-term improvement of performance does not require strong financial inputs and is accessible to the majority of digitalized populations. An accompanying longevity physician navigating the measurements and interventions is an optimal way to fully extrapolate and exploit these tools, since they are able to customize the interventions and interpret the measurements for an individual, minding the biovariability, comorbidities, chronological age, and – importantly – personal goals and preferences (which determine the compliance). As mentioned previously, these experts are still underrepresented and imply a speedy

advent of appropriate education. Thirdly, healthcare institutions across virtually all countries globally face overcrowding and limited resources due to high healthcare costs, which in return aggravate the health inequality and inequity [50]. Most cost burden derives from age-related and chronic diseases [51, 52]. Mitigating those is now a priority in the medical and scientific field, as to circumvent a clash of health systems challenged with the spiraling chronic multimorbidities. Another example is the simple illustration of cost and time efficacy of AI-based drug discovery and repurposing, which allows to save millions of USD and several years on identification and testing of new compounds. At the moment, the sobering facts are as follows: 90% of all drug trials fail, very few that do succeed take an average of 10 years to reach the market, and cost ranges from \$2.5 to \$12 billion. In addition, in computero clinical trial simulations are promising to bring more equity: algorithms can be trained and retrained to include features that are largely ignored, such as the aspect of biological sex and gender, elderly, multimorbid patients, ethnic minorities, and importantly the age [53, 54].

Surely, as for any emerging field, also precision medicine will face barriers related to socioeconomic inequities and demand solutions toward financial viability, especially in systems based on solidarity. Targeting and empowering coordinated discussions of multidisciplinary stakeholder by continuous updates on the current state of science by KOLs in a transparent manner is a crucial approach toward a successful democratization of longevity medicine for all [55].

Since healthy longevity medicine is precision medicine driven by aging biomarkers and is not seeking a bare extension of life, but an extension of a healthy, productive lifespan, the field can notably contribute to improve the economy of healthcare and as a whole.

AI Applications in Medicine: The Fundament of Precision Medicine

Tangible AI applications in medicine are rapidly increasing in number, complexity, and accuracy, even though overall, they are still in very

preliminary stages [56]. The vast variety of areas and problems that securely designed AI systems in medicine can tackle in practice bear major opportunities toward improvement of the healthcare as entity. At the entrance of the new decade (2020), most AI appliances are targeted at assisting physicians in their diagnoses and treatment decisions [57]. The ultimate goal for the reactive medicine is to achieve an individualized prediction which treatment will work for which patient and how well in order to avoid chronification, physical and emotional burden, and costs. There are several overarching AI appliances that trespass current healthcare. Firstly, the basic prerequisite for AI applications – the data – is now mostly collected in a planned electronic manner. Secondly, AI allowed telemedicine to be established and flourish speedily. Public health impacts are indisputable alone through the provision of medical care in rural regions with a low density of specialists (thus, faster diagnosis, better prognosis, less morbidity and mortality, less costs, less burden on the patients and caregivers, etc.).

AI-based diagnostic systems are able to detect features quickly, quantitatively, objectively, and reproducibly and thus classify conspicuous skin lesions with high accuracy. Machine learning supports diagnostics in numerous specialties, e.g., oncology (lung cancer detection [58, 59]), neurology (CT-assisted stroke detection), ophthalmology (early detection of maculo- and retinopathies [60]), cardiology (risk assessment of myocardial events, sudden cardiac death based on ECG and cardiac MRI), dermatology (detection and classification of dermal lesions based on a body scan or even images [61]), etc. The latter exemplifies the abundant potential of AI applications in patient care, e.g., remote care, patient engagement, and auto-monitoring. Even though the dermatologic smartphone apps for self-examination by patients are still under a strict scrutiny and depend on compliance, pre-identification of suspicious skin lesions by the AI algorithm and a following analysis by specialists improve the early detection of, e.g., melanoma [62]. “AppDoc-Online Dermatologist” and the “Derma-App” are prominent examples in Germany. More studies are needed to confirm the outperformance of AI over dermatologists, based on verified benchmarks [63–65]. A

close follow-up of conspicuous lesions in high-risk patients is further enabled with digital dermoscopy, a 3D whole-body photography [66, 67].

AI can further facilitate and optimize medical processes, such as division and delivery of blood products – a problem that is virtually universal and leads to massive losses in resources (both time and costs). “AutoPiLoT” AI system and app, for example, approaches this issue by evaluating past data and thus is able to make predictions of amount and timing of blood units needed in a specific hospital, as well as to recognize patterns that can further be readjusted individually. The app has now also implemented blood donation, capturing the donor data and thus simplifying the matches [68].

AI can also simplify the diagnostics of complex diseases, through complex diagnostic tools, such as MRI in multiple sclerosis (MS). AI algorithms, encapsulated in a user-friendly app, will allow nonexperts (such as GP) to accompany the patient, interpret complex images over time, and gain experience [69].

Tailoring an optimal treatment for a patient involving all aspects of the clinical picture is considered but optimally also other information about the patient’s biological features (e.g., genetic data), health data, and examination results. Data from a large number of patients must be analyzed and intelligently linked to predict the course of the disease and the optimal therapy for a specific group of patients sharing similar features. AI is incumbent in order to conduct these steps and thus enable what is defined as precision medicine.

Conclusion and Future Perspectives

Longevity medicine is a groundbreaking dynamic field, emerging as one of the most essential medical disciplines combining the most advanced and complex diagnostic and interventional approaches. As an AI-driven precision medicine, longevity medicine harnesses innovative and state-of-the art technologies and science to exploit the potential of the human genome, deep quantitative phenotyping, -omics (e.g., epigenomics, metabolomics, proteomics, etc.), microbiome, radiogenomic precision

imaging, etc. With the help of continued data collection, the development of new features, improvements in ways of interpretation, and further optimizations in the implementation of an individual patient protocol, longevity medicine will be self-perpetuating. The longitudinal approach enables a trifold dynamic, interrelated longevity practice: data mining, patient compliance, and physicians’ lead. This shifts reactive medicine with limited human data analysis capacity toward longevity doctors that can collect and apply gigabytes of patients’ data toward identification, mitigation, and elimination of actionable diseases, preferably years and decades ahead.

Abstract

Nanotechnology and its sister field of quantum technologies are interdisciplinary sciences that have been touted as one of the holy grails of technological advancements still yet to reach critical mass and unveil their transformative potential. Similarly, artificial intelligence and machine learning constitute another technological advancement that has captivated scientific hearts and minds, with both leading to next generation industrial revolutions.

The unification of the latter and former technologies has thus elevated opportunities for exciting emerging discoveries and promises to offer further combinatorically exponential translational discoveries for medicine and humankind. This chapter explores the use of AI in the subfield of nanomedicine. We explore the applications of machine learning algorithms to aspects of drug discovery, toxicology and regenerative medicine, as well as medical and surgical robotics.

Keywords

AI in nanomedicine · Nanotechnology · Nanoethics · Nano-neuroscience · Quantum surgery · Nanorobotic · Nanoformulation · Drug delivery · Nanocarrier · Gold nanoparticles

Introduction

Nanotechnology and its sister fields of quantum technologies have delivered on their promise as exciting scientific disciplines continuing to revolutionize our understanding of the atomic-scale properties of matter. Here we adopt the European Commission's definition of "nano" at 1–100 nm for >50% of the number size distribution of particles sizes, excluding materials with surface area

by volume in excess of $60 \text{ m}^2/\text{cm}^3$ [1]. With respect to environmental health and safety or pollution-related concerns, this number size distribution threshold of 50% may be substituted by a threshold between 1 and 50% [1]. A formal definition of nanomedicine is the use of nanomaterials for the diagnosis, monitoring, control, prevention, and treatment of disease [2]. Nanomedicine thus leverages nanomaterials for medical disease theranostics (a combination of diagnosis and the simultaneous potential for therapeutics) and has allowed remarkable medical nanomaterial discoveries to be made. The fabrication of these nanomaterials is either in a top-down or a bottom-up approach [1]. Either method influences the material properties and as such the constraints that must be considered before construction and modeling of the material is achieved. However, this does allow for a multitude of possibilities designing different types of materials from their bulk substrates.

On the nanoscale, the significant characteristics that allow the properties to differ from the bulk material are determined by the materials' intrinsic and physiognomically determined properties. These properties include: size, shape, surface curvature, and chemical composition, as well as properties such as crystallinity, porosity, particle heterogeneity, roughness, zeta potential or surface charge—determining hydrophobicity and hydrophilicity, and conferred ability for functionalization, etc. Toxicological properties include particle aggregation, dissolution features, the ability of the material to be in a state of dispersion, which aids its solubility, the ionic strength, pH, temperature, and the internal surrounding environment that the particle is interacting with, which may have the presence of large organic molecules (for example, proteins) as well as the external environment after the particle's life cycle and hence biodegradability.

The general principles of nanotechnology for medicine thus include [3]:

- Size and environmental interactions
- Self-assembly and pseudo-intelligence
- Feedback control
- Biomimicry
- Molecular machines
- Cross-collaborative multidisciplinary approaches such as from biology, engineering, chemistry, physics, and medicine

It is unsurprising that several of these described characteristics of nanomaterials can

be studied and predicted using applied machine learning and artificial intelligence methodologies. For a complete treatment of artificial intelligence, we refer you to the respective chapters, but have summarized the process in Fig. 1. However, this chapter will look at areas where machine learning techniques have been leveraged to help resolve complexities associated with nanomaterial design and drug discovery in nanomedicine. The literature and argument for machine learning methodology in nanomedical

Machine Learning Cycle

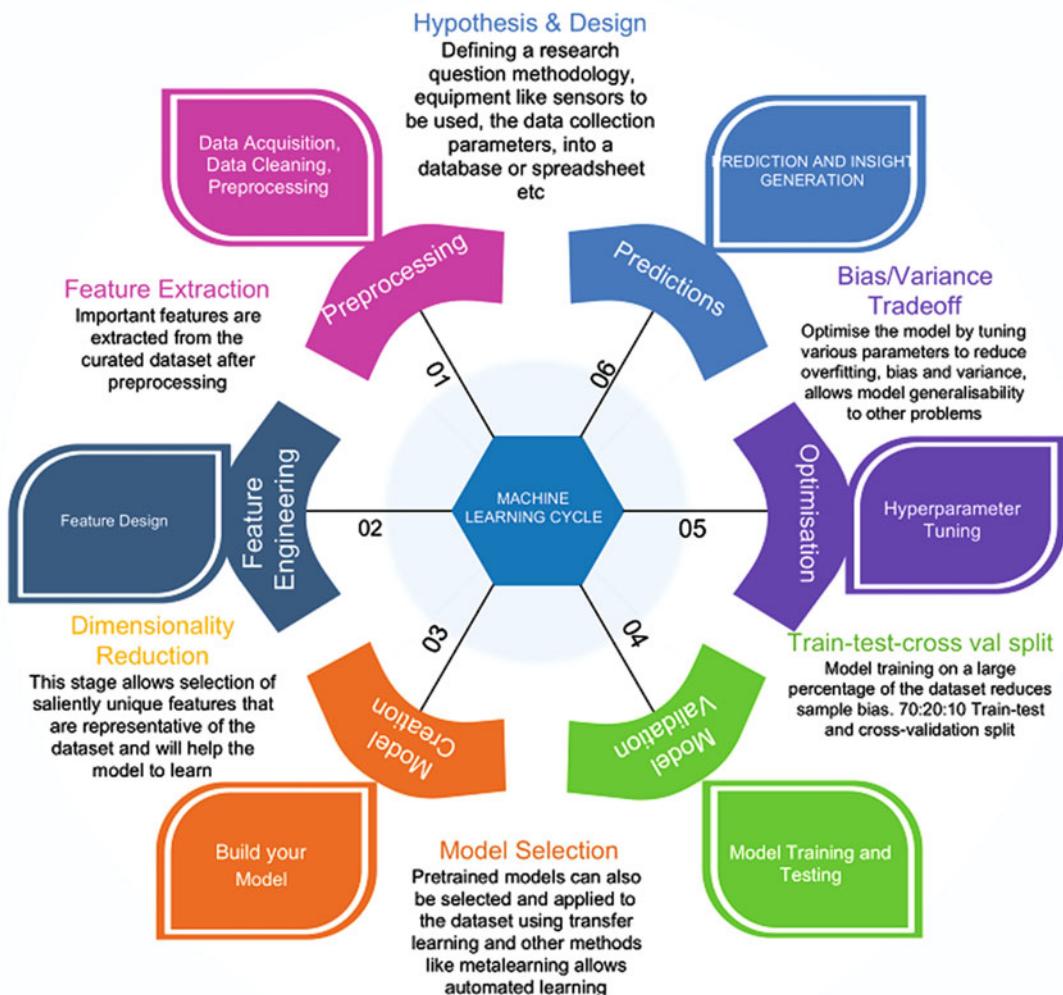

Fig. 1 A representational example of the machine learning cycle. Methodologies vary, but the underlying central tenets

remain ubiquitous. The cyclical nature is seen whereby there is transition from one step to the next in an iterative fashion

discovery is still embryonic, compounded by the argument that the study and fabrication process is usually probabilistic. This makes model explainability challenging with some machine learning methods, such as deep learning, very difficult due to its “blackbox” processes. Nonetheless there are various areas where successful inroads have been made with machine learning, including in the fields of nanotoxicology, nano-oncology, DNA and other genetic nanotechnologies and regenerative nanomedicine, etc. Nanoparticles can augment cancer drug delivery to increase efficacy with a wide range of formulated customizations available to counteract cancer drug resistance, immune cloning for reduced drug clearance and drug distribution, etc. Identifying these unique customizations will benefit from methods that can allow combinatorically unique feature and entity extraction to aid drug design [4].

The chapter begins with a review of the literature in this area and tackles various aspects of the application of artificial intelligence to facilitate nanomedicine discovery. We also discuss nanobots in medicine, their inherent intelligences, and the challenges faced in terms of control. We then conclude our discussions looking at some of the ethical and regulatory aspects of nanomedicine discovery and applications.

Review of Literature

We searched the following databases:

- “Artificial Intelligence” and Nanomed\$.mp. [mp = tx, bt, ti, ab, ct, sh, hw, tn, ot, dm, mf, dv, kw, fx, dq, id, cc, ac, de, md, sd, ip, vo, pg, pu, ib, is, yr, et, jn, dp, ja, bd, ar, bs, cf, pj, pa, dt, rf, so, pb, nm, kf, ox, px, rx, an, ui, ds, on, sy], generated 139 results

Results and Discussion

The literature from the above databases identified 293 results in total, suggesting that this is still an area that will continue to grow in the coming years, with the required further research investment, and that it has the potential to deliver innovative approaches. Table 1 summarizes the results of AI models used in nanomedicine research through additional citation tracking and analysis of review articles.

Recent decades have seen an explosion of interest in nanobiointerface technologies, which have their origins deeply rooted in nanomaterial engineering principles and are also coupled with various biological entities such as extracellular matrix scaffolds. Nanoparticles can interact with DNA,

Table 1 Machine learning models identified in literature for nanomedicine

Author	Type of nanomaterial studied	Tissue of interest	Machine learning model proposed	Reported model accuracy
Ban et al. 2020 [5]	Multiwalled and single-walled carbon nanotubes, metallic (e.g., Ag, Au, and Fe ₃ O ₄), nonmetallic (e.g., SiO ₂ and Si), and liposomal nanoparticles (e.g., cholesterol-phosphatidylcholine and thiolated amino-poly[ethylene glycol]; 3 kDa) N-acetyl-L-cysteine and thiolated L-asparagine), cationic (e.g., 11-amino-1-undeca- nethiol and hexadecyltrimethylammonium bromide), neutral (e.g., carboxymethyl-poly[ethylene glycol]-thiol [5 kDa] and bicyclononyne), common (e.g., carboxyl [COOH] and citrate [CIT]), and rare (e.g., Pluronic F-127 and 16-mercaptopentadecanoic acid) surface ligands	Plasma from healthy samples, serum, blood, or cell culture medium	Random forest, neural networks, and linear regression	R ² = 0.80
Basso et al. 2021 [6]	Cationic lipid, glycerol-based lipids, GLY1, and GLY2 conjugates Drugs included: calcium, atorvastatin, and curcumin	Brain tumor cells	Unsupervised: Row-wise principal component analysis, hierarchical clustering analysis Supervised: PLS regression with noniterative partial least squares, neural networks with TanH linear and Gaussian activation functions	R ² = 0.95–0.99
Sayes and Ivanov [7]	Metal oxide nanoparticles, titanium oxide	Rat alveolar macrophages and immortalized cell lines studying LDH release	Linear discriminant analysis for classification	R ² = 0.77
Puzyn et al. [8]	Metal oxide nanoparticles (ZnO, CuO, V ₂ O ₃ , Y ₂ O ₃ , Bi ₂ O ₃ , In ₂ O ₃ , Sb ₂ O ₃ , Al ₂ O ₃ , Fe ₂ O ₃ , SiO ₂ , ZrO ₂ , SnO ₂ , TiO ₂ , CoO, NiO, Cr ₂ O ₃ , and La ₂ O ₃)	<i>E. Coli</i> bacteria looking at EC ₅₀	Multiple regression	R ² = 0.85
Liu et al. [9]	Metal oxide nanoparticles (Al ₂ O ₃ , CeO ₂ , Co ₃ O ₄ , TiO ₂ , ZnO, CuO, SiO ₂ , Fe ₃ O ₄ , and WO ₃)	BEAS-2B looking at membrane permeability	Logistic regression models	Accuracy = 100%

Davids and Carlisle [17]	Gold nanoparticles	Looking at the formation of gold nanoparticles of various sizes	Deep neural networks	Accuracy = 93.85%

Modified from Jones et al. [9, 14, 17, 18]

proteins, cell membrane lipid bilayers, and various intracellular organelles, such as endosomal compartments, to establish a series of connected interfaces between the material and cellular substrate [19].

This interaction enhances the biophysico-chemical, thermodynamic, and kinetic properties. Example interactions include protein corona formation and intracellular uptake. The design of these nanobiointerfaces by interfacial chemists, physicists, engineers, and medics to help study and resolve various diseases necessitate a combinatorial approach. A few

approaches in the past decades have leveraged combinatorial methods to help decipher the complexity, variability, and interspecies differences of these biointerfaces in colloidal form. The boundaries that shape the interfaces themselves encompass three aspects: (1) the nanoparticle surfaces that have features derived from their unique size and shape-determined physicochemical properties, which have been modeled using combinatorial machine learning; (2) the contact zone between the particle and its surrounding environment or media before it is

interfaced with the biological tissue surface; and (3) the zone of interactivity, where the nanomaterial comes into contact with the biological surface, can also be modeled combinatorically [19]. However, the challenge of computational complexity limits the resolution. The process is also computationally resource intensive for dynamic modeling to be effective. Here too applications of machine learning approaches, such as generative adversarial networks and in particular quantum machine learning, could augment the process for building nanobiointerfaces through intelligent material design by resolving molecule-molecule interactions. The behavior of these interfaces, surface chemistry, and how they interact with each other and other molecules within the body are areas that will continue to benefit from other machine learning approaches for which deep learning will prove useful.

It is imperative that force and bonding interaction modeling such as hydrogen bonding, Van der Waals, and ionic interactions be achieved using quantum machine learning because of the probabilistic quantum characteristics of the electron cloud behavior necessitating more advanced methods of data capture and processing. Quantum computing and advances in this space are allowing modeling of hydrogen bonding to be fully appreciated and studied at better atomic resolutions. The next section describes some of these machine learning models in specific areas of nanomedicine. We begin with drug discovery and nanoformulation.

Machine Learning for Nanodrug Discovery and Nanoformulations

Drug Delivery Systems and Formulation

Various approaches are adopted to ensure that the designed nanodrugs are delivered in a timely manner. One approach includes modifications to the pharmacokinetics and pharmacodynamics to improve patient compliance while sustaining optimal treatment [20]. Contrary to

immediate release preparations, modified release preparations can also be designed that allow effective maintenance of the drug concentrations within acceptable limits to counteract the side effect profile and also ensure appropriately consistent drug dosing. These approaches are achieved through a variety of technologies including liposomal formulations, microsphere platforms, nanoparticle suspension conjugates, or nanoemulsions [20]. For an in-depth review of the approaches used please see the detailed work by Cottura et al. and with a summary of their findings in Table 2 below [20]. This area has benefited from mathematical modeling using QSAR and nano-QSAR for predicting nanoparticle to cellular interactions such as toxicity, cellular uptake, drug loading and release profile, and nanoparticle receptor binding characteristics [8, 12, 18]. Current approaches that also utilize artificial intelligence through reinforcement learning for computational decision-making in drug discovery and nanoformulation have been discussed by Vamathevan et al. [21]

Machine Learning in Specific Areas of Nanomedicine

Mathematical Machine Learning Modeling for Cancer Nanomedicine and Theranostics

Cancer remains a very challenging area of research with rapid advancements and discovery on a daily basis. Understanding cancer data is paramount for modeling and drug discovery [24]. In silico models offer an opportunity for deriving insights into cancer drug discovery. However, the vast dataset and heterogeneity makes the description of information on cancer drug development and progression at times uncorrelated [25]. Many researchers therefore continue to seek new big data-driven and machine learning in silico modeling techniques that correlate with *in vivo* data for cancer drug discovery. [25]

Drugs such as contrast agents and RNA silencing therapies all require a nanocarrier-based design to carry the drug to the required location

Table 2 Summary of pharmaceutical nanoformulations that have been adopted to augment drug delivery

Delivery system	Drug	Active ingredient	Composition	Company	Indication	Approval date
Liposome	Doxil ^a	Doxorubicin hydrochloride	HSPC and PEG	Janssen	Ovarian cancer, sarcoma, myeloma	1995
Ambisome	Amphotericin B	HSPC and DSPG	Astellas	Fungal infection	1997	
Depocyt	Cytarabine	DOPC and DPPG	Pacira	Lymphomatous	1999	
Epxarel	Bupivacaine	DOPC and DOPE	Pacira	Local anesthetic	2011	
Marqibo kit	Vincristine sulfate	Eggs sphingomyelin	Talon	Acute lymphoblastic leukemia	2012	
Onivyde	Imiquimod hydrochloride	DSPC and MPEG-2000-DSPE	Ipsen	Adenocarcinoma of the pancreas	2015	
Microsphere	Lupron Depot	Leuprolide acetate	PLGA	Abbvie	Advanced prostatic cancer	1995
Sandostatin LAR	Octreotide acetate	PLGA	Novartis	Acromegaly	1998	
Trelistar	Triptorelin pamoate	PLGA	Allergen	Advanced prostate cancer	2000	
Definity	Perflutren	DPPA, DPPC, and MPEG-5000-DPPE	Lanthus	Ultrasound contrast agent	2001	
Risperdal Consta	Risperidone	PLG	Janssen	Schizophrenia, bipolar I disorder	2003	
Vivitrol	Naltrexone	PLG	Alkermes	Alcohol dependence	2006	
Bydureon	Exenatide synthetic	PLGA	AstraZeneca AB	Type 2 diabetes	2012	
Signifor lar	Pasireotide pamoate	PLGA	Novartis	Acromegaly	2014	
Lumason	Sulfur hexafluoride Lipid-type microspheres	DSPC	Bracco	Ultrasound contrast agent	2014	
Bydureon BCise	Exenatide	PLGA	AstraZeneca AB	Type 2 diabetes	2017	
Triptodur kit	Triptorelin pamoate	PLGA	Arbor	Central precocious puberty	2017	
Bicillin L-A	Benzathine penicillin	Dispersion	King Pharma	Rheumatic fever	1952	
Suspension and nanoparticle	Depo-Provera	MPA	Dispersion (microcrystalline suspension)	Pharmacia & Upjohn	Contraception	1959
Atridox	Doxycycline hyclate	PLA	Tolmar	Chronic adult periodontitis	1998	
Eligard	Leuproreotide acetate	PLGA	Tolmar	Advanced prostate cancer	2002	

	<i>Abraxane</i> ^b	<i>Paclitaxel</i>	<i>Protein nanoparticle</i>	<i>Abraxis</i>	<i>Metastatic breast cancer; non-small cell lung cancer</i>	2005
Somatuline Depot	Lantreotide acetate	Nanotide		Ipsen	Acromegaly	2007
Zyprexa Relپrevv	Olanzapine pamoate	Microcrystal	Eli Lilly	Schizophrenia		2009
Invega Sustenna	Paliperidone palmitate	Nanocrystal	Janssen	Schizophrenia		2009
Feraheme	Ferumoxytol	Carbohydrate-coated iron-oxide nanoparticle	Amag	Iron deficiency anaemia		2009
Abilify Maintena	Aripiprazole	Nanocrystal	Osuka	Schizophrenia		2013
Ryanodex	Dantrolene sodium	Nanocrystal	Eagle	Malignant hyperthermia		2014
Invega Trinza (3-month)	Paliperidone palmitate	Nanocrystal	Janssen	Schizophrenia		2015
Aristada Sustol	Aripiprazole lauroxil Granisetron	Nanocrystal Ortho ester	Alkermes Heron	Schizophrenia Nausea and vomiting		2015 2016
Sublocade	Buprenorphine	PLGA	Indivior	Moderate to severe opioid use disorder		2017
Perseris Cabenuva	Risperidone Rilpivirine	In situ forming gel Dispersion	Indivior Janssen	Schizophrenia HIV		2018 Clinical trials
Emulsion Intralipid	Soybean oil	Fat emulsion	Fresenius	Parenteral nutrition		1975
Haldol Cleviprex	Haloperidol decanoate Clevidipine	Oil depot Lipid emulsion	King Pharma Chiesi	Schizophrenia Reduction of blood pressure		2000 2008
Smoflupid	Fish oil	Lipid emulsion	Frerenius	Parenteral nutrition		2016
Cinvanti	Aprepitant	Lipid emulsion	Heron	Acute and delayed nausea and vomiting		2017

HIV, human immune deficiency virus; DOPC, dioleyoylphosphatidylcholine; DOPE, dioleoylphosphatidylethanolamine; DPPG, dipalmitoylphosphatidylglycerol; DSPC, distearoylphosphatidylcholine; DSPE, distearoylphosphatidylethanolamine; DSPG, distearoylphosphatidylglycerol; HSPC, hydrogenated soyphosphatidylcholine; MPA, mycophenolic acid; MPEG, methoxypolyethylene glycol; NA, not applicable; PEG, polyethylene glyco; PLA, polyactide; PLG(A), poly(lactic-co-glycolic [acid])

^aFirst US Food and Drug Administration approved nanodrug

^bFirst US Food and Drug Administration approved nanotechnology-based target drug delivery

Adapted from Cottura et al. [20, 22, 23]

using stealth-cloaking systems to bypass the body's immune system and avoid premature clearance [20, 26]. The voyage and fate of the nanodrug from entry into the body is a: (1) vascular, (2) trans-vascular, (3) interstitial, or (4) a pinocytic-clathrin-mediated transport allowing inspissation into cells or a diffusion-based trans-cellular mechanism [20, 26–28].

Immediately after injection, they encounter a high proportion (60–80 g/L) of plasma proteins, such as albumin, and phagocytes, opsonins, and lipopolysaccharides that they have to avoid by means of adsorption, which transforms the biochemical and molecular identity and fingerprint of the particle by creating biomolecular corona around it [20, 28]. This biomolecular corona has hydrodynamic capabilities giving it a newer bioidentity. Augmented bioidentities affect charge-charge interactions, enterohepatic and hemodynamic interactions determined by changing capillary network pore sizes, which affect the particle-to-pore size ratio, hydrophobicity, and pH changes that the drug will encounter on its journey to the destination of interest. These can be modeled using machine learning and big data approaches to allow effective predictions for the newly fabricated nanodrug.

When at its destination, an effective design must allow the carrier system to exploit the characteristic biophysicochemical milieu of the tumor microenvironment to jettison its payload to the tissue of interest. Through a phenomenon known as margination, the nanoparticle that has now gained the ability to enter the cell accumulates at the microvasculature cell wall boundary [29].

After it has performed its desired effect, toxicity limiting measures must be built into the nanocarrier and nanodrug to allow their removal or clearance to minimize damage to the convalescing normal tissue. The interaction of nanodrugs with both noncancer and cancer cells has thus gained considerable research focus with significant rigor.

The drugs can accumulate through passive accumulation, ionic binding, or Van der Waals interactions depending on the ability to functionalize the nanoparticle with another bioconjugate, which causes pharmacokinetic and pharmacodynamic modifications [20, 26, 28]. This often leads to half-life changes, triggered release by

enzymatic or electromagnetic interaction, temperature, and pH-dependent changes when the environment interacts with the nanodrug. These drugs can now be fabricated as organic, polymeric, or liposomal drugs or inorganic, gold, silica, diamondoid, and carbon-based and even DNA/RNA/aptamer-based constructs all with unique characteristics that lend themselves to added interaction complexities, which the nanomedic must appreciate and learn to exploit or overcome. Such combinatorial vastness lends itself well to artificial intelligence and big data solutions to help overcome complex interaction analysis. What remains intriguing from various cancer nanomedicine meta-analyses is the fact that on average only 0.7% of the drug reaches the destination tumor [20, 25, 28, 30].

Consequently, areas such as enhanced permeability retention characteristics or leakiness of the tumor microvasculature, and interactions of these microenvironments with nanochemotherapy drugs require augmented methods to advance discovery of the features that lead to suboptimal nanocarrier drug delivery. Machine learning is one such area that promises a supporting role for effective mathematical modeling within this space.

In silico models of the entry of the particle into the body include kinetic and thermodynamic models and molecular dynamics simulations, all of which can be theoretically achieved with machine learning. Particle transport and extravasation into the targeted tissue environment have been modeled using mesoscopic length scale, continuum, and discrete modeling. Machine learning models like random forests have also been used to predict the corona formation [5]. In Ban et al's study, corona compositions classified by physicochemical and functional properties such as length, theoretical isoelectric point (pI), molecular weight, grand average of hydropathicity (GRAVY) score, and function were utilized. We describe another example model below for corona formation [5]. Dogra et al. provide a spatiotemporal classification of mathematical models for nanomedicine cancer therapeutics: (1) convection, diffusion, reaction kinetics, PKPD models, (2) continuum discrete hybrid models, and (3) agent-based models that enable molecular dynamic simulations to be generated [28].

Modeling the protein nanoparticle interactions with cancer cell receptors was proposed by Dell'Orco and colleagues who derived the equations below [31].

$$\frac{d[\text{Nanoparticle} \times \text{Protein}]}{dt} = n_{\text{protein}} k_{\text{protein}}^{\text{on}} [\text{Nanoparticle}] [\text{Protein}] - k_{\text{protein}}^{\text{off}} [\text{Nanoparticle} \times \text{Protein}] \quad (1)$$

where

$[\text{Nanoparticle}]$ = Concentration of nanoparticles

$[\text{Proteins}]$ = Concentration of proteins

$k_{\text{protein}}^{\text{off}}$ = Off-rate constants when there is non-bound protein to receptor

$k_{\text{protein}}^{\text{on}}$ = On-rate constant when there is protein bound to receptor

$$n_{\text{protein}} = \frac{4\pi(r_{\text{nano}} + r_{\text{protein}})^2}{\pi r_{\text{protein}}^2} \quad (2)$$

where n_{protein} is the number of available binding sites on the nanoparticle surface, r is the radius of either the nanoparticle and the protein (assuming that the protein is a sphere) to give a total cross-sectional area for the protein surface.

This was extended by Darabi Sahneh and colleagues to include the concentration of available binding sites [32].

$$\frac{d[\text{Nanoparticle} \times \text{Protein}]}{dt} = n_{\text{protein}} k_{\text{protein}}^{\text{on}} [\text{Protein}] Y - k_{\text{protein}}^{\text{off}} [\text{Nanoparticle} \times \text{Protein}] \quad (3)$$

$$\text{where } Y = \left([\text{Nanoparticles}]_0 - \sum_{j=1}^m \frac{[\text{Protein}_j \times \text{Nanoparticle}]}{n_{\text{protein}_j}} \right) \quad (4)$$

The dynamic evolution of the corona formation is thus captured. Physically, force modeling including drag coefficients could also be included to augment these models, but may be deemed

negligible under certain conditions for model simplification. Theoretically these models can form templates for dynamic time series-related pharmacokinetic machine learning model design using real-time sensors to capture the data, but in practice other methods may be preferred. The models are summarized in Table 3, but for an extended review the reader is directed to Dogra and colleagues [28]. The above metrics can be encoded as unique features and fed to a quantum deep learning algorithm to enable predictions for how the particle journeys and interacts with protein receptors as well as its clearance from the body. We are likely to continue to see this more and more in coming years.

Other mathematical models like quantitative structure–activity relationships (QSAR) and their nanoscale equivalent (nano-QSAR) are heavily used for nanotoxicity predictions and are discussed in the section below [40].

Machine Learning in Precision Nanotheranostics for Cancer

In brain tumor research for a safer alternative to a cationic compound for nanodrug delivery, glycerol-based lipids with alkylated chains and glycerol backbones were evaluated using supervised and unsupervised machine learning techniques to identify structural similarities in GLY1 and GLY2 nanolipid carriers, which differ in their polarity, and also to assess the hemocompatibility profile. They showed that GLY1 nanocarriers demonstrated better zeta potential profile with decreasing particle size and also demonstrated reduced cytotoxicity [6, 41].

In renal adenocarcinoma, current AI platforms have focused on optimization for chemotherapeutic drug combinations. Most have been designed to streamline feedback controls that optimize combinatorial drug variations to inhibit the viability of renal adenocarcinoma cell line 786-O [42]. Others have aimed to also optimize nano-diamond to chemotherapy drug combinations (e.g., nano-diamond-doxorubicin conjugate, nano-diamond-mitoxantrone, and nano-diamond-bleomycin) for the best cancer cytotoxicity

Table 3 A nonexhaustive summary of mathematical models that can be augmented using machine learning for cancer theranostics and drug discovery adapted from Dogra et al. [28]

Author	Mathematical model presented	Area of interest	Results described and application
Dell'Orco et al. [31] Darabi Sahneh et al. [32]	Kinetic models see Eqs. 1, 2, 3, and 4	Biomolecular corona formation	Law of mass action, nanoparticle to protein interaction. Series of first-order differential equations modeling the protein concentrations, concentration of protein to nanoparticles, association and dissociation constants. Corona formation. Evolution of metastable to stable state
Lopez and Lobaskin [33]	Coarse-grained molecular dynamic simulations	Biomolecular corona formation	Characteristic protein adsorption energies were modeled and simulated. Modeling results revealed the size-dependent nanoparticle to drug protein receptor binding rather than charge
Gentile et al. [34]	Continuum modeling	Microvascular transport, margination, and binding	Hematocrit and vessel permeability-related reduction in nanoparticle diffusion coefficient
Zhdanov, and Cho [35]	Augmented kinetic models	Adsorption and desorption of proteins	Diffusion rate constant drops at the colloid solid interface
Huajian et al. [36]	Discrete modeling	Cellular internalization of the nanoparticle	There is a threshold minimal particle size and ligand density needed for endocytosis-mediated transport
Dogra et al. [37]	Pharmacokinetic modeling	Whole-body biodistribution and clearance	The smaller the size of the particles the longer they stay in the circulation and are able to evade the immune system. Excretion is achieved by positively charging the nanoparticle. Cloaking reduces their vulnerability to sequestration
Chauhan et al. [38]	Hybrid modeling	Drug delivery into the tumor	Size and other physical and chemical characteristics affect interactions with blood vessels which in turn has a consistent influence on the enhanced permeability retention properties
Pascal et al. [39]	Pharmacodynamic modeling	Therapeutic efficacy and toxicity models	Dose and integration time-dependent effect on how toxic the nanoparticle can be when it comes into contact with the tissue of interest

with a minimal toxicity profile for the surrounding tissues [42]. Nano-diamonds have superior infratoxicity profiles compared to other nano-conjugated and bulk chemotherapeutics and optimization enables rapid toxicology profiling and also can make them likely candidates for computer vision applications [43]. Other noteworthy nano-related platforms designed for uro-oncology include the Quadratic Phenotype Optimization Platform identifying the optimal combination from a pool of 114 FDA approved drugs, including dactinomycin and decitabine [42].

In metastatic castration resistant prostate cancer theranostics, CURATE.AI was used for a guided combination therapy consisting of ZEN-3694 (a bromodomain and extraterminal inhibitor) and enzalutamide (an androgen receptor

inhibitor) [42]. The CURATE.AI was leveraged for patient treatment response monitoring by enabling cautious dose modifications to the ZEN-3694 and enzalutamide chemotherapy drugs. The CURATE.AI-guided treatment was shown to reduce prostate-specific antigen levels and stopped disease progression.

Machine Learning for Nanotoxicology

In nanotoxicology, *in silico* models are predominantly developed for predicting the toxicity of nanoparticles and their interactions with various tissue constructs. The quest to design safer and more cost-effective nanoparticles for nanomedicine has led to a reliance on machine learning and data

mining for drug discovery [40]. Structure-based mathematical models remain the most reported and heavily studied for nanomaterial-induced toxicity, and include quantitative structure–activity relationships (QSAR) and their nanoscale equivalent (nano-QSAR), which attempt to model and predict physicochemically defined, biofunctional molecular properties. These properties include point of zero zeta potentials predicting agglomeration behavior [40].

Other structural-based machine learning models also include Bayesian methods and Markov Chain Monte Carlo simulation. Other models discussed include quantitative nanostructure activity relationship (QNAR) models [20]. What is clear is that different species can have different drug absorption pharmacokinetic features that need to be modeled differently.

Table 1 provides a summary of artificial intelligence and machine learning methods that have been used for various nanotoxicology studies. Most reported studies on toxicity demonstrate predilection toward the use of metal oxide nanoparticles for theranostics. Cytotoxicity from polyamidoamine dendrimers, which are useful delivery systems for nanodrug delivery, were identified using a data mining approach with an accuracy ranging from 60.2–83.5%. Jones and colleagues built a decision tree that indicated that if the isoelectric point was greater than 12.63, dendrimer toxicity was predicted [14]. The predictive toxicology of cobalt nanoparticles in various cell lines representing the lungs, liver, kidney, intestines, and immune system was compared with their ionic forms using a J48 decision tree machine learning model [44]. Their model predicted concentration as the highest rank determinant for toxicity, with a hierarchy of cell sensitivity toward cobalt ions. They also concluded that the toxicity profile of aggregated cobalt nanoparticles was related to their dissolved ionic forms.

Machine Learning and Quantum Enabled Technologies

The purported meteoric rise of quantum computers from works of fiction to big research laboratories and now to their near decentralized

distribution into smaller institutions has allowed quantum machine learning algorithms to permeate into recent consumer testing platforms [45]. IBM, Google, Microsoft, and many others have all invested heavily for quantum supremacy [46]. Quantum computers and the machine learning algorithms developed from them are allowing simulation at atomic-scale resolution for biomolecular interactions, biochemical reaction modeling, and personalised genomic patient data discovery with the promise of reduced drug toxicity and precision medicine and surgery [45]. Current NeuraLink technologies explore these quantum concepts in computational chip design for brain machine interfaces in the quest for human-machine symbiosis [47].

Machine Learning and Regenerative Nanobiology

Regenerative medicine promises to enable treatment of neurodegenerative disease, facilitate new organ regeneration for transplantation, and achieve better tissue scaffold constructions. It works through reprogramming the body's stem cells or inducing pluripotency and direct lineage differentiation to replace an injured or diseased cell [48]. Current augmentations with CRISPR-CAS-9 genomic engineering and gene editing technologies hope to evolve the process even further [49].

Next Generation Machine Learning for Nanorobotic Surgery

A progressive review by Ashrafiyan et al. discusses the evolution and various generations of robotics and the cost implications for surgery and how this will impact anesthesia in the future [50]. Their insight into fifth generation autonomy with human consciousness and the fact that this still remains conceptual is worth noting. As such, we will not place too much emphasis on surgical anesthesia here. However, we will discuss potential future applications of nanorobotics in ophthalmology and neurosurgery, including areas such as neurosurgery and nano-neurosurgical theranostics

[51]. We will also briefly consider conceptually the feasibility of quantum neurosurgery and programmable matter.

In ophthalmology, experimental nanorobotic agents with propellers have been designed and proven to be able to navigate through vitreous humor to facilitate drug delivery or ophthalmic surgery and treat age-related macular degeneration [52].

Neurosurgery also involves leveraging microscopic techniques to allow micrometer gains in accuracy to be achieved. The surgical corridors are usually very much narrower and restrictive compared to other surgeries. As a consequence, the operative risks and margin of error are significantly elevated compared with other surgical specialties. Precision is vital and as a result the increased adoption of minimally invasive methods leveraging microscopy have become the gold standard for most subspecialties within the field [53]. The proximity of eloquent structures to lesions has to be accounted for and tractography is sometimes considered for connectivity-related data discovery [54]. Nano-neurosurgery and quantum neurosurgery purport to offer an even more elevated level of precision surgery, reducing or even eliminating the margin of error to negligible levels. The future of neurosurgery will be augmented by tele-nano-neurorobotic platforms that will enable theranostic efficacies far beyond what is available now, together with facilitating long-distance surgery. This would be possible due to advances in quantum computational speedups, which will help overcome the Brownian challenge of controlling nanoscale devices. As such, enhanced master-slave capabilities and autonomous nanorobotic variations will become available provided the institutional and global cost-benefit analyses are favorable. Patients and clinicians will both have a panoply of choice for targeted therapies.

The design of the operative microscope will also continue to evolve into modular intelligent nanoscopes with femto-level resolution, capable of resolving cellular-to-cellular and subatomic interactions in diseased tissue. The combination of nanorobots and advanced AI algorithms *in vivo* would facilitate programmable matter during in

situ surgery. This will be useful for dynamic real-time cancer nanoablative and precision nano-lesioning surgery, augmented intracellular organelle probing for nano-neurogenetic surgery, reduced surgical complication, and personalized patient-specific nanosurgical presimulation. At these considerable subatomic-scale resolutions, quantum algorithms will be required to stabilize the systems and enable dynamic image processing. There is considerable potential for most of these advancements to no longer be just theoretical or hype in the coming decades. Although realistically it will be dependent upon the surgical need and the preference of the surgeon to adopt newer techniques, which will also need to go through the necessary ethical and regulatory rigor before patients are put at risk.

Ethics and Regulation

The reader is referred to various discussions of AI and ethics in the relevant chapters. However, we will briefly mention some of the issues here. The FDA only recently formally suggested a definition for nanomaterials or nanomedicines issuing only a draft guidance, but no regulatory definition has been established [1].

"The FDA has not established regulatory definitions of "nanotechnology," "nanomaterial," "nanoscale," or other related terms...when considering whether an FDA-regulated product involves the application of nanotechnology, FDA will ask: (1) whether a material or end product is engineered to have at least one external dimension, or an internal or surface structure, in the nanoscale range (approximately 1 nm to 100 nm) and (2) whether a material or end product is engineered to exhibit properties or phenomena, including physical or chemical properties or biological effects, that are attributable to its dimension(s), even if these dimensions fall outside the nanoscale range, up to one micrometre (1,000 nm)." [55]

This consequently creates controversy as to the design of nanomedicines, as there is a lack of regulatory clarity, global consensus view, or established ethicolegal frameworks.

Appreciably, even a change in shape or size might affect its physicochemical interactions

within the body and could lead to altered toxicological profile. Machine learning algorithms should therefore be primed with strict definitions for nanomaterials in their predictions for drug design to ensure that they do conform to regulations and safety parameters.

Machine learning algorithms are only recently starting to also gain regulatory scrutiny as medical devices [56]. They published a discussion paper in 2019 about a proposed regulatory framework for modifications to artificial intelligence–/machine learning–based software as a medical device [56]. MHRA have also had discussions for the regulatory impacts for artificial intelligence for safety monitoring and diagnostic services, but have yet to discuss how the unity of these two technologies would be scrutinized [57]. Regulatory sand-boxing to test these are no doubt in progress [58]. A recent document outlines the three main regulatory areas of concern and include the following [59]:

- Level of autonomy introduced by AI technologies
- Ability of continuous learning systems to change their output over time in response to new data
- Ability to explain and understand how an output has been reached

As regards the nanoethical perspective of nanomedicines, the fact that we still do not fully understand the toxicity profiles of most nanomedicines and nanomaterials make it a problem for new material development and design applications to be translated to patients. It can also take several decades from conception to clinical trials for eventual treatments to be released, which is too costly a risk for the medical and pharmaceutical stakeholders and makes them apprehensive. So, the addition of another black box process such as artificial intelligence and specifically deep learning, where model explainability is necessary, ethically compounds this problem even further. However, as hippocratic physicians, the casuist viewpoint still holds that we have a moral obligation to develop newer and more effective treatment modalities

using artificial intelligence and nanotechnologies to minimize harm in medicine.

decision-making, e.g., during diagnosis and therapy management, but similarly could help to implement interventions, e.g., to provide reminders and nudges. This chapter gives an overview on AI-empowered wearable and implantable computing systems and their use in medicine. First, context awareness and its implementation is introduced. AI application examples are detailed. Subsequently, AI methods for personalization and optimal system design are reviewed, including methods for fabrication planning and monitoring. The chapter is concluded by discussing procedures to validate medical wearable and implantable systems, from safety assessments to usability tests.

Introduction

Wearable and implantable devices can collect vital signs, behavior, and exposure data in everyday life outside of controlled clinical settings. The volume, velocity, and variety of collected data cannot be examined manually by clinicians

[1]. Instead, AI methods and Machine Learning (ML) models can be adapted to automatically recognize relevant patterns or statistically summarizes data recorded by worn or implanted sensors as well as interaction with the devices. AI can be integrated on devices to achieve one of the following tasks [2]:

1. Help preventing chronic conditions by predicting the prognosis.
2. Support the diagnosis based on retrieved information. In addition, devices can improve existing screening protocol for early disease detection.
3. Monitor patient parameters and detect anomalies to improve the therapy management.

A key driver of wearable and implantable computing is to manage individual patient needs and to optimize patient-related outcomes by integrating data of the environment (exposome) and behavior (behaviorome) into the care process [1]. In fact, close-to body monitoring data is a basic requirement for personalized prevention and care, as the environmental and behavioral data is not accessible to classic clinical analyses. The rapid adoption of smartphone apps for specific medical needs – even with insufficient clinical evidence – demonstrates, personalizing technology has the potential to revolutionize medical care. Initiatives on personalized or precision medicine specifically consider data-driven technologies for monitoring, as well as diagnostic and treatment support [3]. However, systematic reviews in digital health on the benefit of medical and health apps show that at present many have a small effect [4]. While there are various medical applications, where the functions of smartphones can be leveraged for patient interaction, there are many areas where dedicated or local sensors and actuators are meaningful or essential. An example on the benefit of wearables are the SARS-CoV-2 inspired initiatives to track infection symptoms: The German “Corona Datenspende” has excited more than 500k users to donate smartwatch data including resting heart rate and step count, which may indicate fever, e.g., resting heart rate increase by 8.5 beats per minute per additional 1°K body

temperature, details in [5]. Similar efforts to monitor the pandemic are underway elsewhere. Besides the ability of wearables and implants to produce big data, the tracking initiatives show that the devices provide data several days faster than institutional influenza reports.

Advances in embedded systems have been driven by technology miniaturization, digital sensors, and more recently, by algorithms. In particular, wearable and implantable systems are benefitting from the advances and systematically integrate all key computing components. Data input come from a combination of sensor and user interaction channels, powerful and efficient microcontroller architectures provide comprehensive resources, displays, actuators, data storage, low-power communication interfaces round-off the feature set. The convergence in embedded computing can be observed from the extended function and instruction sets offered by modern microcontrollers: On the peripheral side, a variety of digital busses and analog interfaces have become a standard. At the computing core, microcontrollers offer signal processing functions, e.g. compute the Fast Fourier Transform, or even programmable logic, besides standard instruction sets and integrated memory. Wearable and implantable systems build on the concepts of edge computing and internet-of-things (IoT) [6], i.e. to integrate and aggregate data locally as far as possible, which necessitates further controller features that support AI algorithms, including functions for large matrix operation and deep network processing. Empowered by the advanced computing around the body, users and developers find themselves confronted with a wide application and solution space. However, it is similarly important to note that electronics miniaturization has slowed down since the 2010s already, which brings resource efficiency, personalized design, and material technology into the focus of further research and development efforts [7]. An overview on the design challenges of wearable computers [8] details placement-related wearable design considerations related among others to wearability, robustness, social acceptance, safety, and cost.

An important long-term trend for wearable and implantable computing systems is that the

boundaries of on-body vs. in-body technology get blurred. Whereas with the first wave of biosensors in the 1970s [9], recent monitoring devices may be on-body but half-implanted, such as hearing aids and earables, e.g. [10], or contact lenses, e.g. [11]. For example, recent advances in continuous glucose monitoring (CGM) have yielded on-body, “insertable” monitoring devices that maintain a subcutaneous sensor, i.e. an electrode under the skin, while protecting the compromised tissue layers from infections by a wearable patch [12, 13]. For specific insulin bolus calculations, the CGM measurements alone are insufficient. Additional data from user interaction or sensors, e.g. for physical activity, are needed for optimal bolus estimation. Consequently, CGM insertables may communicate readings or estimates to the users smartphone that serves as data integration and analytics hub for those other sensors too. The focus of this chapter is on the AI-related data and computing, e.g. data abstraction and pattern recognition, performed at the wearable and implantable device, thus mostly disregarding the mobile phones.

The chapter is structured as follows. Section “[Context Awareness](#)” focuses on context awareness in wearable and implantable systems, i.e. methods to recognize the situation of the device and user as well as to derive digital biomarkers. Section “[Selected Recognition Problems](#)” presents selected application examples of context-aware systems and discussed their AI methods as well as open challenges. Subsequently, section “[Design and Construction](#)” illustrates AI methods for designing body-worn devices and section “[Validation](#)” deals with the device and algorithm validation.

Context Awareness

This section provides a concise overview on the principles of context awareness and their implementation in wearable and implantable systems. Starting from the problem framing and definitions, a typical AI processing path is discussed. Subsequently, the context types and their timing are introduced before providing examples of algorithms and applications.

Definition and Theory

Context awareness deals with the computer representation of any given situation of the device or system, the user, and their environment. Often context is considered from a user perspective, i.e. representing the user's state. There have been several definitions of context offered over time that emphasize different aspects of the situation representation [14, 15]. For example, in their project survey, Chen and Kotz [16] refer to environmental states and settings that determine application behavior or events that are interesting to the user. In 2001, Dey et al. [17] described context as any information that helps characterizing the situation of entities. Derived from the definitions of context, an application or system is context aware when it uses context information to filter information and/or adjust the application behavior. Dey et al. offer an overview on conceptual components and architecture of context aware systems, including sensors, widgets, interpreters, aggregators, services, and discoverers.

- **Sensors:** Provide data input, e.g. from measurements of location.
- **Widgets:** Hide the complexity of the sensor source, e.g. whether an radio-frequency indoor positioning system is used or a sensor floor, and abstract context information for applications. Widgets are providing context information in the form needed by application, e.g. room changes, not fine-grained position changes within a room. They serve as reusable building blocks for applications.
- **Interpreters:** Raise abstraction of context information, e.g. by AI-based inference. Similar to the concept of a widget, interpreters are building blocks that applications may use.
- **Aggregators:** Collect multiple pieces of context information. Aggregators are needed when context information is generated in a distributed form, e.g. by different widgets. In addition, the component is used to infer context based on the information available at an aggregator.
- **Services:** Execute actions on behalf of an application. Services are responsible for controlling or changing a state, e.g. using an

actuator. Similar to widgets for the sensor side, services abstract the complexity inherent to changing context state.

- **Discoverers:** Maintain a registry of available widgets, interpreters, aggregators, and services. In particular for wearable and implantable systems, certain widgets and services may be only temporary available due to changes in the environment, location, or resources. For example, during low energy states, some services may become unavailable.

In their 2016 survey, Yürür et al. [18] follow a conceptualization related to Dey et al., but generalize sensors to *context sources* that may reflect the nature of virtual sensors, e.g. activity state of a user-activated panel or screen and information sourced implicitly from user interaction. Aggregators relate to *context managers* that integrate context sources and an adaptation manager to query, process, and filter all context information. Yürür et al. denote that all described processing components are part of a context-aware middleware platform that resides between data sources and the context-aware application.

Context awareness has fundamental challenges related to the interpretation and representation of the world in any computer. Assuming that the world can be represented by a random process of ideal internal states, it is immediately evident that context must be a subset of those states, which are actually observable. In other words, internal states may remain hidden, if there is no mapping function found to relate the internal states to observable ones. The lack of mapping functions is the first fundamental challenge of context awareness and the related context recognition.

Another fundamental challenge of context awareness is related to observations. Assuming that a state-dependent random process of all potential observations exists, measurements denote a subset of all possible observations given the technically available means. Thus the second challenge of context awareness is that available observations and measurements are sparse, e.g. discrete time samples, and noisy, e.g. limited by the performance of the measurement device.

In summary, context awareness in computing systems is an inverse, underdetermined problem, i.e. starting from sparse measurements to represent an internal world state. Thus, a global context recognition is intractable. Most context recognition thus builds on assumptions, which may imply bias of the developer or the underlying data.

Context Types and Recognition Path

Already in 1994, Schilit et al. [14] described the basic relevance of context aware applications that may build on mobile computing, e.g. for offering location-dependent services, but are not limited to those. In addition, the authors emphasize that context information includes further aspects, i.e. who you are with and what resources are nearby. In more formal terms, they refer to environments, including the computing environment (available processing resources), the user environment (location, social situation), and the physical environment (lighting and noise level). Yürür et al. [18] proposed a hierarchical definition of the context representation into low-level (physical, virtual, and logical sensors), high-level (context of device and user, physical and temporal context), and situational relationships, which is referred to as user state.

From the medical care perspective, any context representation is part of either the environment (exposome) or the behavior (behaviorome) [1]. In a user-centered context typing approach for wearable and implantable medical systems, we extend the representation from Lukowicz et al. [19] as follows:

- **User activity:** Physical activities, e.g. walking, eating, but including those activities related to social interaction too, e.g. speaking, listening. Measurements may include body motion, user utterances.
- **User state:** Physiological and cognitive state, e.g. muscle fatigue, mental arousal, arterial fibrillation, which may reflect physical effort too. Clearly, many disease symptoms are reflected in the user state and thus render user state estimation as an essential feature of

context awareness. Measurements may include heart and respiratory rate.

- **Environmental state:** Physical status of the user's surrounding, e.g. rainfall, open window. Measurements may include light and sound.
- **Location:** Navigation and position data related to the user's spatial point, which may be indoors, e.g. in the office, in an elevator, or outdoors, e.g. at the train station. Measurements may include wireless signal strength from hotspots or in-building beacons, as well as global positioning system data.
- **Digital activity:** Activity in digital and social media, e.g. website visits and blog posts. Measurements may include number of posts and likes.
- **Background data:** Subsumed information, typically in a statistical representation, of historic data. Data examples include a patient's electronic health record, frequency statistics from questionnaires, and similar. Background data could be understood as a prior for an AI-based inference system and may be used explicitly by the available data (see above examples) or implicitly by assumption or design (e.g. informative priors or expert knowledge).

While context types provide a spatial categorization and help to maintain separate AI models, their timing is concurrent, e.g., a location is associated to any user activity and state. But even within a context type, parallel processes exist, e.g. standing and shaking hands, and therefore often requiring individual AI recognition models and segmentation. One promising context recognition strategy is then to design one-vs-all or hierarchical pattern recognition models and report the top-K probable models.

However, the context modelling approach is application-dependent, given that in many cases the application requires a crisp single-state result.

From the perspective of data and information flow, a common context processing chain consists of the following stages (cf. Fig. 1):

1. **Data/signal acquisition:** Comprises various context sources, including physical sensors to measure phenomena properties, virtual sensors

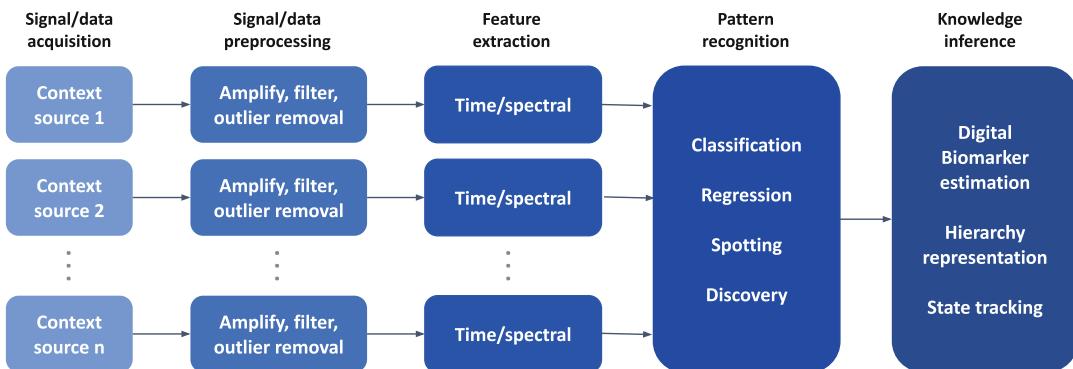

Fig. 1 Schematic of the context processing chain for wearable and implantable devices. The processing chain can be implemented with various AI components and for

all context types. Data input comes from device-integrated sensors and/or user interaction

that represent states of a system, as well as explicit and implicit interaction.

2. **Data preprocessing:** Depending on the context data source and data modality, different preprocessing is required. For physical sensors, the preprocessing may in part comprise signal amplification, signal filtering, and analog-to-digital conversion. For digital sources, algorithms include data-based filtering, outlier removal, and segmentation.
3. **Feature extraction:** Algorithms typically depend on the data modalities considered. Time-domain features include statistical signal representations, e.g. mean, variance, kurtosis, etc. Frequency-domain features are used to represent, e.g. electromyographic and acoustic signals. Other domains include wavelets and discrete spaces, e.g. for symbolic data representation. For an overview see, e.g., Figo et al. [20].
4. **Pattern recognition:** Algorithms range from supervised to unsupervised and typically target classification of context states, regression of a context variable, spotting of context events, or discovery of context states or events. Examples can be found in section “Selected Recognition Problems” below.
5. **Knowledge inference:** Whereas the pattern recognition stage is deriving discrete or continuous variables, the inference integrates variables into a (hierarchical) context representation, e.g. using topic models from text mining [21], or layered Hidden Markov Models (HMMs) [22]. By calibrating variables or further

estimation steps, digital biomarkers can be derived. Another task of this stage is variable tracking, i.e. to perform inference based on trends and states of recognition results.

Selected Recognition Problems

Context Pattern Spotting and Interpretation

A typical problem in medical context recognition is to identify events or specific physical or physiological situations in daily life using wearable and implantable systems. Context events may be basic state changes in variables, but mostly these are signal patterns with a temporal structure that may be similar to other, arbitrary data that surrounds the event patterns (referred to as *null class*) [23]. For example, food intake gestures show complex motion and orientation dynamics with variable duration in time. While intake gestures were modelled and recognized, e.g. using HMMs using wrist-worn devices, dealing with the null class in daily living data is highly challenging. To deal with the variability of null class patterns, a mined set of HMMs forming a network with the target gesture HMMs could be used [24]. The AI methods can be subsumed as pattern spotting, i.e. a combination of one-class recognition and efficient event search in continuous data.

As situation recognition tasks are typically intended to contextualize data and are followed

by further processing and interpretation steps, not all instances of the situation may be needed. In other words, it is frequently sufficient to attain a mediocre sensitivity, while maximizing the specificity or precision of the retrieval task, such that the further processing of biomarkers is minimally hampered by erroneous input. A typical situation recognition example is walking, indicating a condition of basic independence in or after rehabilitation [25], or physiological arousal [26]. For example, Derungs et al. used expert-designed rules to identify walking phases in hemiparetic patients, thus being dependent on the performance of features and thresholds only. The walking segments were then further interpreted regarding the patients' recovery. For this type of pattern spotting application, sensitivity must just be high enough to maintain a relevant biomarker update rate, i.e. event rate for spotting [24, 27].

Motion analysis is a long-standing topic in wearable computing systems and often tightly related to spotting specific events in data. In their 2020 systematic review, Weygers et al. [28] summarize a wide range of approaches to analyze joint kinematics and biomechanical modelling from inertial sensor units (IMUs). Their review considers preprocessing and information fusion aspects, besides dealing with drift, initialization, and calibration. They found that IMUs require further validation against gold standard methods, i.e. 3D gait analysis systems, and that the interpretation of IMU-based AI methods often builds on biomechanical assumptions and a-priori information. The authors expect that in the future individualized biomechanical joint models could be applied in populations with disturbed movement patterns in out-of-lab settings. Other recent approaches showed success in estimating gait mechanics, e.g. joint angle during motion, from trained Artificial Neural Networks (ANN) and IMU data [29].

Interpretation from Context Hierarchy

An interesting area of recognition problems are related to representing context as a multi-level concept, where top levels represent daily routines and subordinated layers deal with finer temporal

and spatial segmentation down to the level of atomic context, i.e. context that is not further subdivided and therefore must be derived from data sources. Pioneering work on context hierarchies have been developed in computer vision initially, e.g. [22]. Estimating cardiorespiratory fitness as an exemplary digital biomarker was investigated by Altini et al. [26], who considered two context layers (activity primitives, i.e. atomic context and a routine level) within a hierarchical Bayesian regression framework. Their approach demonstrated that the routine level adds essential information to contextualize heart rate for the regression with cardiorespiratory fitness. Similarly, a variety of approaches have built on hierarchical modelling, e.g. to describe daily routines or context composites with topic models [21, 30].

Routines occur in various contexts, where maintaining ordered action procedures is essential, e.g. clinical wards or the operating theatre. In their systematic review, Kolodzey et al. [31] summarized the technology and applications of wearables in the operating room, identifying use cases for telecommunication, safety, and information management, among others. For example, safety included augmented reality systems based on head-mounted displays and limb-worn devices for surgical navigation, and procedure tracking. They highlighted usability, inference robustness, data confidentiality, and runtime as challenges. Delivering in-time information and interaction options with head-mounted displays has been investigated, e.g. by Jalaliniya et al. [32], who focused on touchless, i.e. sterile, interaction, telepresence, and mobile patient record access. Input modalities included voice commands, head movements, and touch interaction. To detect and interpret the interaction forms correctly, context hierarchy information is essential. The authors noted that recognition speed is essential to leverage the interaction forms.

Flu Detection

A trend that started even before the COVID-19 pandemic is to estimate influenza-like symptoms from wearable devices. Radin et al. [33] showed in a population of ~47k individuals that estimates

of resting heart rate from activity trackers can improve the prediction of influenza-like illnesses reports with correlations ranging up to 0.97. Their approach build on linear regression and auto-regressive models to relate the heart rate data to reports. Using statistical summaries of tracker-based optical heartbeat, Li et al. [34] showed that an inflammation condition could be detected.

Major COVID-19 tracking approaches that build on the above insights mostly use expert knowledge modelling, primarily driven by the epidemiological characteristics of the studies, e.g. that no individual diagnostic data was available [5]. Mishra et al. [35] describe a study cohort with 5k participants using smartwatches to analyze physiological and activity data with signal alterations detectable in 80% of the COVID-19 infected cases. The physiological alternations appeared in 85% of the cases before symptoms became evident. The authors computed a HROS feature from heart rate and step count and applied an anomaly detection based on a Gaussian distribution assumption. Furthermore the online COSUM method was used to detect signal changes.

Situation Interpretation in Implants

Implantable computing systems are typically functioning as biosensors [36], organ support devices, e.g. autonomous pacemakers (APMs) or implantable cardioverter defibrillators (ICDs) [37], or ingestible monitoring or actuating system [38]. Implantable devices need to function with constraints on available system energy, potentially for several years, which limits computing resources. In addition, for actuating devices as APMs and ICDs, reproducibility of the intervention decisions are key for their risk assessment and medical device clearance. Simultaneously, several variables and patient conditions must be monitored for the devices to operate correctly. For example, inappropriate shocks of an ICD appear in about 15% of the patients and deteriorate quality of life for the patient [39].

ICD detection algorithms process electrocardiography (ECG) signals to determine the

timing of arterial and ventricular depolarization. A basic approach is to analyze the RR interval for detecting tachyarrhythmia, e.g. ventricular tachycardia (VT) [40]. However, further conditions exist, e.g. supraventricular tachycardia (SVT), which must be discriminated from VT to avoid inappropriate therapy. Overall, there are several conditions that can lead to VT or SVT. A typical implementation is thus a decision tree with three main branches [41]: (1) ventricular rate faster than atrial rate, denoting VT; (2) ventricular rate slower than atrial rate; and (3) both rates are equal. For conditions (2) and (3) various substates are considered to further subdivide the decision space. As the intracardiac signals vary with cardiac rhythms static sensing thresholds cannot be used in ICD devices. Instead, additional signal filter and estimation stages are implemented to adjust the thresholds dynamically.

Design and Construction

Wearable medical devices are designed to work in a biological environment that is challenging. Not only they have to be unobtrusive and autonomous, but they also have to fulfil ergonomics and comfort requirements. Among the new emerging technologies, AI can help designer in optimizing the wearable design and ensure a good quality product. According to the existing research work, AI has been applied to wearable design and construction to support developers at different stages of the process. The following sections provide an overview on how can the use of AI be beneficial to the development and fabrication. Along with the development of smarter wearable devices, design aspects such as the device geometry and material selection have gained more importance due to their impact on ergonomics and user acceptance. Although various mechanic and electronic Computer-Aided-Design (CAD) software are nowadays available to the designers, the integration of CAD with AI could further support the developers in the prototyping process and help solve fabrication issues ahead of time.

Topology Design and Optimization

When designing wearables with complex geometries, AI can check the presence of structural errors. For instance, in Additive Manufacturing (AM) process, CAD tools can perform quick design check and verify the device printability [42]. Lu et al. [43] proposed a Support Vector Machine-based (SVM) classifier that, based on features extracted from the design, i.e. structure complexity, as well as other fabrication parameters, i.e. printer model, could determine whether the design could be printed or not. The approach could be further developed by including other environmental indicators in the model, e.g. production time, cost, model dimensions etc. A Genetic Algorithm model could be used to analyze what factors influence the manufacturability and to which extent [44].

Despite AI could significantly reduce time and costs in designing complex geometries, to date its use has been limited and not fully investigated [45]. Yao et al. [46] proposed a hybrid machine-learning model for AM design feature recommendation. They proposed a hierarchical clustering for AM design features and target components and use a SVM classifier to determine the optimal design features. Although the work proved that AI can help inexperienced designers selecting the best AM design features, the proposed features had still to be tested through manual iterations and no automatic optimization process was implemented.

A more automatic approach to infer the optimal topology design was presented by Sosnovik et al. [47], who addressed the optimization problem by using a Convolutional Neural Network (CNN). Intermediate topologies from traditional topology optimization solvers based on Finite Element Method were used to train the CNN and predict after a few iterations the optimized structure. The method was later extended [48] to include 3D geometries. The trained model could predict optimized structures with 40% time reduction compared to traditional iterative topology optimisation approaches. With the use of Generative Adversarial Networks (GAN), it is also possible to predict the topology without using

iterative optimization. Given the design specifications, a trained GAN-model can generate possible multiple designs whose structure satisfy the set requirements [49]. However, training the model still relies on the results from standard topology optimization solvers.

In CAD-based apparel design, only basic fabric patterns can be automatically generated with AI. When more complex styles have to be developed, the standard approach still relies on decisions from experienced designers. Nevertheless, knowledge-based systems could ease developers in the design of a specific garment [50].

Wearable Personalization

In order to meet system performance, ergonomics, and comfort user needs, device personalisation should be taken into account during the design. A wrong fitting or misplacement on the body can invalidate measurements and impact vital signs monitoring [51]. Developers should adjust the wearable dimensions and shape and adapt them to end-user needs, yet the process requires precise anatomical measurements and thus can be tedious and time-consuming. A classic approach followed by manufacturers and researchers is to fabricate devices in different sizes and use geometry-adaptive materials to fit as many users as possible. However, in particular anatomical regions with complex morphology, such as ears, the optimal fitting could not be achieved with standardized device dimensions. Not only the optimal fitting but also the optimal sensor on-body position should be addressed. Personalized digital twins could help designers evaluating the sensor performance based on the on-body position, as proposed by Derungs and Amft. [52]. They analyzed the optimal position of inertial sensors to achieve best gait marker estimation in running athletes and hemiparetic patients.

To speed up the personalization, the wearable adjustment step could be optimized with the help of AI. Body measurements are automatically extracted with high accuracy by using photometric scanners that reconstruct the body 3D model from multi-perspective images or videos.

Afterwards, different models can be employed to improve the design. For instance, heuristic rules could be used to adjust the device parametric model based on the user's measures [53]. As a further development, ANN could be trained to output the best garment pattern design based on the input body model [50].

Prefabrication and Process Planning

After defining the wearable specifications and structure, other process fabrication parameters, including material choice need to be defined. Depending on the device requirements, some assumptions can be made earlier. When designing new, custom wearable prototypes, first experiments may imply several steps of trial-and-error to find the optimal parameters and material properties required for the application. The approach can be time-consuming and expensive, especially when conventional manufacturing techniques are employed for the construction. If an AM technique is used, simulation tools can help predicting parameters including mechanical robustness, production time, and amount of material needed. For instance, the 3D model can be sliced into planes orthogonal to z-axis to simulate the layer-by-layer deposition and evaluate the final quality of printed part based on fabrication settings i.e. layer height, nozzle diameter. In addition, the simulation could analyze the nozzle trajectory to determine whether the path could cause defects in the structure during the printing. The path optimization is an important aspect in the printing process, because it influences the fabrication time and final quality of the wearable [44]. In order to better support the parameter selection, a recent approach used in AI-enhanced AM is the use of Multi-Criteria Decision Making (MCDM) systems. In the MCDM approach, a set of possible parameters options including inter-factors relationships can be generated by existing databases or knowledge bases. The fabrication can be formulated as an optimization problem and solved based on user-defined requirements. For example, Wang et al. [54] proposed to use a hybrid MCDM system and rank possible solutions by employing a modified

technique for order preference by similarity to an ideal solution approach.

Besides supporting designers in the process and parameters selection, AI can be employed to predict the final mechanical material properties after the fabrication. Depending on AM parameters such as the infill pattern or density for 3D designs, properties like tensile and compressive strength may vary. Among the existing AI algorithms, the Multilayer Perceptron has been extensively applied to investigate macro-scale mechanical parameters. The analysis can be further extended to nano-scale properties when analyzing the surface conditions with classifiers such as SVM [45].

When employing smart garments as wearables, predicting the mechanical properties of fabric during manufacturing is fundamental to ensure quality devices. Specifically, it is important to evaluate upfront the seam efficiency. For example ANNs have been used to predict the textile performance during sewing [50].

Not only mechanical properties but also the fitting and comfort can be evaluated with AI. For instance, a Fuzzy-Logic system could predict fabric thermal comfort based on thermal and moisture sensations [55].

AI-Assisted Fabrication of Wearables

Although common fabrication processes are nowadays widely automatized, defects during the production could still occur, especially when using AM techniques. In particular, AM processing could cause defects including cracks, delamination, distortion, rough surface, and porosity. Most of the production failures originate from the layer deposition and selected process parameters. For example, interlayer adhesion or precise layer placement i.e. because of uncontrolled filament flow during the nozzle extrusion must be addressed. It is therefore beneficial a defect check during the construction.

AI can help developers by automating the in-process quality control. For this purpose, different sensing modalities have been tested by researchers to monitor AM. For instance, the

acoustic waves emitted from extruders i.e. in the Fused Deposition Modelling process during fabrication can be analyzed. The acoustic pattern could be examined with K-means clustering to determine if the printing was successful or anomalies occurred [45].

Among the existing monitoring approaches, optical-based techniques are mostly adopted. An infrared camera could be used to capture thermal images of the process and monitor the melt pools during Selective Laser Melting of metallic powders. Trained models including SVM or CNN could detect in thermal images defects like lack of fusion or keyhole porosity [45]. Alternatively, the wearable structure could be inspected by examining the surface condition or by employing CT images [45]. The visual inspection during the process could be also used in the fabrication of smart fabrics. ANNs have been extensively used to detect knitted fabric faults by comparing patterns with stored images of defects, e.g. see [50].

Validation

Despite the extensive research and large investments from healthcare stakeholders in medical wearable devices, a standardized framework for validation of wearable and implantable systems does not exist. The current, fragmented frameworks employed to validate AI-integrated wearable solutions cannot ensure product quality standards, i.e. effectiveness and low harm hazard [56].

AI System safety assessment

AI is commonly employed to support experts and users by automating iterative, analytical processes or augmenting data visualization. The more processes are automated, the more user decision or behavior relies on AI. Ideally, AI could augment any clinical decision-making process. If algorithms perform higher-level tasks, as proposing diagnosis, model error risk will increase as well as explainability due to task complexity [57]. It is therefore important to rigorously assess the

system accuracy and robustness during the device validation. When testing medical AI systems, retrospective cohort studies are widely used for the evaluation [57]. The study design usually consists of the following steps.

1. **Clinical question formulation:** First, the study objective is outlined. Typically, in the evaluation of AI systems the study aims to quantify how well the system can perform a certain task compared to a reference method. For instance, the accuracy in detecting dietary activity events with worn sensors could be the study objective [23]. As reference method, a standard medical practice is employed. Alternatively, the AI algorithm could be compared against opinions of human experts. For context-aware wearable and implantable systems, a variety of methods have been established to determine ground truth (see below).
2. **Ground truth:** After the study objective is defined, the approach to evaluate the AI model has to be designed. The AI output has to be compared to a known outcome, or ground truth, in order to determine if the algorithm response to a certain input is correct or not. Although ground truth information should be ideally perfect, missing data or errors can occur and decrease not only the AI model performance but also invalidate the performance assessment itself. It is therefore preferable to adopt objective measurements rather than human interpretations as ground truth. If human evaluation has to be used as ground truth, it is advisable to establish criteria to be followed from human raters that are as objective as possible. The rating criteria are necessary to avoid bias in the model. In addition, the ground truth should be based on the consensus opinion of more experts to maximize stability.
3. **Target population:** Subsequently, a population to be modelled by the AI algorithm has to be selected. The population includes patients, their clinical data as well as other indicators including sex, age, and other factors that are relevant to the study. For instance, if the wearable device aims to monitor digestion

and bowel motility [58], behavioral factors, e.g. dietary schedule, are relevant to study, because they influence the digestive process. The data from the target population are used to build and train the AI model. Hence, the dataset should be ideally large and uniformly distributed across all expected operational states of the AI model to avoid model bias or overfitting. Unfortunately, especially in medical AI systems, the availability of data is often limited and strategies need to be employed to increase the system robustness and generality. Data augmentation can be for example used when training deep ANN to overcome the dataset limited size. Combinations of data-driven and expert knowledge-based modelling can balance bias and variance in the system's performance, e.g. [59].

4. **Cohort:** Once the model is trained on a subset (train set) of the target population, the model performance is evaluated on another unseen subset (test set). Usually, at the beginning of the model design, the population is randomly divided into train set and test set. Since the train set is used to set the model parameters and the dataset size is generally limited, AI developers tend use a smaller subset of the original population as test set and employ most of the individuals in the training phase. Nevertheless, the cohort size should have an appropriate size to achieve a good generalizability of the results. Determining the proper cohort size is non-trivial and depends on the model task [57].
5. **Metrics:** A set of tools and methods are needed to assess the AI model performance. Typically, the model output tested on the cohort is compared against the ground truth. The most commonly used measurements are sensitivity (true positive rate) and specificity (true negative rate), which are often presented in visual form of a confusion matrix that for a binary classification resembles the truth table. Confusion matrices not only show correct predictions but also the algorithm mistakes are indicated in the form of false positive (negative cases predicted as positive) and false negative (positive cases predicted as negative). The algorithm performance should be evaluated

depending on the application goal. For instance, if the wearable is intended to be used for screening purposes, i.e. to detect COVID-19 symptoms [35], a highly sensitive algorithm should be preferred despite low specificity. The same metrics can be used also while training the model, in order to find the parameters yielding the best model performance. For various digital biomarker estimation tasks, continuous outputs are generated. To assess performance for continuous model outputs, error is measured based on distance metrics, e.g. signed or absolute difference, relative distance, etc.

Implantable System Testing

Given their elevated health risk, safety and certification procedures for implantable systems are more complex than those for wearables. The principal steps for implantable safety testing including the following, e.g. [60]:

1. **Concept checking:** During the conception of a new system design, experience of the developers is used to mentally assess the system's feasibility, including imagining its fabrication, its operation, and any potential issues.
2. **Computer simulation:** Ideally, the full system, including the AI functionality can be tested in co-simulations of the system and its application environment within the human body. The goal of the test is to assess whether all mechanisms operate as intended. Computer simulations are often limited by the fidelity of the models for the systems and the human body.
3. **Laboratory test:** Powering test on the benchtop are useful to assess fabrication quality and the matching of anticipated system properties and the AI models, e.g. whether the device's sensors produce data compatible with the AI model.
4. **Phantom test:** First operational and performance evaluation in a synthetic replica of the targeted environment within the human body. The testing produces data to re-validate the AI

models, but remains limited by the fidelity of the replica, e.g. soft silicon material to represent tissue.

5. **Ex-vivo test:** Where feasible, testing in actual biological tissue samples although under controlled laboratory conditions can offer insight on the complete system functionality. For example, interactions of complex tissue with sensors or actuators can be analyzed, communication to the body outside (when applicable) can be tested, etc.
6. **Cadaver/animal model test:** The closest testing to in-vivo human implantation is to assess feasibility and performance under the actual condition of a complete target environment. Algorithm updates are still feasible in this step. Human cadavers are donated bodies for testing medical procedures. Animal models provide similar environments to the targeted one within the human body. For example, certain pigs types have a similar gastrointestinal tract to humans and thus could be used for final stage testing of ingestible devices.
7. **In-human test:** After regulatory review and meeting all ethical and safety standards, implantable devices are finally tested in humans volunteers during a clinical trial. The test is providing additional qualification data for medical device risk assessment and certification by authorities.

Self-Checking AI Systems

Wearable device robustness and accuracy could degrade over time due to sensors failures or device displacement. An advantage of embedding AI on wearable devices is the possibility to not only calibrate the sensor based on the user, but also to adapt the measurements in case of device displacements. The detection and compensation of anomalies in the sensor readings can therefore ensure that degradation of inference functions are avoided. For instance, integrating information from multiple data sources within a decision tree [61] could help identifying sensor errors. While the accidental device displacement could decrease, i.e. accelerometer reliability, rotation

data from gyroscopes could compensate reading errors and avoid false detections. Furthermore, unsupervised methods can be employed to adapt for motion-induced drifts, without requiring information redundancy from multiple sensors. For example, if the data distribution shifts over time, an Expectation-Maximization-based algorithm can be applied to recover the original distribution, even online during system deployment [62].

Usability

Since most of the medical wearable devices are designed to operate in a long-term setting, it is important to ensure user acceptance and engagement by evaluating and testing the wearable usability. Firstly, the usability could be reviewed according to human experts. For instance, Jakob Nielsen in 1994 defined ten heuristic rules to help developers in the usability evaluation of interfaces. Additionally, the wearable usability could be tested by asking volunteers to use the wearable within a clinical trial and make them compiling questionnaires afterwards. A commonly used questionnaire is the System Usability Scale, proposed by Brooke in 1996 [63]. The form includes eight questions rating the system usability and two additional questions rating the system learnability, and it proved helpful to evaluate human computer interaction-based systems, i.e. mobile apps. However, the mentioned methods were design to mainly tests user interfaces. A more general procedure to evaluate wearable and implantable systems usability, including less interactive systems, is still missing and should be further developed.

Abstract

The need for noninvasive, easy-to-use, and inexpensive methods for point-of-care diagnostics of a variety of ailments motivates researchers to develop methods for analyzing complex biological samples, in particular human breath, that could aid in screening and early diagnosis. There are hopes that electronic noses, that is, devices based on arrays of semi-selective or nonselective chemical sensors, can fill this niche. Electronic olfaction uses data processing and machine learning to build classification models based on the responses of

several sensors in the form of multivariate datasets in order to discriminate between disease and healthy control based on a unique fingerprint. However, the introduction of this technique in clinical settings is limited by methodological issues which can, to some extent, be remedied using artificial intelligence. In this chapter, we provide a brief introduction to the electronic nose technique and outline its applications in medical diagnostics. We also discuss the ways in which data processing and machine learning techniques can be used to facilitate the use of electronic olfaction in the detection of disease.

A Brief Introduction to the Electronic Nose Technique

The term “electronic nose” usually refers to a technique in which a device equipped with an array of different chemical gas sensors is used to discriminate between complex gaseous mixtures based on their unique fingerprint, i.e., the characteristic pattern in the response of the sensor array. The concept in its present form was introduced by Persaud and Dodd in the early 1980s [1], and the term “electronic nose” is commonly used in the literature, although some authors point out that it suggests too close a parallel with the mammalian olfactory sense and that “multisensorial system” or “gas sensor array” are more suitable names [2, 3]. One could argue, however, that the former is more general and could refer to, for example, electronic tongues [4] or other techniques not necessarily used to analyze gaseous samples, while the latter describes the detector element of the conventional electronic noses. Still, the comparison with the operation of the human sense of smell might be useful to illustrate the principle of operation of electronic olfaction. In the mammalian olfactory system, after sample acquisition, either passive (odorants reaching the human nose through diffusion) or active, by inhalation, the volatile substances come in contact with specialized, selective chemoreceptors located in the nasal cavity, in the olfactory epithelium. The axons of these sensory neurons then project to the olfactory bulb, where they produce spatial patterns of activity which overlap to a certain extent, but vary for different odors [5]. Similarly, in electronic noses, the gaseous sample is collected either passively or, more commonly, actively by means of a small vacuum pump and directed into a sensor chamber in which the analytes come in contact with an array of chemical sensors (see Fig. 1). The response signals of these sensors are in turn digitized, and the characteristic response patterns of the entire array are analyzed using data processing and pattern recognition algorithms [6]. Here, however, a major difference between biological and chemical olfaction has to be indicated: while the biological chemoreceptors are selective [7], a vast majority of chemical

sensors used in the e-nose sensor matrices are either nonselective or partially selective to particular chemical compounds. Furthermore, chemical sensors can respond to chemicals which are not perceivable by the mammalian sense of smell or to odorants below the human odor threshold.

The main advantage of using electronic olfaction is its versatility which stems from the ability to tailor the sensor array to a particular sample or application drawing from a wide range of commercially available and relatively inexpensive chemical sensors. As these devices usually do not require sophisticated peripherals and can themselves be relatively uncomplicated, portable, and easy to operate without extensive training, they can be a valid, low-cost alternative to various instrumental analytical techniques used in applications requiring the analysis of gaseous mixtures, e.g., in food authentication and quality monitoring, environmental comfort and safety, or medical diagnostics. Furthermore, they can be geared toward nondestructive and remote sensing. This is particularly relevant in the context of equitable chemistry [8], as it could greatly increase the accessibility to analytical tests in everyday life, especially since the computational power required to process the obtained data, and potentially also the user interface, is available in the form of ubiquitous smartphones.

Since electronic noses are usually used to analyze relatively complex gaseous matrices and since the chemical sensors which comprise their detector system are, on the most part, only partially selective, it is difficult to categorize the obtained analytical information as qualitative or quantitative. Instead, the response signals of the sensors are treated holistically as a characteristic fingerprint or rather “smellprint” of the sample. This fingerprint can then be compared with an existing reference library either to classify the sample or to perform a regression task based on a target reference value. This is achieved through AI and more specifically through pattern recognition algorithms and machine learning (ML).

In practical terms, the raw signals of the sensor array are passed through an analogue-digital converter and registered using a computer or an equivalent device. After a series of measurements,

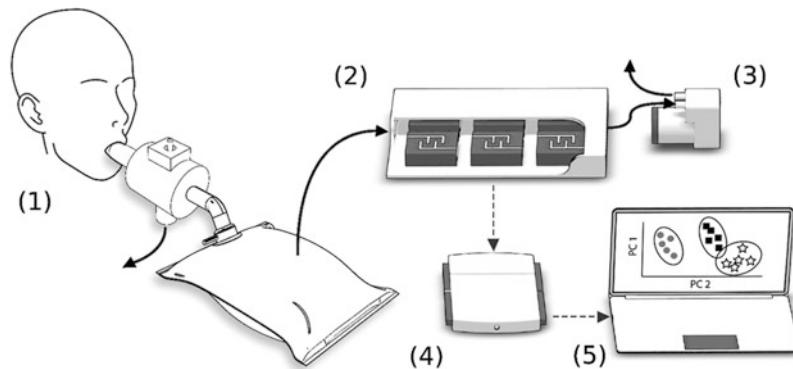

Fig. 1 A schematic representation of an electronic nose used for analyzing a breath sample: (1) sampling setup consisting of a device that captures only the end-tidal breath fraction based on the measurement of CO₂ concentration and a Tedlar bag, (2) an array of six different

chemical sensors with (3) active sampling using a vacuum pump, (4) analogue-digital converter, (5) data pre-processing and feature extraction. (Modified from [10], Copyright 2018, with permission from Elsevier)

a dataset is obtained, with signals from each sensor constituting a separate variable and values obtained in each run constituting separate objects. In order to process this multidimensional data, it is usually necessary to use multivariate statistical analysis. The aim of this process is to develop a model trained using machine learning algorithms that will be able to either identify an unknown sample as belonging to a particular discrete category based on its unique “fingerprint” or to predict a continuous numerical value corresponding to a result of a reference method. The entire procedure could be separated into distinct stages, namely, (i) preprocessing, (ii) feature extraction, (iii) development and validation of a machine learning model, and finally (iv) classification [9].

Preprocessing usually involves filtering the signal of the sensors to remove noise, temperature, and humidity corrections and defining the response. The raw response of an electronic nose consists of a number of time series equal to the number of sensors in the array. These time series are usually characterized by a transient state during which the signal changes as the sensors are exposed to the analytes, followed by a steady state during which the signal becomes nearly constant. How soon this happens depends on multiple factors, of which perhaps the most important one is the characteristic of the sensors themselves. In most electronic noses, analytically useful signal

is obtained in under 5 min and often in approximately 1 min [11]. The most straightforward procedure is to subtract the baseline signal recorded before the sensors were exposed to the analytes from the response in the steady state after sampling, but other approaches are also utilized [12]. Next, the data is normalized in order to increase the performance of further data processing and ML stages which might be sensitive to noncomparable variables. This is commonly achieved by centering each feature and then scaling the values by standard deviation, in the range -1:1 or 0:1. In cases in which the ML model will utilize an algorithm geared toward classification, continuous target variables assigned to the dataset might also be discretized at that stage.

After the data is converted into the feature space, preferably with several objects (discrete measurements), the input features might be transformed into new, salient features [13]. This is often done in order to reduce the dimensionality of the dataset, i.e., to lower the ratio of the number of features to the number of objects, which is particularly important in the case of e-noses which are not based on an array of chemical sensors and instead extract the features, e.g., from a mass spectrum or ion mobility spectrum, and where the number of features might easily exceed the number of objects leading to overfitting of the ML model [14]. In such a case, the

model shall reflect the idiosyncrasies of the training data and underperform in real-life applications [15]. The most commonly employed technique for dimensionality reduction is principal component analysis (PCA). It creates a new coordinate system in a way that maximizes the variance along with the first and subsequent new coordinates (component), each orthogonal to the previous one. The result is a new set of variables in which a majority of the variance of the original dataset can be explained by a couple of the new features. Other techniques for dimensionality reduction include linear discriminant analysis, fast Fourier transform, discrete wavelet transform, clustering in feature space, etc. [16]. In cases in which the sensor array of the electronic nose was not tailored to the specific application and so it likely contains sensors that do not contribute to the analysis of the particular matrix, the most relevant features with relation to a target reference value can also be selected using analysis of variance (ANOVA).

The last and perhaps most important stage of processing the data obtained using electronic noses is the use of pattern recognition algorithms. They can be broadly categorized based on their use for either classification or regression task, with an overlap in methods used in both applications. It is important to note that since the response of the sensor matrix is difficult to describe qualitatively and quantitatively, especially in the case of complex matrices such as human volatilome, the supervised pattern recognition algorithms require a target variable obtained using a reference method for training. This variable can be either categorical or continuous – hence, the distinction between classification and regression tasks. In the case of medical diagnostics, this target variable could be as straightforward as diagnosis (patient/control) or a parameter determined using a more time-consuming method, such as the concentration of short-chain fatty acids in feces for the purpose of diagnosing inflammatory bowel disorders [10]. The algorithms which are most commonly used in ML in electronic olfaction include artificial neural networks (ANN), support vector machines (SVM), random forest (RF), k-nearest neighbors (k-NN) classifiers, and Bayesian networks. The trained models are then validated,

which is best done using a dataset that was obtained in a separate experiment [17]. Other approaches include drawing separate training and testing datasets from the same dataset, leave-one-out validation, and stratified cross-validation.

While pattern recognition ML methods for classification and regression tasks are the main and crucial application of artificial intelligence in electronic olfaction, they are not specific for its application in medical diagnostics. For a more comprehensive review of this topic, the reader is referred to [12, 18, 19]. In the following sections, we focus instead on the use of AI in mitigating the issues which hinder the use of electronic noses in medical diagnostics and which mostly stem from the limitations of gas sensors and from the complexity of the matrix, i.e., sensor drift, effect of humidity, and background volatiles in point-of-care testing.

An Overview of Electronic Nose Application in Medical Diagnostics

The use of the human sense of smell to detect indicators of disease was mentioned as early as 400 BCE, and the olfactory diagnosis was commonly used in traditional Chinese medicine [20]. This is unsurprising since various disorders might cause changes in the human volatilome which can then be used as diagnostic indicators. The successful use of trained dogs to recognize urine of cancer patients [21] has spurred interest in the development of diagnostic methods based on the analysis of fingerprints of breath and the headspace of other biological samples. While it is important to reiterate that electronic noses are noses by name only and the sensor matrices react to chemical compounds which do not necessarily contain odorants, they are nonetheless well-suited for discriminating between complex mixtures of volatiles. Ideally, a disease could be diagnosed based on the determination of a particular chemical compound which is a characteristic indicator of the particular ailment. Unfortunately, this is almost never the case, and the products of the metabolic, oxidative, and inflammatory processes which underlie various disorders are linked

with several interrelated biochemical reactions which cannot be investigated at the level of single molecules [22]. This is why data processing and pattern recognition techniques are used to identify subtle differences between samples from patients and from the control group.

Gold standards in the field of various ailment detection are usually methodologies that are not only time-consuming and expensive but also cumbersome for the patients. The explicit promise of electronic olfaction in medical diagnostics is the introduction of ubiquitous, relatively inexpensive, and easy-to-operate screening tests which would provide the result within minutes and would not require invasive or otherwise troublesome sampling (e.g., collecting stool samples, which might be taboo for some patients [23]). Thus, the emphasis is increasingly being placed on creating more sophisticated methodologies that would be less troublesome for the afflicted and could, in the future, replace methods such as colonoscopies, tissue biopsies, or multiple blood tests.

In recent years, numerous studies concerning disease detection based on the composition of the exhaled breath or urine, feces, or saliva headspace were carried out with the use of electronic noses. These devices seem well-suited for near real-time monitoring (a single sampling-purging cycle can be realized in less than 2 min) which opens new possibilities in point-of-care diagnostics and could also greatly improve the access to basic testing at first contact medical facilities and field screening tests [13].

E-noses have been successfully applied in multiple studies concerning numerous diseases, especially but not limited to those related to the respiratory system. They were used to distinguish between healthy controls and patients with, for example, asthma, COPD, and lung cancer [24–27], as well as to monitor the severity of the illness or detect the presence of infections during their exacerbation [28, 29]. Moreover, in several cases with the use of electronic nose, it was possible to differentiate between diseases that might manifest themselves in similar ways, such as allergic rhinitis and asthma [30] or COPD and asthma [31], which seems to further corroborate the assumption that electronic olfaction might find

application in routine screening, preliminary diagnostics, or monitoring whether the disease aggravates or alleviates.

While in some studies e-noses were used to analyze the headspace of feces, urine, or wounds, disease diagnostics is, most commonly, performed based on the analysis of exhaled air. Breath samples are collected in inert bags or delivered through a mouthpiece directly to the electronic nose. However, in certain cases, the electronic nose is designed to have a module that allows unmediated breath sampling, as is the case with, for example, SpiroNose (Breathomix, Leiden), which is a coupling of e-nose and spirometer [32]. By far the most popular technique for reducing the dimensionality of the dataset prior to the development of the ML model is principal component analysis (PCA). However, the application of analysis of variance (ANOVA) or covariance (ANCOVA) can be useful in experiments in which the difference are the main focus as is the case with research concerning differentiation between sick patients and healthy controls [33]. In the majority of reviewed studies, receiver operating characteristic (ROC) curve is utilized to assess the performance of the classifier – something that is more commonly seen in medical research than in other areas of e-nose applications. It would seem that artificial neural networks (ANN) in their various guises are becoming increasingly popular compared to other ML algorithms. It is mostly due to its appropriateness for situations in which additional data points are added over time and retraining is necessary [34]. This characteristic of neural networks would be a major advantage in the instance of possible future real-life application of electronic noses for routine screening and disease diagnostic purposes. Selected applications of electronic olfaction in medical diagnostics since 2015 are listed in Table 1. It supplements a previous, similar listing with more recent studies [13]. Detailed reviews of the various applications of electronic olfaction in medical diagnostics can be found in the works of Wilson and others [20, 35–40].

Despite these advances and the seeming suitability of electronic olfaction for rapid, noninvasive diagnostic tests based primarily on breath

Table 1 Selected applications of electronic noses in medical diagnostics

Diagnostic application	Matrix	Sampling method	Data analysis	Ref
Airway inflammation	Breath	Tedlar bag	PCA, k-nn	[42]
Allergic rhinitis	Breath	Tedlar bag	PCA, CDA, ROC curve	[43]
Amyotrophic lateral sclerosis	Breath	Inert bag connected to the e-nose	PCA, ANOVA, CDA, ROC curve	[44]
Aspergillus fumigatus	Breath	Tedlar bag	PCA, ROC curve	[45]
Asthma	Breath	Mouthpiece connected to the e-nose	PCA, logistic regression, ROC curve	[46]
Asthma	Breath	Tedlar bag	PCA, PLSDA	[29]
Asthma	Breath	Tedlar bag	PCA, ROC curve	[24]
Asthma	Breath	Mouthpiece connected to the e-nose	ANN	[47]
Asthma	Breath	Tedlar bag	PCA, ANCOVA	[48]
Asthma	Breath	Mouthpiece connected to the e-nose	PCA, ANOVA	[49]
Asthma	Breath	Tedlar bag	PCA, CDA, ROC curve	[30]
Chronic kidney disease	Breath	Tedlar bag	PCA, SVM, HCA, PLS-regression	[50]
Colorectal cancer	Urine	Urine headspace	LDA	[51]
COPD	Breath	Tedlar bag	PCA, ANCOVA	[26]
COPD	Breath	Mouthpiece connected to the e-nose	ANOVA, PLSDA	[52]
COPD	Breath	Mouthpiece connected to the e-nose	PCA, ANOVA	[31]
COVID-19	Breath	Mouthpiece connected to the e-nose	ANN	[53]
COVID-19	Breath	Mouthpiece connected to the e-nose	DFA, ROC curves	[54]
Cystic fibrosis	Breath	Mouthpiece connected to the e-nose	ANN	[47]
Diabetes	Breath	Tedlar bag	PCA, k-nn	[42]
Diabetes mellitus	Breath	Tedlar bag	PCA, SVMs, HCA, PLS-regression	[50]
Gastric cancer	Breath	Mouthpiece connected to the e-nose	ANN	[55]
Head and neck, bladder, and colon carcinomas	Breath	Mouthpiece connected to the e-nose	ANN	[56]
Head, lung, and neck carcinoma	Breath	Mouthpiece connected to the e-nose	ANN	[57]
Infection during COPD exacerbation	Breath	Tedlar bag	LDA, SLR	[28]
Infections in acute COPD exacerbations	Breath	Mouthpiece connected to the e-nose	ANN	[58]
Inflammatory asthma	Breath	Bag	PCA, ROC curves	[59]
Inflammatory bowel disease	Breath	Bio-VOC connected to the e-nose	SVMs, RF, SLR, ANN	[60]
Interstitial lung disease	Breath	Mouthpiece connected to the e-nose	PLSDA, ROC curve	[61]
Locoregional recurrent head and neck squamous cell carcinoma	Breath	Mouthpiece connected to the e-nose	ANN	[62]

(continued)

Table 1 (continued)

Diagnostic application	Matrix	Sampling method	Data analysis	Ref
Lung cancer	Breath	Tedlar bag	LDA, SVM, ROC curve	[63]
Lung cancer	Breath	Bag	GRU-AE-MSEP framework	[64]
Lung cancer	Breath	Tedlar bag and mouthpiece connected to the e-nose	k-nn, RF, LDAm SVM	[25]
Lung cancer	Breath	Tedlar bag	PLSDA, ROC curves	[65]
Lung cancer	Breath	Bag	SVMs	[66]
Lung cancer	Breath	Mouthpiece connected to the e-nose	ANN	[67]
Lung cancer	Breath	Bag	DFA, K-fold cross-validation, CART	[68]
Malignant pleural mesothelioma	Breath	Tedlar bag	PCA, ROC curve	[69]
Necrotizing enterocolitis	Feces	Feces' headspace	PCA, ROC curve	[70]
Obstructive sleep apnea	Breath	Tedlar bag	k-nn, CDA, ROC curves	[71]
Esophageal adenocarcinoma	Breath	Mouthpiece connected to the e-nose	Cross-validated prediction model	[72]
Overlap syndrome [obstructive sleep apnea with COPD]	Breath	Inert bag	PCA, CDA, ANOVA	[73]
Parkinson's disease	Breath	Mylar bag	DFA	[74]
Persistent asthma	Exhaled breath condensate	Condensate's headspace	PCA, ROC curve	[75]
Pneumoconiosis	Breath	FlexFoil Plus bag	LDA, SVMs	[76]
<i>Pseudomonas aeruginosa</i> and airway bacterial colonization in bronchiectasis	Breath	Tedlar bag	PCA, ANOVA, ROC curve	[77]
Psoriatic arthritis	Breath	Tedlar bag	PCA, DA, AUC, ROC curve	[78]
Renal failure	Breath	Tedlar bag	PCA, k-nn	[42]
Response to small-cell lung cancer treatment prediction	Breath	Mouthpiece connected to the e-nose	ROC curve	[79]
Rheumatoid arthritis	Breath	Tedlar bag	PCA, DA, AUC, ROC curve	[78]
Seasonal allergic rhinitis	Breath	Mouthpiece connected to the e-nose	PCA, HCA, SVM	[80]
Sepsis	Feces	Fecal headspace	PCA, ROC curve	[81]
Tuberculosis	Breath	Mouthpiece connected to the e-nose	ANN	[82]
Tuberculosis	Breath	Tedlar bag	PCA, k-nn	[83]

Wound infections	Wound swabs	Bacteria headspace	LDA	[89]

analysis, the technique still does not appear to be ready for widespread clinical use [22]. This is in part due to technical limitations of detection systems comprised of arrays of chemical sensors – in particular difficulties with reproducibility and sensor drift – and in part due to the fact that human breath is a notoriously difficult matrix. It contains thousands of volatile compounds but at very low concentration levels. The exhaled air does not significantly differ in composition from ambient air, and only a fraction of each breath takes part in the gas exchange in the body. While this small fraction does contain volatiles which might be used as indicators of disease, they are present at relatively low concentration levels. For instance, the most abundant volatile organic compound (VOC) present in the expiration of healthy subjects is acetone, and its concentration ranges from approximately 1 to 2 ppm [41]. This likely demarcates the highest practical limit of detection of gas sensors in the e-nose array, and should not be taken for granted when considering the use of low-cost sensors. Furthermore, many sensors, including the prolific metal oxide semiconductor (MOS) sensors, are sensitive to changes in relative humidity – a nontrivial issue when considering direct breath sampling. While this can be to some extent mitigated by using dedicated sampling mechanisms [10] or collecting samples into Tedlar bags, as was done in the majority of reviewed studies (see Fig. 1), it remains an obstacle in developing practical and low-cost solutions for breath analysis. Electronic noses are very sensitive to changes in environmental and sampling conditions, and the real field conditions often differ significantly from the laboratory conditions in which the devices were calibrated. In the case of breath analysis, this might entail the aforementioned issues with relative humidity but also changes in temperature and sampling flow, especially if it relies solely on the subject breathing into the device.

It is also necessary to overcome the issue of sensor drift. While the initial results obtained in numerous test studies are very promising, they do deteriorate rapidly as the sensors' response to a given sample shifts in time due to thermo-mechanical fatigue, poisoning, as well as

adsorption and desorption on the elements of the pneumatic setup [18]. Such a shift in sensor responses invalidates over time the initially trained ML models. Since frequent recalibration of the devices would not be cost-effective, researchers are looking for applications of AI in correcting the sensor drift, as outlined in the following section.

Another issue is that human volatilome is hardly a stable and immutable background for the changing concentrations of possible disease indicators. Indeed, its composition depends on a myriad of long- and short-term factors such as age, sex, diet, habits, time of day, or whether or not the subject had a mild exercise such as ascending a staircase prior to sampling [10, 22]. This further compounds the difficulties with extracting diagnostically useful information from the non-selective responses of the array of chemical sensors and makes the need for the use of elaborate data mining techniques more acute.

Machine Learning in Enhancing the Diagnostic Capability of Electronic Noses

The determination of trace volatile markers of disease is a major challenge. These compounds, mostly volatile organic compounds (VOCs), are present in the expiration at, at best, ppm levels and more commonly at ppb and ppt concentration levels [90]. Analysis of trace compounds is not easy to realize using state-of-the-art instrumental techniques based on mass spectrometry, and so the chemical sensors used for the same task have to be characterized by at least comparable sensitivity to the selected volatile indicators. More than 99% v/v of a breath sample does not carry analytically useful information, and the approximately 6% v/v of H₂O and 5% v/v of CO₂ can produce signal suppression in chemical sensors and matrix effects. This is why it is necessary to process and filter the raw sensor response signals, often using ML techniques, in order to extract information about the subject's condition, as outlined in the previous section. However, interfering substances are only a part of the overall challenge. When

contemplating the implementation of electronic olfaction in medical diagnostics, one has to consider issues specific to chemical sensors, i.e., the noise generated by the sensors during measurement and the long-term signal drift.

Denoising Algorithms

All changes in the sensors' response which are not a direct effect of exposure to the sample and which are caused by the electronic nose lead to noise generation. This in turn negatively impacts the device's detection capabilities, particularly in instances in which the differences between several complex biological samples are minute. Noise can be to some extent reduced using dedicated hardware solutions; however, part of it remains in the form of irreducible noise [91]. This is where signal processing algorithms, including ones based on ML, can be particularly useful. These include median filtering (MF), singular value decomposition (SVD), and PCA for noise reduction [91] or discrete wavelet transform (DWT) [92] among others reported elsewhere [93]. The most recent example of denoising algorithms is the discrete wavelet transform and long short-term memory (DWTLSTM) [94].

A good example of the implementation of these solutions is the use of ML to remove random

noise in the case of electronic noses equipped with an array of optical sensors, in which the removal of spectra noise is crucial for correct sample classification. The most common denoising methods such as Fourier analysis [95], wavelet transform [96], and Savitzky-Golay filtering (SG) [97] often produce very good results; they are, however, not flexible. One of the proposed alternatives is the use of least-squares support vector machine (LSSVM) filtering as a denoising tool for improving optical e-nose performance [98]. The results of its implementation were juxtaposed with other methods, i.e., moving window average (MVA), SG, and wavelet threshold filtering (Fig. 2). Apart from eliminating the random noise, the LSSVM algorithm was capable to preserve the relative extremes of the original spectrum, unlike other methods.

Sensor Drift Compensation

The issue of sensor drift was outlined in the previous section. It represents a major obstacle in the large-scale introduction of standardized, low-cost electronic nose devices for point-of-care diagnostics. Attempts are being made to mitigate its effect through hardware modifications, e.g., through replacing individual sensors [99] or by developing

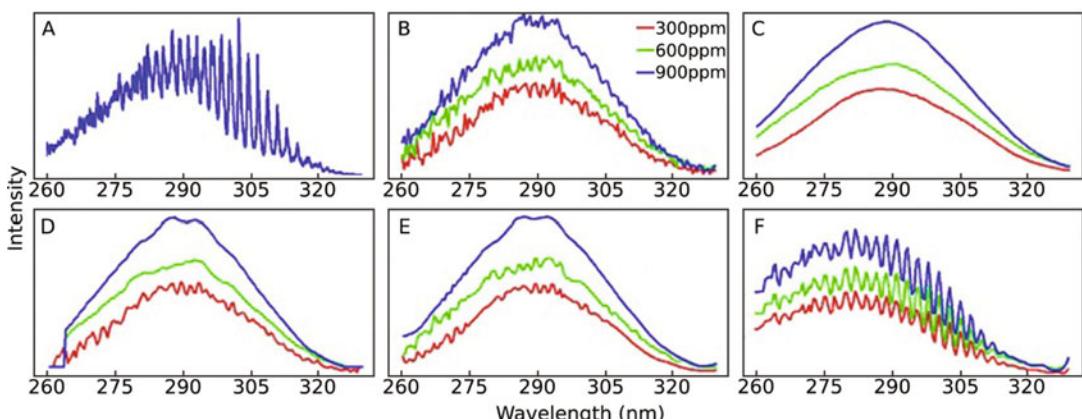

Fig. 2 Performance of denoising algorithms applied to the response signal of an SO_2 optical sensor evaluated based on the normalized correlation coefficient (NCC). The reference spectrum (**a**) was obtained from the HITRAN database. The real spectrum (**b**) was transformed using WMA

(**c**), SG (**d**), wavelet transform (**e**), and LSSVM (**f**) algorithms. Using an ML protocol, it was possible to obtain the highest NCC value of approximately 0.98 regardless of the gas concentration. (Modified from [98], Copyright 2018, with permission from Elsevier)

novel types of carbon nanotube-based sensors which self-compensate for changes in relative humidity [100]. However, compensating for drift at the data processing stage seems to be more practical. The most straightforward approach here would be to recalibrate the sensors using a reference gaseous mixture. This is, however, relatively costly and time-consuming. It is often based on linear response models, which are only applicable in situations in which the drift is linear in nature (e.g., baseline shift) [18]. Another solution is to employ univariate analysis (to the response signal of each of the sensors in the sensor array). Examples include baseline manipulation, frequency analysis, and differential analysis. These methods, while computationally undemanding, require manual calibration. It is also possible to perform multivariate statistics [18], in which the drift compensation is applied not to the response of a single sensor but to the response of the entire sensor matrix [93]. However, all the solutions outlined above require user's involvement – a step which ideally could be bypassed using artificial intelligence.

One solution is to use supervised ML methods such as component correction (CC) or sequential

minimal optimization (SMO). Unfortunately, this entails preparing a training set prior to drift compensation [101]. An alternative is to use semi-supervised methods such as Weighted Geodesic Flow Kernel [102] or multifeature kernel semi-supervised joint learning model (MFKS) [102]. However, the current trend is to try to develop a fully unsupervised approach. Such new developments can now be validated against a common benchmark which allows to juxtapose different models and assess their performance and facilitates the development of novel drift compensation algorithms. This was made possible by the publication of an open dataset of sensor responses prepared by Vergara et al. [103]. It contains 13,910 measurements of 6 gases over a period of 36 months. Another dataset that is commonly used to validate new drift compensation protocols is the CQU sensor drift dataset which contains 1604 measurements using 3 devices, of which 1 was the master device and the 2 remaining ones operating as slave devices, with 5 years of difference between devices of both categories [104]. Selected ML models for sensor drift compensation developed in recent years and validated using the UCI dataset [103] are listed in Table 2

Table 2 The juxtaposition of selected sensor drift compensation methods which were validated using the UCI dataset [103]. Average classification accuracy denotes the percentage of samples from batches 2 to 10 of the dataset,

Type of drift removal method	Method name	Average classification accuracy [%]	Ref.
Component correction	CC-PCA	45.7	[104, 106]
	CC-LDA	49.9	[104, 106, 109]
Label-free correction	MFKS	77.6	[109]
	DRCA	77.6	[104]

CC-PCA, component correction PCA; CC-LDA, component correction LDA; MFKS, multifeature kernel semi-supervised joint learning model; DRCA, domain regularized component analysis; SVM-rbf, SVM radial basis function; SVM-comgfk, SVM combined with kernel of geodesic flow kernel; ELM-rbf, ELM radial basis function; DAELM-T, target domain adaptation ELM; ODAELM-T, online target domain adaptation ELM; AL-ACR, AL adaptive confidence rule; AL-DC-ER, AL dynamic clustering error reduction sampling; AL-ISSMK, AL instance-selection strategy on a mixed kernel

containing signals which drifted over time, was correctly classified as the initial signals from batch 1 after the application of the method

together with the corresponding average classification accuracies.

One of the fully unsupervised algorithms for drift correction is the anti-drift which is based on domain regularized component analysis (DRCA) [104]. It projects the data onto a new subspace in such a way that the clusters (more-or-less discrete groups) of the source domain and the target domain have a similar distribution. Another fully unsupervised method is the online target domain (alternatively source domain) adaptation extreme learning machine [101]. Some algorithms assume that the drift is the same for each feature, which is not always the case, especially when the sensor matrix of the electronic nose is comprised of different types of chemical sensors. Selected features can be targeted, e.g., using the discrete binary particle swarm optimization-cosine similarity (DBPSO-CS) classifier which identifies drift-intensive features [105]. It should be noted that the datasets compiled, appended, and continuously concatenated throughout the use of a set of electronic noses developed for a particular diagnostic task might be vastly different depending on the settings, number of analyzed samples, device construction, and numerous other factors. This means that it is difficult to find a versatile drift compensation solution that will be applicable in such scenarios. This issue could be solved using approaches akin to the recently developed discriminative dimensionality reduction algorithm [106] which, owing to the use of two trade-off parameters, can adjust the drift compensation to a given scenario, offering some degree of flexibility. The last 2 years also saw the introduction of methods that are based on the active learning mechanism, including the instance-selection strategy on a mixed kernel (ISSMK) [107] and the active drift calibration sample selection (AC-CSS) [108].

Some ML-based algorithms are aimed at solving more than a single issue. For instance, the multi-classifier tree model can be used for both sensor drift compensation and fixing problems with delayed sensor response. It is a complex approach that also involves the removal of outliers (noise artifacts) using the boxplot approach. The mitigation of the delayed sensor response issue is

achieved by using the sensor response in the transient state (the initial, rapid change of the signal) instead of the steady state, which makes it possible to curtail the time of a single analysis by not waiting for the signal to stabilize [99].

While the use of a single common dataset for the validation of the newly developed drift compensation algorithms certainly facilitates the assessment of their performance, there are drawbacks of using data obtained in strictly controlled settings and for a handful of gaseous substances which might impact the robustness of the models. This is why a recent trend is to supplement the validation protocol with data from own measurements of more complex mixtures of volatiles [108].

Conclusions

At first glance, electronic olfaction seems to be very well suited for the development of low-maintenance, inexpensive tools for noninvasive screening tests and point-of-care diagnostics, thanks to its ability to extract useful information from very complex gaseous mixtures. This ability is realized using artificial intelligence in the form of elaborate machine learning algorithms. However, several methodological issues conspire to prevent the technique from reaching maturity sufficient for widespread adoption in clinical settings. These are related to the complexity of the biological matrices in general, and of breath in particular, and to the hardware limitations of the conventional electronic noses equipped with chemical sensors, such as sensor drift, high limits of detection, and susceptibility to humidity. While some of the difficulties with the realization of electronic nose-based medical diagnostics can be overcome using hardware solutions such as elaborate sampling setups, others, such as sensor drift, can be at least in part alleviated using the recent advances in AI. This is reflected by the recent proliferation of ML algorithms for processing the raw signals and data from sensor arrays and for mining analytically useful information. Even if in the future researchers will abandon the hope of utilizing electronic noses equipped with

low-cost gas sensors in medical diagnostics in favor of their counterparts based on ion mobility spectrometry [110] or mass spectrometry [111], even more will be asked of AI in order to handle the large multivariate datasets and to extract from them diagnostic data while avoiding the curse of dimensionality.

the responsible use of information and communication technologies. From a steady pace of progressive expansion, telemedicine has grown exponentially worldwide due to the emergence of the COVID-19 pandemic. The addition of artificial intelligence to telemedicine can expand and improve its capabilities, giving endless possibilities for developing solutions for specific healthcare needs. AI in telemedicine can make a significant contribution for the implementation of the continuum of healthcare and promote and facilitate greater access to integrated healthcare, where and when necessary. The potential impact of AI in telemedicine can be identified around four emergent trends: patient monitoring, healthcare information technology, intelligent assistance and diagnosis, and information analysis collaboration. However, their implementation

in healthcare faces safety, ethical, efficacy, efficiency, regulatory, and financial challenges. Their adoption will increase if physicians serve as knowledgeable and supportive guides and leaders in the process. The evidence of the benefit of AI will need to be convincing enough for the medical community and the patients to adopt the technology. For physicians AI can be helpful in aiding in decision-making and for specific tasks to improve healthcare delivery. It is also of extreme value by automating administrative tasks to free up valuable time that can be dedicated to the direct care of patients. AI-enabled telemedicine should suit with existing clinical practice. It requires a framework that could be based on technical and clinical considerations, reliability, reproducibility, usability, accessibility, and costs. This chapter also discusses their benefits and limitations in several medical specialties.

Keywords

Telemedicine · Artificial intelligence · Medicine · Physicians · Machine learning · Deep learning · Education · Benefits · Limitations

Introduction

Telemedicine is considered one of the main innovations in healthcare. It increases the accessibility to healthcare services and improves the quality of medical care and organizational efficiency [1].

The addition of artificial intelligence (AI) to telemedicine can expand and improve its capabilities giving endless possibilities for development of solution of specific needs. Both can assist doctors in providing better quality healthcare services to patients. The association of AI with telemedicine can improve health outcomes and enhance patient's experience. They can also improve and speed screening and diagnosis of diseases, make diagnosis more precise and personalized, and reduce patients in person visits.

AI in telemedicine can make a significant contribution to the implementation of the continuum of healthcare. They can promote and facilitate

greater access to integrated healthcare, where and when necessary throughout the citizen's life cycle. The management of chronic diseases, for instance, needs a multidisciplinary continuous and coordinated care. The consistent communications and connections across different elements of healthcare delivery can be supported by remote care. AI can help address this need, by enabling the intelligent information and communication environment in which health professionals could interact and by providing a knowledge base for patient's management [2].

The Basics of Telemedicine

The World Health Organization defined telemedicine as “the delivery of healthcare services, where distance is a critical factor, by all healthcare professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation, and for the continuing education of healthcare providers, all in the interests of advancing the health of individuals and their communities.” [3]

Despite having been published approximately 22 years ago, this definition continues to be used, and some of its components might need to be reviewed such as “where distance is a critical factor.” The use and experience gained by patients, doctors, and health services demonstrate that even patients who are close to health centers can benefit from telemedicine. Each time more the care of people in their homes is being valued, due to the comfort and safety they bring, especially in times of SARS-CoV-2 pandemic.

Although in several publications telemedicine and telehealth are considered synonymous and used interchangeably [4], technical and regulatory aspects and specificity of various health professions indicate that they should be considered as different. For this chapter, we will distinguish telemedicine from telehealth with the former restricted to service delivery by physicians only and the latter signifying services provided by health professionals in general, such as tele-nursing, telenutrition, telepsychology, and others.

We propose a simpler but no less efficient definition of telemedicine: “Telemedicine is the practice of medicine, between different places, through the responsible use of information and communication technologies.”

By responsible use of telemedicine, we mean the need for its practice to be ethical (in the same way as we practice in face-to-face care) and safe, with privacy and confidentiality (for patient’s protection) and with quality (seeking the best possible patient’s outcomes).

Several new terms are being used to bring a broader and holistic view of people’s healthcare in a digital era, such as digital health, eHealth, virtual care, connected care, and connected health. They might have small differences in their meanings and so should be understood in the contexts in which they are used. One can consider that telemedicine is inserted within these denominations.

Digital health can be simplistically defined as the use of digital technologies for health. It encompasses advanced computing sciences in big data and artificial intelligence. Mobile health (mHealth) is defined as “the use of mobile wireless technologies for health.” [5]

Telemedicine can be practiced synchronously or asynchronously (store-and-forward). Among its modalities we can list the following:

- Teletriage – assessment of symptoms for referral of the patient to the care they need.
- Teleconsultation – physician direct to patient or interaction between physicians.
- Telediagnosis – transmission and registration of complementary exams of the patient to be interpreted by specialists.
- Telemonitoring – continuous collection of physiological parameters, transmitted to a provider for diagnostic and therapeutic purposes.

These terms and definitions vary between countries. Remote patient monitoring (telemonitoring) includes transmission, registration, processing of body parameters, and medical management through electronic systems. It can be performed using wireless devices and wearable or implantable sensors. It allows continuous support and management of chronic diseases and can be synchronous or asynchronous, depending on

the patient’s needs. The application of AI and machine learning can allow better disease surveillance and early detection, incorporate and coordinate data from additional tools like location finders (GPS), improve diagnostics, and support for clinical decision.

It should be emphasized that telemedicine is a method of healthcare. It is not a tool. Tools are hardware, software, Internet, and others that allow technical support for the practice of telemedicine. As a method of healthcare, it should be learned by physicians through a qualified training process to allow it to be practiced safely and with quality. Telemedicine also has limitations, and doctors must know about them together with the specific characteristics of its practice in different medical specialties.

There is ample evidence in the scientific and real-world literature confirming the safety, efficacy, and cost-effectiveness of telemedicine [6–8]. The main benefits are the following:

- Contributes to the digital transformation strategy
- Expands access and brings citizens closer to health services
- Increases healthcare efficacy and effectiveness
- Contributes to improve clinical outcomes
- Increases patient involvement and self-care
- Strengthens coordination of care
- Assists in resolving geographic and social health inequalities
- Allows continuous and articulated monitoring between different levels of care
- Contributes to the organization of health systems
- Reduces health costs

The benefits of telemedicine have been demonstrated in several medical specialties. A meta-analysis of the effectiveness of telemedicine in diabetes mellitus showed that telemedicine interventions were more effective than usual care specially in managing type 2 diabetes [9].

In cardiovascular patients remote monitoring is cost-effective and safe, and it decreases the staff workload and improves the prognosis of heart failure patients [10].

In teleoncology, several effective interventions were identified: telepathology, remote chemotherapy supervision, symptom management, survivorship, and palliative care [11].

However, despite these benefits, telemedicine represented a small fraction of all healthcare activities and spending. Barriers to its development include regulatory uncertainty, uneven financing and reimbursement, and unclear governance.

This scenario seems to be changing. As a clear evolution of the use of digital health and telemedicine, the recent Digital Healthcare Act in Germany has made possible for some health applications such as apps and web-based programs to be prescribed by doctors with the costs covered by the statutory health insurance.

Moreover, with the emergence of the COVID-19 pandemic, there was an exponential growth in the use of telemedicine, and it was possible to explore and demonstrate all the potential benefits of this method of healthcare. Through telemedicine, people can receive a wide range of medical services at home, overcoming the distance barrier. It has been possible to remotely screen patients with symptoms, avoid unnecessary visits to health services, and assist symptomatic patients who can be cared for at home. By keeping potentially infected individuals out of health services, there is a reduction in the risk of contamination from other people, doctors, and health teams.

Of great importance has also been the care of people with chronic diseases, when face-to-face visits are not necessary, especially the elderly, who have a high risk of complications and death when contaminated by SARS-CoV-2.

Hospitals and doctors more experienced in handling serious cases at COVID-19 can support colleagues in multiple hospitals, anywhere in the country or even from other countries [12].

The Integration of Artificial Intelligence in Telemedicine

Among the most commonly used definitions for AI two can be highlighted: (1) computer systems that perform tasks normally requiring human intelligence and (2) AI as “augmented

intelligence”: computer algorithms designed to enhance the capabilities of highly trained professionals.

In medicine, AI is expected to address the high rate of avoidable medical errors and workflow and delivery inefficiencies associated with contemporary healthcare provision [13].

The potential impact of AI in telemedicine can be identified around four emergent trends: patient monitoring, healthcare information technology, intelligent assistance and diagnosis, and information analysis collaboration [14].

Despite these impacts the integration of AI in telemedicine into everyday practice has been limited. Their implementation in healthcare faces safety, ethical, efficacy, efficiency, regulatory, and financial challenges. Their adoption will increase if physicians serve as knowledgeable and supportive guides and leaders in the process [15]. The evidence of the benefit of AI will need to be convincing enough for the medical community and the patients to adopt the technology [16].

AI may be proven to be more accurate than a physician and detect features humans cannot in specific situations. However, one cannot expect that algorithms will be able to replace the comprehensive role of physicians.

Physicians are trained to react when more information from a patient becomes available and make new diagnosis and therapeutic decisions once needed, in a dynamic approach. AI gives its opinion based on “engineered” data as input, and whatever happens to the patients afterward is disconnected from the AI’s original opinion increasing the risk of errors/mistakes. Physicians need to understand what is behind the AI proposed diagnosis to understand what the possible consequences or unintended side effects are. AI is unable yet to diagnose and manage patients without physician input. At present, it has an assistive role with clinician oversight and ultimate responsibility.

For physicians AI can be helpful in aiding in decision-making and for specific tasks to improve healthcare delivery. It is also of extreme value by automating administrative tasks, through its smart algorithms, to free up valuable time that can be dedicated to the direct care of patients [17] as

approximately 50% of a physician's time is spent working on electronic health records [18]. An innovation that could help physicians is speech recognition in replacing the use of keyboards to enter and retrieve information.

The role of history taking in the initial diagnosis of a patient's health problem is higher than patient's physical examination. Some studies had reported a contribution of 76% by history and 11% by examination [19]. As of today, the art of history taking and examination are getting compromised by the increased availability and use mainly of imaging tests such as computed tomography and magnetic resonance. History taking consumes much of a physician's time, so it tends not to be used to the extent feasible via telemedicine. AI as a part of a telehealth application could help in the diagnosis process by providing prompts and clues and suggesting the right next questions based on the answer, thus saving the doctor's time [20].

To be scalable AI-enabled telemedicine should suit existing clinical practice. Real-world validation requires a rigorous and transparent framework, flexible enough to be applied to a broad range of technological innovation. Such a framework could be based on technical and clinical considerations, reliability, reproducibility, usability, accessibility, and cost [21]. It should also include an independent governance and ethical aspects.

AI can be effectively advantageous when it comes to analytical reasoning and problem-solving, particularly when large amounts of data are involved. However, AI should not be overutilized and disregard the vital physician skills in healthcare [20]. AI is unable to fully take and interpret contextual information or determine between relevant versus nonrelevant informational input. Physicians are required to deal with the contingencies of healthcare. An AI-powered system should prioritize the collective good and performance based on evidence-based management principles [20].

Patient data are sensitive in nature and subjected to numerous regulations and legislations such as HIPAA and GDPR to ensure that patient data are collected and stored in compliance with security norms. Adequate measures are needed,

which also include data encryption and blockchain, which add a layer of security in relation to storage and sharing of healthcare data.

While regulatory bodies attempt to provide guidance for users and payers for new technologies, they are challenged by the rapid change of pace of AI and its use in telemedicine. The legal aspects of AI adoption need to be better clarified. The American Medical Association (AMA) advocates that in case of system failure or misdiagnosis from autonomous AI systems, the developers must take liability and maintain their own medical liability insurance with their users [22].

The cost of AI embedded in telemedicine is also a potential barrier to adoption. The heterogeneity in the insurance policy and medicolegal regulations are key challenges for its clinical implementation.

Telemedicine and Artificial Intelligence

Teleophthalmology and AI

Individuals diagnosed with diabetes mellitus need regular and repetitive annual retinal screening for detection and treatment of diabetic retinopathy. Diabetic retinopathy is an increasing problem and early screening, and timely treatment can reduce the burden of sight threatening. Such screening is done by fundus examination by ophthalmologists or by color fundus photography using conventional fundus cameras. In teleophthalmology programs, the digital retinal images are sent to a centralized reading center for assessment for the presence of DR.

The lack of specialized professionals in relation to the demand of patients who should undergo this exam could be solved with the provision of an automated imaging system. Using AI and machine learning, a subfield of AI, with devices within easy reach of the patient, the diagnosis can be made by teleophthalmology. AI systems embedded in the screening process could analyze retinal images and compare them with previous samples to determine the stage of diabetic retinopathy.

However, the available automated imaging systems and devices still have sensitivity and specificity below 90%, so false-positive and false-negative results might occur. The dilated eye examination remains the gold standard of screening. Once proven to be sensitive and specific enough, AI systems can change screening programs and population-based teleophthalmology. A comprehensive practical guidance on telemedicine in diabetic retinopathy has been recently published by the American Telemedicine Association Ocular Telehealth Special Interest Group [23].

Deep learning has also been used in teleophthalmology for the screening and diagnosis of other vision diseases, such as glaucoma and age-related macular degeneration [24].

Telestroke and AI

Stroke is one of the main causes of mortality and disability worldwide. Several studies have shown that stroke has a huge global impact with a considerable financial cost for both health and care services and to patients and their families. Stroke mortality varies considerably according to social and economic development, and approximately 85% of strokes occur in low- and middle-income countries with one-third affecting the economically active population. The demographic transition occurring in most developing countries toward an increase in the older population will amplify the impact of stroke [25].

Delays in diagnosis and treatment increase the risk of death and poor prognosis. The limited diagnostic and therapeutic window and the shortage of neurologists with experience in stroke management has made telemedicine a method for providing neurological care readily available. Teleneurology has been shown to be a safe, efficient, and cost-effective way of improving stroke outcomes [26]. The accuracy of telestroke in diagnosing acute stroke has proven to be equivalent to that of bedside evaluations [27].

Telestroke systems have included AI algorithms using machine learning to automate reading and classification of radiologic imaging. The efficiency and quality of care depend on the rapid interpretation of clinical data and brain images.

Identification of stroke location, classification and severity can directly impact management decisions [28].

The addition of deep learning algorithms has shown the ability to identify abnormalities such as intracranial hemorrhages and its subtypes, midline shift, and mass effect [28]. In large vessel occlusion ischemic strokes, selected patients could benefit from endovascular reperfusion therapy. The incorporation of automated perfusion processing to interpret perfusion is helping in the treatment decision-making process [29].

AI algorithms have been integrated into various processes of acute stroke management. Prehospital notifications sent to the emergency department can alert an incoming stroke, allowing for the adequate preparation of patient's appropriate management according to the type and other characteristics of the stroke (i.e., neurointerventional, neurosurgical, or neurocritical care teams) [28].

Telestroke programs are using platforms providing automated information about various components of the acute stroke triage pathway and clinical workflow. They offer fast and accurate analyses to optimize the delivery of stroke care at spoke and hub hospitals [30, 31].

Acute stroke patient candidates for thrombolysis can be rapidly detected with the help of machine learning algorithms for the identification of ischemic infarction on computerized tomography (CT) or magnetic resonance (MR) diffusion-weighted imaging. AI has been effective to identify core infarct volumes on MR DWI and large vessel occlusion, essential for selecting patients who could benefit from mechanical thrombectomy.

ASPECTS is a widely used 10-point quantitative topographic CT scan grading system for assessing the extent of early ischemic stroke in the selection process of thrombectomy candidates. ASPECTS scoring software platform (e-ASPECTS, Brainomix) performed as well as neuroradiologists in patients with acute stroke [32]. However, in patients with acute stroke with baseline non-normal-appearing CT (e.g., leukoencephalopathy, old infarcts, or other parenchymal defects), e-ASPECTS did not perform as well as neuroradiologists [33].

RapidAI is another neuroimaging software, which collects and analyses data from the CT

perfusion scan. It provides a real-time view of brain perfusion with a quantitative value of the volume of brain tissue that is irreversibly damaged and the volume of tissue that can be recovered if blood flow can be restored quickly [34].

The current application of AI in the telestroke field has allowed significant improvement in treatment decision and clinical outcomes and future studies validating AI techniques are needed to allow its widespread use.

Teledermatology and AI

Teledermatology (TD) is transforming healthcare recently. The evidence to date supports the accuracy and cost-effectiveness of teledermatology and the possibility of bringing greater access to the specialist.

Dermatological diagnosis relies mainly on morphological features, and most diagnoses are based on visual pattern recognition. Skin imaging technology has become an important tool for clinical diagnosis of skin diseases, and TD is one of the telemedicine areas in which AI image recognition capabilities for assisted diagnosis have been well explored. TD with AI integration might also be an effective screening tool. However, there are limitations as a recent systematic review of currently available teledermatology mobile-based apps concluded that studies done so far relied on heavily biased patient samples, limiting the conclusions on the efficacy of these automated-diagnoses systems [35].

In primary care setting, artificial intelligence-driven image diagnosis could help general practitioners to make a correct diagnosis by feeding a skin lesion picture to an application to diagnose common dermatological conditions. By linking such applications to a remote central enriched with image-based diagnostic database that analyzes the images, the non-dermatologist physician can receive the probabilities of diagnosis or differential diagnoses.

Several studies have evaluated AI-driven image diagnostic technology for skin cancers against dermatologist diagnostic performance, showing the same accuracy as the trained dermatologists [36, 37].

Deep learning technology stands to disrupt dermatology, both in person visits and by teledermatology.

However, studies using such technology have shown a limitation for non-skin cancer disease conditions. Low specificity and specificity for these pathologies have been found meaning that they are inaccurate enough to rely on AI-driven image analysis alone. If a certain dermatological condition is excluded from the AI model's database, a patient with this condition may be misdiagnosed with a similar-appearing condition. Bias may also be introduced when lesions that were deemed worthy of capturing via photograph or being biopsied may not be representative of the lesion type. As a result, by using images from datasets, the sensitivity of clinician diagnosis may be lower than in a normal clinic [38].

Telemedicine, Artificial Intelligence, and Education

For the responsible (ethical, safe, and quality) use of new technologies such as telemedicine and AI, it is of paramount importance to provide prime quality education and training for medical students, residents, and physicians. Despite efforts and the recent growth of telemedicine teaching in medical education institutions, there is still a great lack of education and training in this field. The knowledge and practice of telemedicine are and will be even more valuable in the near future to serve populations in need of quality medical care.

During medical school, a curriculum that integrates telemedicine training should be competency-based and outcomes-oriented with multiple teaching modalities. The latter may include (1) asynchronous lectures; (2) discussions on applications, ethics, safety, etiquette, and patient considerations; (3) faculty-supervised standardized patient telehealth encounters; and (4) hands-on diagnostic or therapeutic procedures using telehealth equipment such as live video, the store-and-forward method, remote patient monitoring, and mobile health [39].

Such curricula should allow students to learn how to maintain a strong patient-doctor

relationship, protect patient privacy, promote equity in access and treatment, seek the best possible outcomes, and learn the benefits and limitations of telemedicine [40].

The COVID-19 pandemic has caused an exponential growth worldwide in the use of telemedicine. The incorporation telemedicine and AI teaching into medical school curriculum will also increase their understanding of the complex ethical, regulatory, and legal issues related to the use of such technologies [39]. The main domains of such curriculum could include (1) access to care, (2) cost, (3) cost-effectiveness, (4) patient experience, and (5) clinician experience [39].

The education on telemedicine and AI should also be expanded for practicing physicians. The American Medical Association recommends medical specialty societies and boards to consider the production of specialty-specific educational modules related to AI [22]. AMA also highlights the need for continued medical education regarding assessment, understanding, and application of data in patients' care.

Nowadays, physicians should have skills and competencies to work with electronic health records and understand the true potential of the new technologies. They should have the ability to manage data and supervise AI applications, to use it as clinical decision support.

Physicians do not need to become experts in AI; rather they should have sufficient understanding of the capabilities and limitations of AI algorithms to allow them to make the best use of it. However, it is important to ensure that the use of AI and telemedicine does not harm the humanism enshrined in the practice of medicine and the patient-physician relationship.

Abstract

Incremental advances in miniaturized transistor technologies and improvements in network infrastructure have paved the way for the development of smartphones and applications augmenting the management of various conditions ranging from respiratory to neuropsychiatric disorders. Other applications have also been borne out of the necessity to streamline services in order to tackle logistical challenges that often arise in medicine and healthcare. These include using smartphone apps to aid diagnostics, such as skin lesion classification, or to leverage online platforms and facilitate easier access to patient information. What would otherwise take up additional unnecessary hospital resources is now achievable through mHealth systems such as patient flow monitoring. The ease with which information can now be accessed, curated, and pre-processed has paved the way for the concept of medical informatics. Informaticians now have the capability to apply artificial intelligence and machine learning to derive critical insights, automate, and make predictive analysis to improve clinical and quasi-clinical healthcare delivery. This chapter explores the global evolution of the artificial intelligence paradigm for mHealth, eHealth, and smartphone and mobile phone apps for medicine. The chapter outlines some of their applications for various medical subspecialties including cardiorespiratory, neuropsychiatric, and rehabilitation medicine.

Keywords

mHealth · Artificial intelligence · Smartphone apps · Machine learning · Deep learning · Supervised learning

Introduction

The fields of telehealth and mHealth are defined by the use of smartphone, network, and wireless technologies to provide direct or indirect health support to patients. They also facilitate technical support for healthcare providers and various healthcare organizations [1]. This has not only received a lot of attention from the global health community, but has also resulted in a considerable amount of innovation to streamline medical care, interventions, patient flow, and hospital logistics coordination – all leading to improvements in multidisciplinary care. These developments were made possible thanks to considerable nanotechnological advances in top-down miniaturization of transistors and other semiconductor chips to create devices that allow for better software-to-hardware integration [2], thus enabling healthcare engineers to facilitate the design and platform execution of multi-agent-based artificially intelligent algorithms. This in turn led to the conception, generation, and deployment of structured machine learning pipelines that can be optimized to work on a mobile device for the benefit of both the patient and the healthcare system. To understand how AI impacts and augments mHealth, we explore some of the key historical milestones that brought us to where we are today. Since earlier chapters have already outlined the origins of AI and machine learning, this will not be a focus in this chapter. However, we will briefly align the chapter's agenda with the origins of networks that paved the way for the mHealth, eHealth, and smartphone app revolution over recent decades.

History

First-generation (1G) mobile networks started with the Japanese Nippon Telegraph and Telephone company in the late 1970s, evolving from

pre-wireless 0G technologies that developed after World War II. The mobile phone industry has made remarkable incremental strides since then, reaching its fifth generation of innovation status in recent years. Many initial drawbacks included the cost, which at the advent of 1G was \$3,995 (present US inflation adjusted cost of \$26,648.19; a 567.0% rise), unreliably poor voice linking, low handoff, and poor network security, which subsequently improved for both the developed and developing worlds. Although 1G was remarkably cost-prohibitive, it still saw widespread transatlantic global adoption with Motorola's DynaTAC being the first to deploy it in the USA in 1983 as well as developments in Europe with popular analogue systems from Nordic Mobile Telephone (NMT) and TACS [3–5].

Second-generation (2G) mobile networks started a cultural revolution and was built on the Finnish contribution of the Global System for Mobile Communications (GSM) standard. 2G not only added a layer of security to wireless telecommunications through encryption systems, but also added clearer digital voice calling with less static interference, thus making it more usable for robust machine learning applications on the audio itself. The introduction of picture and multimedia messages then extended its mass consumer adoption, paving the way for innovations in computer vision applications for mHealth. The 2G era also saw transfer speed innovations from 10kbs to 500 kbps at its bleeding edge [3–6].

In 2001, the packet switching third-generation (3G) mobile networks not only elevated network technology but also introduced standardizations that made these technologies ubiquitously adoptable and easily accessible from all corners of the globe. Launched by NTT DoCoMo, roaming became available for the first time from any international location with data packet transfer-driven technology [5]. With transfer speeds of up to almost 2 Mbps, four times the speed of its predecessor, such augmentations enabled quality video conferencing, streaming, and voice-over Internet protocols (adopted by companies like Skype) [3–6]. Derivations of 3G included EDGE, CDMA2000 [6]. Readers may recall the era of the personal digital assistant, such as the BlackBerry,

with mobile platforms that were highly coveted at that time due to their impressive professional capabilities, technological fidelity, and portable form factor, that is, until they were superseded by the Apple iPhone (see Fig. 1).

4G kick-started the so-called 100Mbps streaming era and introduced the Long-Term Evolution standard, which made high-quality video streaming a reality on small form-factor devices, at the same time parallelizing compute resources to minimize bandwidth deficiencies that the previous generations all harbored [6]. Scandinavian countries such as Norway and Sweden were early adopters of the technology, followed by hundreds of millions of global consumers, thus paving the way for this technology to be utilized by patients, family members, and healthcare teams around the world [3–5]. 4G formed the bedrock for the development of mHealth-powered AI in various medicine-related settings, including augmented reality, medical games, high-definition video conferencing, mixed reality streaming, and other methods utilized for medical ward rounds by centers like Oxford University and Imperial College Hospitals NHS Trust in the UK [7, 8]. Figure 1 summarizes the evolution of some of the smartphone and wearable technologies that are being used in mHealth. This subsequently became crucial during the 2019 SARS-CoV-2 pandemic allowing for adherence to social distancing rules, keeping the quintessential doctor-patient relationship alive while still maintaining effective healthcare delivery and patient safety.

The interlink between 5G and the evolution of the Internet to support it requires a joint treatise. The concept of the Internet itself was borne out of the idea of wireless machine telegraphy circa 1830s [9, 10]. James Clerk Maxwell's theory of electromagnetic radiation was proposed in a lecture to the Royal Society of London in the mid- to late nineteenth century [9]. More than 20 years later, in 1887, Heinrich Hertz in Germany confirmed Maxwell's theories. Irish-Italian wireless pioneer Guglielmo Marconi was the first to equip the Titanic with commercially available wireless telegraphy during its maiden voyage in 1912 [9]. Coupled with the advent of radio-voice communication at the turn of the twentieth century allowed the origins of the Internet and its

(Disclaimer: This is an independent publication and is neither affiliated with nor authorized, sponsored, or approved by Microsoft Corporation)

protocol-driven technologies such as the Internet of Things (IoT) to come to the fore. However, it was not until the advent of early computers in the 1950s at the height of the Cold War that led the Defense Advanced Research Projects Agency (DARPA) to create the ARPANET, conceptualized by JCR Licklider and created in the late 1960s as the predecessor to the World Wide Web

that we know today as pioneered by Sir Tim Berners-Lee and others [10, 11]. At the same time, Global Position Satellites (GPS) developed during the late twentieth century became another primary component for IoT, together with landlines [3–5, 11].

At the time of writing, 5G has not been widely adopted because of marked controversies and

geopolitical tensions; however the concept of the Internet of Things (IoT) and connectivity is not new. Prof. Kevin Ashton is credited with coining the term in the 1990s to secure funding for Radio-frequency Identification tagging Technology (RFID) from Proctor and Gamble [10]. This technology has allowed devices to be tagged and tracked over appreciably long distances. Other complementary short-range methods like QR and barcode technology for digital watermarking have also facilitated digital inventory control that is useful for device-led machine learning and AI approaches in medicine.

An insightful speech by Prof. Ashton outlined the potential of IoT for medical applications but also highlighted the challenges we face as human beings and clinicians when he addressed the management of big data and the need for a paradigm shift in approach. In 1999, he remarked that [10]:

...nearly all of the roughly 50 petabytes (a petabyte is 1,024 terabytes) of data available on the Internet were first captured and created by human beings by typing, pressing a record button, taking a digital picture or scanning a barcode. The problem is, people have limited time, attention, and accuracy. All of which means they are not very good at capturing data about things in the real world. If we had computers that knew everything there was to know about things, using data they gathered without any help from us, we would be able to track and count everything and greatly reduce waste, loss and cost. We would know when things needed replacing, repairing or recalling and whether they were fresh or past their best. [10]

Ashton also postulated the tagging of devices with RFID to provide tracking potential. Early research development by NASA's machine to machine intelligence corps and South Korea's 5G research and development group contributed to where we are today. In fact, Korean companies like KT, LG Uplus, and SK Telecom had already started providing commercial 5G services as early as the end of 2018. The speed of 5G is unparalleled compared to its predecessors with an estimated upload and download speed increase over 20 times the previous generations (up to 20 Gbps) [6–8, 11]. Figure 2 summarizes the global network subscribership over the past 27 years and the most recent data on the number of Internet users.

We now have pervasive computing devices including the latest generation of Apple/Samsung/Fitbit, etc. smart watches/wearable devices that can be used for medical monitoring. For example, Apple watch device can network with smartphone apps using machine learning algorithms to detect cardiac electrophysiological abnormalities and pulse abnormalities. Upon detection, they are able to send the results wirelessly over a 4G network to a specialist cardiologist or general/family practitioner's phone, thus facilitating the early detection of potentially serious conditions. As this example shows, we have already come a long way with AI, but there is still so much more that can and will be accomplished.

The International Telecommunication Union reports 5 billion users of wireless technologies, and a recent survey of 114 countries conducted by the WHO Global Health Observatory categorized about 16 facets of mHealth services as follows [15]:

- Mobile telemedicine
- Raising health awareness
- Medical decision support systems
- Medical treatment compliance
- Managing medical emergencies
- Managing medical disasters
- Health call centers
- Emergency toll-free telephone services
- Medical appointment reminders
- Community mobilization and health promotion
- Mobile patient records
- Information access
- Patient monitoring
- Health surveys and data collection
- Medical surveillance
- Raising health awareness

The four most common areas of mHealth across the globe include health call centers (59%), emergency toll-free telephone services (55%), managing emergencies and disasters (54%), and mobile telemedicine (49%). This is in line with the historical and technological developments pioneered to facilitate mHealth [15]. mHealth now has the potential to enable disseminated cross-border healthcare delivery for

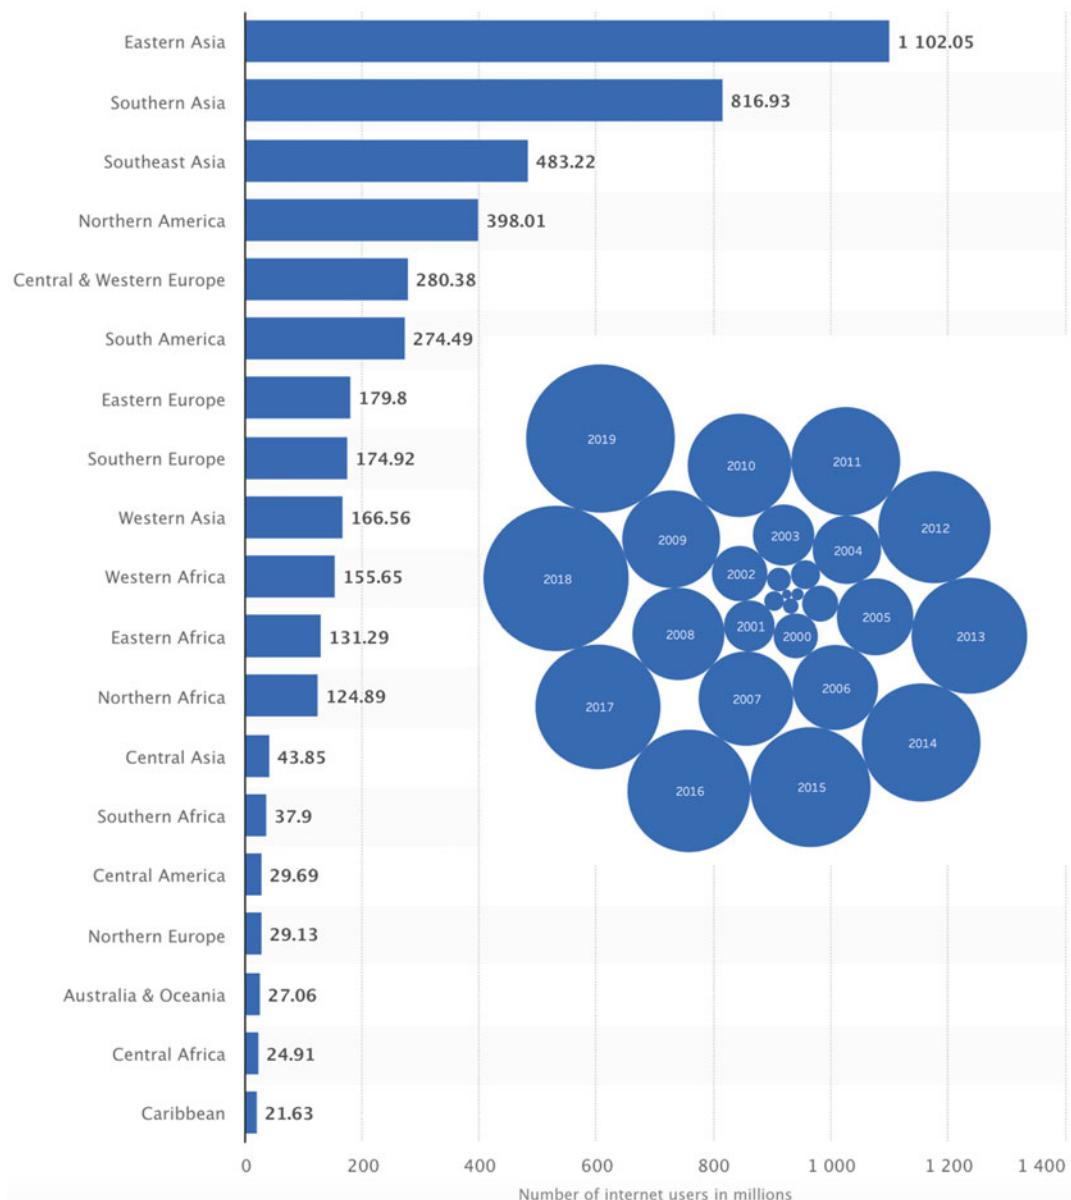

Fig. 2 Graphed data on the number of worldwide Internet users in 2020, by region (in millions), together with a yearly distribution of global mobile subscribership in

millions indicating a growing trend – the highest recorded was in 2019. (Data from [statistica.com](#), [world bank](#) [13, 14])

the benefit of low- to middle-income countries. Multiple governments have expressed their interest in helping to strengthen health systems in line with the Millennium Development Goals [15]:

“... R.D Gardi Medical College carried out a year-long research project that focused on how the use of mobile can benefit reporting on childbirth within

the province. The research covered the population of 1.9 million in the entire district of Ujjain in India.” He continued: “Through the use of mobile, we were able to collect information from 1,800 village works or community members from 152 villages. We relied on them to report their own information, but the use of mobile technology meant that our researchers were able to follow up and verify this information the next day.”

Vishal employed a call center and invited community members to call in to report a new childbirth event. This had a 68% response rate and also revealed that 20,000 prescriptions were taken over 6 months from 9 districts. Vishal added: "There are over 500 unqualified medical providers working in the province. The mobile technology meant we were able to contact the majority of these practitioners to make use of their reporting on child births in the province." Vishal is of the opinion that using mobile technology to conduct research in low- or middle-income countries is highly beneficial and will continue to use this form of reporting.

Above is an intriguing example where mHealth was used to make an impact in this rural India case study reported in the *British Medical Journal* [16, 17].

AI and mHealth in Various Medical Specialties

This section explores the use of mHealth and smartphone applications in various medical specialties, highlighting where they have been used to facilitate patient and clinician education as well as the effective diagnosis and/or treatment of various conditions. We present some of the evidence, where available, for the use of AI and suggest where other artificial intelligence systems could be effective in augmenting mHealth solutions presented in these areas. While the majority have been focused on model development, we suggest, where possible, how some of these AI agent-based models can be extended into mobile apps to support mHealth.

AI and mHealth for Evidence-Based Medicine

The scientific and clinical community are always looking for high-quality, evidenced-based research methods leading to high degrees of evidence-based care. Hierarchically, this includes:

- Systematic reviews and meta-analyses of randomized controlled trials (RCT)
- RCTs with definitive results with non-overlapping confidence intervals

- RCTs with non-definitive results and a clinically significant effect, but with confidence intervals overlapping the threshold for this effect
- Cohort studies
- Case-control studies
- Cross-sectional surveys
- Case reports

Figure 3 illustrates applications of mHealth and AI at various stages of the evidence-based pyramid for the conduct of systematic reviews and meta-analysis using platforms that enable the conduct of systematic reviews.

All of these evidenced-based approaches, but especially clinical trials and systematic reviews, tend to be both extremely costly and time-consuming to conduct, which remain some of the greatest obstacles for the conventional research methodology. Twenty-first-century developments support a clear need to employ novel mHealth systems to address research questions through judicious use of artificial intelligence. This is especially true for analysis purposes. There are tools in existence that allow algorithmic keyword PRISMA-guided search methodologies on various databases [18, 19]. The ability for ubiquitous search term standardization across multiple databases developed by Bond University in Australia known as the S-R Accelerator should be performed simultaneously [18, 19]. Other mHealth apps like Rayan now allow for systematic cross-collaborative screening of the searched data and enable consensus to be reached [20]. Other areas for AI augmentation also include randomization methods for randomized controlled trials, which can now be conducted via online systems such as Criteria2Query that leverage natural language processing [21].

On the conduct of systematic reviews on mHealth, a large meta-analysis of mHealth for hospital appointments reported that in 42 trials, there was significant risk of bias in the conduct of trials, but modest benefits for mHealth in healthcare provider intervention support and management outcomes [22].

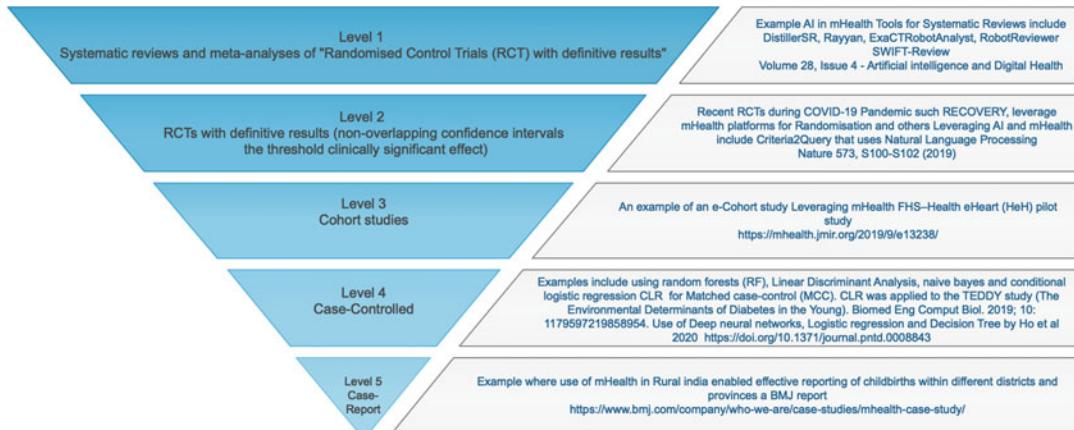

Fig. 3 Evidence-based medicine pyramid. Inverted here to illustrate the weight that each section carries. Examples are provided of how mHealth has made an impact and been used at each of these levels

AI and mHealth in the Field of Genomics

Genomics studies the function of encoded genetic information in the DNA sequences of all organisms. It has seen an explosion of growth in recent years since the entire human genome, containing 20,000 protein coding and 25,000 non-protein coding genes was sequenced in 2001 [23]. Current mHealth platforms enable the identification of specific genetic and epigenetic risk factors, such as copy number variants, to help stratify risks of psychiatric and other diseases. These platforms include the National Cancer Institute's Cancer Genome Atlas project, which has not only developed algorithms for the visualization of large genomic bioinformatic datasets including proteomics and radiomics, but has also developed portals to facilitate data access via mobile devices and tablets [23]. Available structured and labeled datasets for risk stratification and outcome analysis are key and have opened up a whole new world of application programming interface development for mobile phone apps.

Other noteworthy reviews by Leung and colleagues offer a comprehensive overview of machine learning in the field of genomics [24]. They outline that while we have a comprehensive instruction book for the coded make-up of humans, the blueprint of how our genes are organized still remains encoded, which is challenging

in terms of understanding various diseases. Here is where artificial intelligence shines in terms of pattern recognition, latent variable identification, distribution analysis and feature engineering, etc.

Genomics is now allowing ancestral linkage mapping on a global scale, with companies like 23 and Me building business models to capitalize on the genetic mHealth revolution and personalised medicine. The EU General Data Protection Regulation and other ethico-legal considerations and ramifications rightfully limit the extent of how these apps can be used, but they can be developed further under closer regulatory scrutiny to prevent abuse.

AI and mHealth in the Field of Cardiovascular Medicine

In cardiovascular medicine, patients recovering from myocardial infarction require cardiac rehabilitation (CR). CR remains an important evidence-based intervention allowing effective progression to patient recovery following an acute coronary event. Patients receive a structured education and exercise program, which helps to accelerate their recovery time. It also allows lifestyle and behavioral recalibration to reduce the risk of further deterioration in cardiac health. The NHS has approved an mHealth app called the myHeart app, which enables structured

educational and exercise intervention. In one study, 721 participants were placed in one of four groups (class-based CR, class-based CR with mOverallyHeart, home-based CR, and home-based CR with myHeart) [25]. Five hundred and eighty-four patients elected to use class-based CR. Of these, 43 chose to include myHeart to support their rehabilitation [25]. Artificial intelligence can also be applied to support patients looking to augment their lifestyle choices. Recommendation systems constructed from deep neural networks can be integrated to suggest healthy lifestyle alternatives and to widen the choice of food, exercise regimens, and personalized health plans for the patients given the overwhelming amount of available choice [26–29]. In order to achieve a holistic approach, clinicians, dieticians, occupational health specialists, and physiotherapists could be invited to facilitate expert, directed lifestyle interventions on these types of eHealth platforms without the need for face-to-face contact [30].

This could help reduce the patient's risk of recurrent coronary events, reduce their cholesterol levels, and facilitate smoking cessation program e-support, if needed. Chatbots can automate the process, and their integration can facilitate the dissemination of these recommendations to a particular demographic who are at risk of relapse into previous unhealthy habits [31–47].

Another interesting development relates to the release of Apple's iOS 12 with the Apple HealthKit. Their closed ecosystem has some excellent advantages for privacy protection but also allows individuals and medical application developers to build secure permission-enabling apps such as those for heart rhythm analysis. In fact, at the launch, Apple showcased case-studies of individuals who were immediately identified as having acute coronary events and who went on to receive the emergency clinical intervention needed to save their lives. Others reported that AI algorithm-based smartwatch technologies worked well compared to an implantable loop recorder for the detection of atrial fibrillation and will therefore become useful for population mHealth screening [48, 49].

AI and mHealth in the Field of Respiratory Medicine

Chronic obstructive pulmonary disease (COPD) is a common preventable condition and a leading cause of death and disability-adjusted life years. It has considerable physical and psychosocial morbidity affecting around 80,000 people in the UK alone and is a leading cause of hospital admissions [50]. mHealth has also seen significant applications in this field, including educating the public through smoking cessation programs and pulmonary rehabilitation. MyCOPD and others are example of online application support mHealth platforms for patients with COPD receiving education on self-monitoring and self-management [50–52]. MyCOPD offers the capability of implementing and assessing how-to instructional videos with the potential for artificial intelligence chatbot integration to support patients. In their non-inferiority randomized controlled trial of patients aged 40–80 with mild to moderate COPD, comparative outcomes were obtained for online mHealth methods of pulmonary rehabilitation (myCOPD group) against in-person pulmonary rehabilitation. Moreover, the odds of ≥ 1 critical inhaler error was marginally significantly lower in the myCOPD arm (adjusted odds ratio (OR) 0.30 (95% CI 0.09–1.06, $p = 0.061$)). Secondarily, a noticeable increase in the app's usage was linked with a greater CAT score (which measures the recovery rate of symptoms) improvement. The adjusted odds ratio for being in a higher patient activation measurement (PAM) level at 90 days was 1.65 (95% CI 0.46–5.85) in favor of myCOPD. The RESCUE trial also looked at application supported care vs usual standard of care and found superior outcomes with less exacerbations and readmissions than the non-mHealth arms [OR 0.383 (95% CI: 0.074, 1.987; $n = 35$)] [52].

At the time of writing, the 2019 SARS-CoV-2 coronavirus pandemic had curtailed the delivery of face-to-face services with considerable impact on high-risk individuals with COPD. The advantages of mHealth can be noted in its protective role in helping limit and tracking the spread of viruses. mHealth platforms can allow multiple

appointments to be delivered without additional problems with scheduling. Classes could be delivered at the same time to a large number of individuals, whereas in-person scheduling conflicts can affect the delivery of face-to-face sessions. Logistically, a reduction in readmission rates has also been seen with mHealth supporting respiratory conditions such as COPD and asthma [50–52]. Other examples where mHealth was making an impact include Stanford University's 100,000 dataset trained 121-layer convolutional neural network called CheXNet, where an AI platform can diagnose pneumonia based on patient chest radiographs [53]. Other areas such as screening for obstructive sleep apnea have also been studied using artificial intelligence, and apps have also been demonstrated [54].

AI for mHealth for Neuroscience and Neuropsychiatric Disorders

The concept of connectomics looks at the connectivity within the brain from clinical, genomic, physiological, electrophysiological, biochemical, and computational perspectives, uniting these datasets to allow clinicians to manage complex conditions. The Human Connectome and Human Brain projects have utilized platforms to integrate and provide an unparalleled compilation of neural data [55, 56]. The use of AI and mHealth to create an interface to graphically navigate this large dataset providing the tools to derive actionable insights from within the data [56]. It is believed that doing so will facilitate a holistic and semiotic approach to understanding the manifestations and progression of neurological and psychiatric diseases, such as Parkinson's disease, depression, epilepsy, etc.

One area of mHealth with AI augmentation for neuroscience in which machine learning algorithms seem to have been effective was the use of regular expressions in natural language processing to study important risk factors for sudden unexpected death in epilepsy (SUDEP), an important cause of mortality in epilepsy. Barbour et al. identified a gap in how often providers counsel patients about SUDEP and offered the potential

solution of electronically prompting clinicians to provide counseling via automated detection of risk factors in electronic medical records (EMRs) [57]. Apps can be created to support the clinician and in particular the patient by prompting them to be aware of risk factors that could increase the likelihood of SUDEP. An extended review of AI in neuro-electrophysiology is provided with practical aspects in that chapter.

Another example is the smart crisis cross-national comparative study set up to determine whether suicide risks were partly related to sleep quality and poor appetite [58]. This study was conducted by French (University hospital of Nimes) and Spanish (Hospital Fundación Jiménez Díaz Psychiatry Department) institutions in their outpatient population demonstrating the globally diverse use cases for AI and mHealth.

AI in mHealth for Rheumatology

Recently, AI has been receiving increasing interest in the field of rheumatology. Algorithms developed by Versus Arthritis, a UK Charity, and provided to IBM Watson are being used to build an mHealth platform that will support patients to better self-manage their condition [59, 60]. For this mHealth platform, IBM Watson used a collection of algorithms and systems from Versus Arthritis that could learn from over 15,000 pages of unstructured data to develop a chatbot available 24 h a day that can interact with patients from multiple countries who are then directed to relevant and reliable information about rheumatological diseases such as rheumatoid arthritis, etc. Other applications such as symptomate.com utilize chatbots for e-diagnosis [61], whereas the Isabel symptom checker works as a triaging tool and was trained on over 6000 cases [62].

Shiezadeh and colleagues also gathered data from 2500 patients attending an Iranian clinic and used ensemble machine learning and support vector machines to build a rheumatoid arthritis (RA) detector, from which they extracted the 11 most impactful features [63]. They identified these as painful elbow and knee joints, sex, number of affected joints, and erythrocyte sedimentation rate

(ESR) test results. Their best model yielded 85% accuracy and sensitivity/specificity of 44%/74% respectively. A large, highly sensitive, and accurate (92% accuracy, with sensitivity/specificity of 86%/94% respectively) UK-based study with a training set of >15,000 and testing set of >5000 patients from two clinics in Wales used a random forest model to identify eight treatment-related predictors for disease-modifying anti-rheumatoid drugs, prednisolone or methotrexate [64]. Another large-scale early-disease risk assessment study by Chin and colleagues from Taiwan that intended to discover hidden factors enabling clinicians to formalize RA diagnosis was conducted on a dataset of 1000 RA and 500,000 non-RA patients. It used matrix factorization to identify latent risk factors and trained these on a support vector machine in order to identify early-stage RA with sensitivity and specificity of ~74 and ~70%, respectively [65]. Other studies have been done on seronegative arthritides, such as systemic lupus erythematosus, and the prediction of disease progression with mHealth components [66, 67]. The use of mHealth here can extend the identification of at-risk patients with these impactful features and help to optimize therapies for early diagnosis and treatment.

AI in mHealth for Gastroenterology

A recent review showed that about 53 studies have used AI to detect malignant and premalignant intestinal lesions with models ranging from support vector machines, convolutional neural networks, regression, gradient boosting, and Gaussian mixture models [68]. They showed that most ($n = 48$) were focused on endoscopy with a small number extracting features that were mainly demographic, cardiovascular comorbidities, concomitant medication, and digestive symptoms. Another 27 studies were dedicated to improving diagnostic accuracy in cases of colorectal polyps or cancer [68].

The extremely high mortality linked with pancreatic adenocarcinoma means that early detection is paramount for surgery to improve outcomes. Twenty-two studies assessed an AI's potential to help patient identification of liver

and pancreatobiliary disorders [68]. Various studies also tested AI in the detection of pancreatic adenocarcinoma, based on endoscopic ultrasound or markers in serum samples [68, 69]. It was reassuring in some of these studies that patients with pancreatic cancer were identified to a significant degree of accuracy, with an area under the receiver operator characteristics curve of approximately 90%. Future mHealth platforms constructed around the screening of biomarkers and radiomic features can support screening programs for pancreatic conditions.

AI in mHealth for Urology

A PRISMA-guided, Prospero-registered systematic review conducted between 1994 and 2018 reported AI applications in urology including its utilization on ultrasound data for radiomic feature identification to automate cancer detection [70]. It was used to improve outcome prediction and digitize pathological tissue specimen images and for the connectomic combination of patient clinical data with biomarkers gene expression to assist disease diagnosis or outcome prediction. Some studies also applied machine learning methods to plan brachytherapy and radiation treatments, while others used video-based or robotic automated performance metrics to objectively evaluate surgical skill [70, 71]. Compared to conventional statistical analysis, 71.8% of studies concluded that AI is superior in diagnosis and outcome prediction [70]. mHealth extensions include platforms that accelerate the histological diagnosis for the surgeon. In fact, mHealth augmented reality and AI platforms are being leveraged to support the surgeon in robotic procedures to identify locations where tumors and important blood vessels are at risk to improve patient safety during kidney tumor resections [72].

AI in mHealth for Endocrinology

One major international study on patients with diabetes collated a 370 country-year survey with

data on 2.7 million individuals worldwide since 1980 found that the total number of people with diabetes in 2008 was 347 million, more than double the number in 1980 [73]. It also reported that the prevalence of diabetes has risen, or at best remained unchanged, in virtually every part of the world over the last three decades. Type 2 diabetes mellitus (T2DM) remains a global epidemiological challenge affecting both middle- and high-income economies [74]. In a multi-center service evaluation of 83 T2DM patients recruited to use an mHealth app monitored over a 12-week period, 28 chose to use myDiabetes alone, 35 chose only usual care, and 20 chose to use both [75]. During this evaluation, changes in diabetes-related clinical health outcomes such as the patient's HbA1c, blood pressure, and body mass index were monitored. Completed questionnaires highlighting problem areas in diabetes (PAID) were used to evaluate improvement markers in diabetes-related distress. Results showed that the mHealth app was acceptable in this care setting with 31 of 42 patients using it alone or as an adjunct to usual care. Patients using this mHealth app showed the greatest improvement in HbA1c (-7.5 vs -4.4 mmol/mol), systolic blood pressure (-12.2 vs $+3.3$ mmHg), and PAID score (-6.8 vs -5.2). Five hundred and eighty-six educational videos on the app platform were consumed, which accounted for each patient watching 22.5 (SD 19.6) videos. This was reflected in the reduction in PAID scores across all arms, with the app-only arm showing the greatest improvement. Here such an app with the permission could use AI to monitor usage and alert the clinician about diabetes-related distress. Transfer learning of models trained on facial emotions could be leveraged to detect distress in elderly or disabled patients using the app who permit the use of their camera on the app to help detect and alert the clinician or family member to distress.

In the study of thyroid diseases, the cytological features and morphometric analysis sometimes present a challenge to training diagnosticians learning about cytopathology. In this regard, neural networks have also been applied to help improve the diagnosis of fine needle aspiration cytological (FNAC) histological smears. In fact, Savala et al. (2018) applied machine learning to

the morphometric analysis of FNAC [76]. The FNAC smears of histologically proven cases of follicular adenoma ($n = 26$) and follicular carcinoma ($n = 31$) patients were used with a train test ratio of 39:9. The cytological features were analyzed semi-quantitatively by two independent observers, and an ANN model was built to differentiate follicular adenoma from follicular carcinoma. Performance of the ANN model was assessed by analyzing the confusion matrix and receiver operator characteristic curve. Their study reported a 100% diagnostic accuracy or ROC of 1. This system can be incorporated into an mHealth mobile phone application to further support trainees learning about how to diagnose and effectively differentiate two different types of lesions.

AI in mHealth for Dermatology

Esteva and others have proved that the capability of convolutional neural network (CNN) performance was comparable if not superior to most dermatologists in differentiating benign from malignant lesions [77]. Their CNN was trained on a dataset of 129,450 clinical images (including 3374 dermoscopic images); performance was compared to that of 21 board-certified dermatologists regarding melanoma and keratinocytic neoplasm classification using clinical images and melanoma classification using dermoscopic images. In another study by Brinker et al., dermatologists correctly classified skin lesions up to 67.2% (95% confidence interval [CI]: 62.6%–71.7%) and 62.2% (95% CI: 57.6%–66.9%). By contrast, the trained CNN achieved a higher sensitivity of 82.3% (95% CI: 78.3%–85.7%) and a higher specificity of 77.9% (95% CI: 73.8%–81.8%) [78].

Esteva et al. rightly mention an extension for mDiagnostics in the form of a mobile phone app that could facilitate self-diagnostics of a lesion outside the clinic, and this can be achieved by leveraging the smartphone camera. mHealth applications have also been designed to teach the dermatology trainee the latent features within the image that differentiates a benign from a malignant mole (see chapter "AI and Medical Education").

AI in mHealth for Obstetrics and Gynecology and Pediatrics

Obstetrics and gynecology is a highly litigious speciality with the NHS reporting in 2017 and 2018 a sum of £4513.2 million in total indemnity payments (NHS). Forty-eight percent were obstetric-related and 2% were gynecology-related negligence claims, which accounts for 15% of all indemnity payments in NHS litigation [79]. AI and mHealth decision support platforms are useful in terms of improving awareness to patients and clinicians and for risk factor identification. This can help to mitigate the number of litigations.

There is also a considerable psychosocial burden linked to errors in O&G specialties with long-term socioeconomic consequences of adverse events such as hypoxic brain injury and shoulder dystocia-related Erb paralysis, which can lead to significant disability. This is an area of active research investigating algorithms that could support obstetric clinicians with the prediction of conditions like shoulder dystocia [80].

Two studies are discussed here about cardiotocographic monitoring of fetal state [81, 82]. In one study of 2126 recordings, an e-Health platform was built for automated cardiotocographic dataset analysis which was able to differentiate normal and abnormal CTG patterns with a sensitivity of 100% and specificity of 99%. This is the SisPorto 2.0 system which was validated on over 6000 pregnancies [81]. The second leveraged support vector machines, artificial neural networks, convolutional neural networks, recurrent neural networks, and random forests in their machine learning pipeline and reported the MKNet-convolutional neural network to have the most optimal prediction results but difficult to implement [82]. Early warning decision support system application could be designed to warn the obstetrician of a predicted pathological change sequence in the fetal heart rate [81, 82].

Evidence-based personalized pediatric medicine using mHealth such as automated televillages for child health including childhood immunization coverages and in identifying pediatric respiratory disease have been reported [33, 83, 84]. Other applications for mHealth could include non-accidental injury detection mHealth platforms,

which would be of benefit, but run the risk of unintended bias.

AI in mHealth for Consensus Evaluation

Effective training requires communication skills, carefully designed assessments, and the opportunity for purposeful and useful feedback to help safeguard patients against iatrogenic-related and human factor-related error. Dias et al. and Chan et al. have both reviewed and reported on the use of machine learning to assess clinician competency and the challenges associated with implementing this approach [85, 86]. Objective structured clinical examination enables individuals to be assessed on the practical aspects of medicine after they have received training in a specific domain of medical education. The process has always required the presence of a body of responsible individuals who are experts in the field of medical assessments and a standardized approach to the questions being asked, both of which make this a time-consuming and expensive process. One particular disadvantage is that assessors usually have inherent unintentional subjective biases as to what and how they expect performance [87].

Ryan et al. and Butow and Hoque first proposed using machine learning (ML) to improve the evaluation of communication skills [88, 89]. Jani et al. built on this work to use machine learning methods that have now been applied to extract communication and history-taking skills in OSCE transcripts to reduce biased assessment [90]. For example, in their study, Jani and colleagues collated one hundred and twenty-one transcripts of two OSCE clinical scenarios (weight loss [scenario 1] and abdominal pain [scenario 2]) manually annotating each utterance across 19 communication skills and content areas. Combining two types of natural language processing algorithms, Bag of Words and GenSen, utterances were converted to two types of numeric sentence vector representations and trained on a support vector machine, conditional random field, and a bidirectional long short-term memory model. First, these ML models (MLMs) were evaluated using a five K-fold cross-validation technique on all transcripts in a weight loss

scenario to generate precision and recall and their harmonic mean, F1 scores. Second, ML models were trained on all 101 transcripts from scenario one and tested for transferability on 20 scenario two transcripts. A bidirectional LSTM was utilized. Performance analysis with K-fold cross-validation showed high mean F1 scores: median 0.87 across all 19 labels. However, this was significantly higher using a bidirectional LSTM, demonstrating significantly higher performance and transferability score ($P < 0.005$) [90].

Historically, the Delphi method is a process used to arrive at a group opinion or decision by surveying a panel of experts. The experts' responses to several rounds of questionnaires are aggregated and shared with the group after each round. Adjustments are then made to the answer each round, based on how they interpret the "group response" provided to them. The *consensio ultimum* reflects what the group actually agrees. Questionnaires can now be disseminated and results automated using mHealth apps designed for this task.

AI and mHealth in Infectious Diseases

Diseases that are known to impact maternal and child health can benefit from AI augmented mHealth, which is already being applied in maternal and child health. Current programs aim to reduce poverty-linked infectious and transmissible diseases such as HIV/AIDS, malaria, and tuberculosis (TB) in lower- to middle-income countries [91]. Developments by Microsoft using mHealth and AI to track the movement of mosquitoes have also combined robotics and artificial intelligence to manage malaria and dengue fever in tropical endemic regions with these conditions [91]. During the 2019/2020 SARS-CoV-2 viral pandemic, mHealth continued to evolve to become one of the most reliable forms of socially distanced methods of eApps to detect and track infected individuals, e-Healthcare through eClinics, eWardrounds, and other teleHealth methodologies, which could be conducted from a mobile phone. Clinical decisions were happening on platforms like Microsoft Teams and Zoom,

which allowed patients with mobile phones to connect with clinicians from all over the world. This created an effective opportunity for mPlatform data discovery for network companies allowing multiple ecosystems to emerge and flourish that will hopefully support clinical environments during future epidemics.

Summary and the Future of mHealth

As we continue to evolve into *Homo nodi*, the global adoption of technologies like 5G and subsequent 6G–7G technologies together with improvements in computational speedup and quantum efficiency will see the ability to perform higher fidelity simulations and automations through quantum machine learning and artificial intelligence on small form-factor devices like mobile phones and tablets [92]. Imagine exponential data transfer speeds several orders of magnitude greater than 20gbs speeds that will allow quantum computational renderings of molecular structures for various biochemical and pathological processes to be diagnosed at our fingertips. Not only will it be possible to zoom into molecular renderings when studying complex genetic disorders, but federated learning methodologies will also be considerably easier. Cross-collaboration and platform data analytics will allow for seamless integration between medical organizations, government, and health ministries. Data governance and generalized data protection will be the only limitation for cross-border collaboration needing consortia to manage information flow. However, we are continually seeing the blurring between borders for medical informatics with systems like EPIC and CERNER systems allowing for mobile app integration and accessibility, leading the charge and ensuring seamless data access and electronic health record management across organizations.

Have we reached *Homo Digitalis* status and will we see a blending of human with artificial intelligences? Well it no longer seems a distant future, given the fact that devices are now available that can digitally monitor internal processes and manage diseases. An example of this is the US

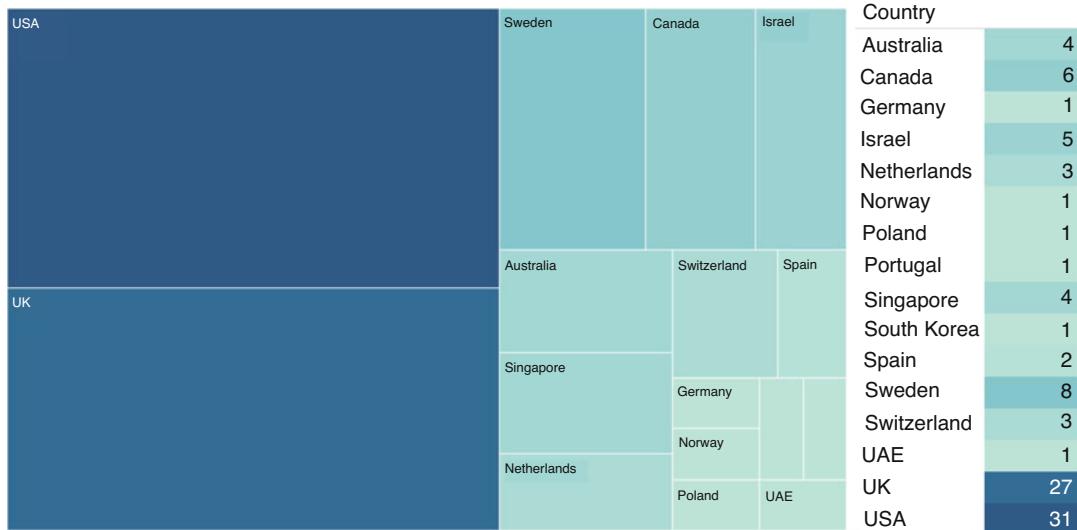

Fig. 4 A sampled distribution of mHealth and AI companies, pooled data from the 2020 Global Digital Health 100 summit illustrating relative contributions within this

FDA-approved Eversense smart fluorescent sub-dermally implantable sensor (made by Senseonics Inc.) that is capable of continuously monitoring blood glucose levels in diabetic patients and forwarding this information to companion smartphone and wearable devices, which can in turn alert the patient if their blood glucose level is too high or too low [93]. mHealth and AI may in the future also facilitate our eventual evolution into *Homo Deus* paving the way to the optimal health we seek [94].

For completeness Fig. 4 summarizes the global distribution of 98 companies making significant progress within the mHealth, eHealth, smartphone, and apps for medicine space. The future for mHealth and AI in medicine is very bright.

space in the developed world. A tableau dashboard presents a non-exhaustive list of companies in the mHealth and AI space based in the UK and abroad [95]

Abstract

Alternative medicine (AM) is one of the medical fields that use more natural and traditional therapies for disease diagnosis and treatment, in which traditional Chinese medicine (TCM) now has been recognized as one of the main approaches of AM. As a clinical and evidence-driven discipline with long histories, AM is also heavily relied on in the utilization of big healthcare and therapeutic data for improving

the capability of diagnosis and treatment. In particular, artificial intelligence (AI) has been widely adopted in AM to deliver more practical and feasible intelligent solutions for clinical operations since 1970s. This chapter summarizes the main approaches, related typical applications, and future directions of AI in AM to give related researchers a brief useful reference. We find that although AM has not been widely used in clinical practice internationally, the AI studies showed abundant experiences and technique trials in expert system, machine learning, data mining, knowledge graph, and deep learning. In addition, various types of data, such as bibliographic literatures, electronic medical records, and images were used in the related AI tasks and studies. Furthermore, during this COVID-19 pandemic era, we have witnessed the clinical effectiveness of TCM for COVID-19 treatment, which

Zixin Shu, Ting Jia, Haoyu Tian, Dengying Yan and Yuxia Yang contributed equally with all other contributors.

Artificial intelligence · Machine learning · Knowledge engineering · Alternative medicine · Traditional Chinese medicine · Clinical therapy · Clinical diagnosis · Network pharmacology · Syndrome · Complementary and alternative medicine

Introduction

Alternative medicine (AM) or complementary and alternative medicine (CAM) is the field for medical products and practices that are not part of mainstream biomedical care [1]. Actually, before the establishment of modern biomedical science in the eighteenth century, the current therapies (e.g., herbal prescriptions) used in AM were the mainstream approaches for healthcare management. People now may use the term “natural,” “holistic,” “home remedy,” or “Eastern Medicine” to refer to AM. However, experts often use five regular related categories to describe it, which are mainly related to treatment or therapies: mind-body therapies (e.g., meditation, hypnosis, and yoga), biologically based practices (e.g., vitamins and dietary supplements, herbs, and special food), manipulative and body-based practices (e.g., massage, chiropractic therapy), biofield therapy (e.g., reiki and therapeutic touch), and whole medical systems (e.g., Ayurvedic medicine, traditional Chinese medicine (TCM), and homeopathy) [2, 3]. AM is used along with standard medical treatment but is not considered by itself to be standard treatment, for example using acupuncture to help lessen some side effects of cancer treatment or a special diet to treat cancer instead of cancer drugs that are prescribed by oncologists [4, 5].

From 2014, the National Cancer Institute (NCI) and the National Centre for Complementary and

Integrative Health (NCCIH) have been sponsoring or cosponsoring clinical trials that test AM treatments and therapies in people, which include 65 related cancer AM trials (<https://www.cancer.gov/about-cancer/treatment/clinical-trials/cam-procedures>). Evidence suggests that several herbal medicines and dietary supplements can alleviate the side effects of cancer treatments, such as nausea, pain, and fatigue [6]. In addition, TCM has been increasingly adopted as a complementary medical therapy for various kinds of diseases, such as cancer [7], rheumatoid arthritis [8, 9], migraine, and functional disorders [10]. As of 2015, there were 3966 TCM hospitals and 45,528 TCM clinics across China (<https://www.who.int/westernpacific/health-topics/traditional-complementary-and-integrative-medicine>). In this COVID-19 pandemic, as a typical effective solution for virus-related infections, TCM plays a significant role in the relative low mortality rate of COVID-19 inpatients amid the situation of heavy healthcare overload during early days in Feb–Apr 2020 [11]. For example, a recent retrospective cohort study had shown the clinical effectiveness of add-on herbal prescriptions for COVID-19 patients, which even largely reduced the mortality of COVID-19 severe inpatient cases [12, 13].

Due to the empirical nature of medical science, the discovery and updating of clinical evidence and solutions are heavily relied on in the utilization of various kinds of clinical data. Therefore, biomedical science needs artificial intelligence (AI) essentially to assist the generation of new knowledge and decision-making for clinical operations. Since the early work of medical AI (e.g., MYCIN [14]) in the 1970s, the related AI methodologies in medicine have evolved from production rules to data mining and now to deep learning [15, 16], including AI techniques such as fuzzy expert systems, Bayesian networks, artificial neural networks, and hybrid intelligent systems used in different clinical settings in healthcare. Since the recent ten years, the most popular medical AI techniques have been machine learning and deep learning for clinical diagnosis [17], treatment recommendation [18], and healthcare management [19], which recruit big chunks of investments, owing to their higher social and business values compared with other

fields. The related historical events, trends, and techniques are similar for AM. With the first bunch of work on medical expert systems since the 1970s, now the main AI approaches adopted in AM are data mining and deep learning, with particular applications on decision support system and precision medicine [20, 21].

Methodological Approaches

Data Sources

AI applications in AM are heavily relied on in available data sources. Typically, several types of data sources, such as bibliographic literature, curated structured databases, terminological systems, and clinical databases have significant contributions to the development of AI applications and methods in AM fields. Here we will introduce the information fields of the data sources by taking classic database examples.

First, bibliographic literature, which is published by medical researchers, holds significant knowledge for various medical fields, including AM as one of the subsets. PubMed proposes the largest data collection of bibliographic literature, which is a high valuable data source for AI applications. The bibliographic literature records include the fields title, abstract, full text (partially), Medical Subject Headings (MeSH), and other biometric fields (e.g., authors, publication date, and citations), which deliver a large-scale data source for medical text mining and the curation of subject-specific structured databases (e.g., drug-indication association database).

In the TCM field, a similar bibliographic literature database, the Traditional Chinese Medical Literature Analysis and Retrieval System (TCMLARS), contains more than one million records of traditional Chinese medicine literature since 1949. It is a large-scale traditional Chinese medicine database established by the Institute of Information on TCM of the China Academy of Chinese Medical Sciences, with a corresponding English version [22, 23].

Second, many subject-specific structured databases, such as herbal database, prescription

database, disease database, and pharmacological databases, were curated from textbooks, AM dictionaries, and bibliographic literature database. The content of these databases consists of both structured and text fields. For example, herbal database would contain typical fields such as herbal name, synonyms, indication, herb-related ingredients, and related studies. In recent years, pharmacological databases, such as TCMSP [24], ETCM [25], HERB [26], and SymMap [27], which have herb-related pharmacological information, were curated and proposed as a significant data source for network pharmacological research. For example, SymMap contains 499 herbal medicines and 1717 TCM symptoms derived from the 2015 edition of Chinese Pharmacopoeia and maps TCM symptoms to 961 Western symptoms. At the same time, 5235 diseases associated with these symptoms; 19,595 herbal ingredients; 4302 drug targets; and the correlation between these six types of data were included. SymMap links traditional Chinese medicine and modern medicine from a phenotype to a molecular level, which has been increasingly used for network pharmacological studies.

Third are terminological systems, including controlled vocabularies and medical ontologies, that propose the semantic mappings of medical terms and entities in different data sources. For example, in 2000s, a TCM medical ontology named the unified traditional Chinese medical language system (UTCMLS) was developed, which supports TCM language knowledge storage, concept-based information retrieval, and information integration for bibliographic records [28]. In order to solve the problem of expression difference in TCM terms, a clinical terminology system similar to SNOMED CT was developed to standardize the terms and expressions of clinical TCM concepts, which would be an important terminology database for AI research in TCM [29]. With the formal introduction of the concept of knowledge graph by Google in 2012, the knowledge graph for alternative medicine has been gradually developed. For example, the traditional Chinese medicine language system (TCMLS) semantic network, including 127 semantic types and 58 semantic relations, and knowledge graph of TCM characteristic therapy, including

auricular point therapy, moxibustion therapy, medicinal wine therapy, cupping therapy, and bloodletting therapy, were developed in recent years.

Fourth, clinical case database is one of the most significant data sources for medical knowledge discovery and clinical decision support, which would often not be publicly available, owing to ethnic and privacy issues. For example, in 2010, Zhou et al. [21] developed a clinical data warehouse that incorporates the structured electronic medical record (SEMR) data for medical knowledge discovery and TCM clinical decision support (CDS) and integrates 20,000 TCM inpatient data and 20,000 outpatient data.

Knowledge Engineering Approaches

Knowledge engineering (KE) is one of the substantial techniques of AI [30], which has been developed during the early days of AI's timeline. This type of AI technique also has been adopted as the main approach for AI in medicine to develop a knowledge base and expert system for clinical decision support. It is even important for AI in AM since the AM field involves practical issues related to various terminological representations of medical concepts and rich empirical knowledge from even ancient literature for disease treatment. In the following, we would introduce the main KE techniques adopted in the field of AI in AM.

Expert System

Since 1970s, in AM field, researchers had tried to collect expert knowledge and build knowledge base to simulate the decision process of AM experts. For example, Guan Youbo's computer program for the diagnosis and treatment of liver diseases, the first TCM expert system in China, has played an important role in the development of TCM diagnosis and the treatment decision support system since it came out in 1979 [31]. After that, hundreds of TCM expert systems with rule reasoning and machine learning as the main methods have been developed. The main function of these systems is to support TCM diagnosis, including some general TCM expert system

development tool software, such as GTS (1985) [32], Monkey (1988) [33], YHW-CTMEST (1988) [34], etc. Similarly, in 2014, Nopparakiat et al. developed a rule-based expert consultation system for skin problems, which combines Thai traditional medical knowledge to propose Thai herbal formula and Thai herbal cosmetics for the treatment of skin problems [35].

Ontology and Knowledge Graph

Medical ontology and knowledge graph have been focused by AI researchers since large amount of empirical knowledge from textbooks and ancient literatures is available in AM. Furthermore, due to the various types of data sources and individualized treatment, the terms on diagnosis and treatment are often nonstandardized and diverse [36]. Knowledge representation methods provide a formal semantic approach for traditional medical knowledge, which would help to preserve knowledge in this field and share common understanding among different clinical communities and groups. Therefore, many regions, for example, China, India, Greece, South Korea, Indonesia, Thailand, and the West Africa, have developed their own medical ontologies. The unified traditional Chinese medicine language system (UTCMLS) [28] is a system developed by 16 Chinese medicine universities and hundreds of researchers, which promotes the development of TCM knowledge base through ontology methodology and structure design. The traditional Chinese medicine language system (TCMLS) [37] is an integrated system of Chinese medicine language based on the subject system of traditional Chinese medicine. It covers the subject system of traditional Chinese medicine and the natural and human science vocabularies related to traditional Chinese medicine, such as biology, plant and chemical engineering, etc. On the other hand, the knowledge graph of TCM characteristic therapy systematically integrated the knowledge of TCM characteristic therapy, including auricular point therapy, moxibustion therapy, wine therapy, cupping therapy, and bloodletting therapy [38].

In a study conducted by Raja Mohan and Arumugam, an ontology was developed and inferred for Indian medicinal plants using the

Protégé software [39]. Hyunchul Jang et al. started with medicinal materials to express the relationship between symptoms, disease, and the treatment of patients and constructed an ontology of traditional Korean medicine (TKM) [40]. SysMEDTRAD is a West African traditional medicine management system based on ontoMEDTRAD (an ontology of West African TM associated with a visual approach), which automatically generates iconic recipes of plant-based medicines from the ontology [41].

Machine Learning and Data Mining Approaches

To discover the hidden knowledge and propose automatic clinical decision capabilities for disease management, various kinds of data mining and machine learning methods were used in AI in the AM field, which has mainly received its attention since the 2000s. For well-defined and structured data, besides the traditional methods (e.g., decision tree, Native Bayes, and regression) that were widely used in AI in medicine, typically data mining methods, such as association rule, frequent itemset, and complex network, and machine learning methods, including classification methods (e.g., support vector machine, Bayesian network, multilabel learning, and deep learning) and clustering methods (e.g., latent class model and primary component analysis) were frequently applied in AM diagnosis and treatment analysis tasks. In addition, due to the significant role of electronic medical record for the storing of clinical manifestations and diagnoses of AM clinical procedures, text mining or information extraction has been a rising focus task for AM clinical data analysis. However, in AM field, time series analysis and image processing were relatively less studied due to the lack of data availability.

At the beginning of the twenty-first century, more AI systems incorporating machine learning methods have emerged. For example, the combination of multiple data mining techniques mainly used improved hybrid Bayesian network learning techniques to build a new type of TCM diagnosis self-learning expert system, which has achieved

encouraging results [42]. In order to fully demonstrate Thailand's traditional medical knowledge, a rule-based expert system was researched and developed for skin problem consultation [35], which helped promote Thai traditional medicine. In addition, machine learning algorithm such as support vector machine (SVM) [43], Multiple Asymmetric Partial Least Squares Classifier (MAPLSC) [44], Naive Bayes [45], K-nearest neighbor (KNN) [46], and other methods were used to diagnose the collected clinical images [47–51], especially in the tongue and vein field [50]. Association rule learning in data mining is a frequently used method. This method has been applied to the field of Chinese medicine since 2000 and is still widely used. The most widely used field is the study of the combination regularities of herbal prescriptions. Yao et al. [52] applied association rule analysis technology to conduct exploratory analysis and research on the scientific connotation of Chinese herbal compound compatibility for the treatment of diabetes. Huang et al. [53] used modern statistics and data mining techniques to analyze and excavate acupuncture and moxibustion treatment of insomnia.

Cluster analysis is the use of mathematical methods to study and process the classification of a given object, which reflects the general rule “Things are gathered by clusters, and people are divided by groups” [54] and proposes a significant machine learning approach for AM data analysis. Cluster analysis in the AM field began to develop at the end of the twentieth century. For example, Qi et al. [55] used the fuzzy cluster analysis to study the differences between different species of *Scutellaria baicalensis* Georgi and discussed the reasonable selection of substitutes and obtained satisfactory results. Furthermore, cluster analysis is also widely used in the detection of syndrome groups, symptom clusters, and drug combinations. For example, Wang et al. [56] applied the variable cluster analysis to detect the TCM syndromes of advanced lung cancer. Tang et al. [57] proposed a complex system entropy clustering method for discovering new Chinese medicine prescriptions. Among the clustering methods, the most important one is the latent tree model, which is a particular type of probabilistic graphical

model developed by Zhang et al. [58]. Wang et al. [59] used the latent tree model to analyze the collected kidney deficiency data sets. The established model is consistent with the theory of TCM: latent variables correspond to syndrome factors, and latent clusters correspond to syndrome types. This indicates that the latent tree model is a feasible and reliable method for detecting the underlying syndrome structures in TCM, which might fit for other AM fields as well. Extracting meaningful information and knowledge from free text is an important research topic in the field of machine learning and data mining, and text mining has become one of the most active research branches in the field of data mining in the AM field [23]. For example, using dictionary-based or rule-based machine learning and statistical methods for named entity recognition (NER), Cao et al. [60] developed an ontology-based system for extracting knowledge on TCM drugs and formulations from semi-structured texts.

The application of deep learning also began to sprout in the AM field in 2015. A deep-learning-based multilabel learning framework was used to effectively process the modeling tasks of TCM data [61]. A Graph Convolutional Network was also applied to obtain the TCM meridian prediction model and discover the relationship between herbal compounds and meridians [62]. In particular, deep representation learning was used for text mining tasks (e.g., NER) often with state-of-the-art performance. The addition of deep learning allows NER to be better developed in electronic medical records. Ji et al. [63] proposed a collaborative cooperation of multiple neural-network-model-based approach, which consists of two BiLSTM-CRF models and a convolutional neural network (CNN) model, obtaining the best performance on NER in Chinese electronic medical records on the 2019 China Conference on Knowledge Graph and Semantic Computing. Furthermore, due to the needs of translational bioinformatics approach to connect the clinical discoveries with their underlying biological molecular mechanisms, a complex network approach was used to integrate real-world clinical data and network medicine data sources for detecting the potential novel clinical disease subtypes. A

complex network approach was used to integrate real-world clinical data and network medicine data sources (e.g., phenotype-genotype associations) for detecting the potential novel clinical disease subtypes. For example, Shu et al. [64] used TCM clinical electronic medical records (EMRs) of 6475 liver inpatients to construct a liver disease comorbid network (LDCN) to investigate the significant clinical subtypes of chronic liver diseases.

Compared with other AM fields, it is obvious that the literature published on AI in TCM, in particular herbal therapies or medicine, has the highest proportion. In other therapies, although there is much less work conducted, data analysis and AI methods were already used for more specific clinical solutions, such as massage [65] and Tai Chi. For example, AI systems were tried to help design a Tai Chi robot control system [66]. The use of AI in AM is also reflected in essential oil therapy. Related work in 2015 proposing to use artificial neural networks to predict the antibacterial activity of essential oils has made essential oil therapy more widely used [67]. In traditional Indian medicine, the “Prakriti” method in the Ayurvedic medical system is verified by using a variety of machine learning methods, proving that the clinical methods of Prakriti evaluation are nonempirical and, further, can be recapitulated and formalised through advanced machine learning approaches. Due to poor applicability and difficulty in collecting data samples, and other various reasons, there is few relevant research in other AM fields.

Applications and Related Work

Clinical Diagnosis

AI has been widely used in the clinical diagnosis of AM for a long time. It includes tongue [68], pulse [69], acupuncture [70, 71], herbal medicine [72], etc. The key aspects of application can be listed as follows: feature extraction [73], clinical decision support [74], and image classification [75]. Many diseases are involved in clinical practice, such as angina pectoris [76], lung cancer [77], polycystic ovary syndrome [78], etc.

With the rapid development of AI, the combination of Chinese medicine and AI will provide

assistance for the inheritance and modernization of Chinese medicine. For example, the colors of the tongue and the thickness of the tongue coating can be identified by a KNN-based feature matching method [75] with two steps (i.e., region separation and color recognition). The experiments showed that the proposed method was simple and highly robust and can be applied to tongue characterization effectively. For the objective research of the four diagnosis of TCM, AI technology can quickly complete the collection of various physical signs of the patient's body and give relevant diagnosis suggestions [74, 79]. Related researchers studied the intelligent model of TCM syndrome diagnosis differentiation through a variety of methods. According to 1134 clinical survey data of patients with type 2 diabetes, Li et al. [80] used artificial neural networks (ANN) and fuzzy systems (FS) to establish an adaptive fuzzy inference system model based on dynamic Kohonen networks. The model was used to mine clinical data, based on the basic theories of TCM, to obtain the diagnostic criteria for common syndromes of type 2 diabetes.

In traditional Indian medicine, Aniruddha Joshi et al. [81] described a system of generating pulse waveforms and used various feature detecting methods to show that an arterial pulse contains typical physiological properties. In Korean medicine, Kwang-Baek Kim et al. [82] proposed a self-diagnosis system of Korean traditional medicine based on Korean Standard Causes of Death Disease Classification Index (KCD) and the fuzzy ART/inference method. It can accept symptoms of a user from a certain part of their body where they feel inconvenient. Then five most probable diseases, with their causes and treatments extracted from Korean traditional medicine books, were picked up based on the fuzzy ART algorithm and fuzzy inference engine. It is verified by field experts in Korean traditional medicine knowledgeable in the collection of symptom-disease-treatment relationships and performance evaluation of experiment results.

Besides the above applications, AI has many other applications in AM. With the development of big data, the Internet, and 5G technology, AI will undoubtedly be more widely used in the

medical and health fields in the future [78], providing more help to humans, and its influence will become more extensive and deeper, and even promote changes in the medical models, reshaping the entire medical industry. However, all sciences and technologies are the crystallization of human wisdom, and medical AI is no exception. While making innovations and breakthroughs, it also continuously produces new problems and new difficulties that people have never encountered before; the related challenges, such as ethical issues, human-computer interaction, subject responsibility, etc., are necessary to review and reflect on a new level of understanding.

Clinical Therapies

The application of AI in clinical therapies is mainly reflected in the area of assisting in the decision-making of clinical treatment. At the end of the 1970s, artificial intelligence was introduced into the field of TCM, which provided advanced productive forces for the modernization of TCM, and the expert system of TCM came into being [83]. However, due to the problem of objectification and standardization of the four-diagnosis information, for a long period, the TCM expert system stayed in the stage of assisting clinical diagnosis and preserving the academic thought of old TCM doctors and did not make substantial progress [84]. Until recent years, the TCM expert system has gradually experienced the development process from TCM prescription analysis to clinical decision support and then to prescription recommendation for specific diseases. In 2007, Liu et al. [85] developed the intelligent analysis system of TCM prescription (CPIAS), which was the first attempt to analyze clinical prescriptions and for the first time introduced the quantitative method through the extraction of four-diagnosis information and prescription from TCM medical cases to carry out a series of prescription analysis, and obtain the pattern of syndrome differentiation, but still did not involve clinical decision-making. In 2011, Zhou et al. [21] developed the TCM clinical data warehouse platform for medical knowledge discovery and decision support based on structured electronic medical record (SEMR)

data. This platform has greatly promoted the development of medical knowledge discovery and TCM clinical decision support. Then in 2015, the Clinical Auxiliary Decision-Making System of Traditional Chinese Medicine TCM-CDS came out [86]. The system used agent technology to process clinical thinking artificially and intelligently and used a large number of machine learning algorithms to realize the system's independent decision and constructed an intelligent expert decision system. Subsequently, the TCM prescription intelligent decision-making system for various diseases (e.g., lung cancer [87], hypertension [88]) began to develop gradually, which greatly improved the clinical decision-making capability of TCM.

Traditional Ayurveda medicine has also developed AI-related systems. As early as 1989, the Resource Center for Indian Language Technology Solutions-Malayalam designed and developed an expert system named Prakes, which provided diet advice, daily health advice, and the possibility of disease and preventive measures [89]. In 2013, the Ayurvedic Medical system released a groundbreaking product, AyuSoft [90], an interactive software that provided end-to-end medical solutions based on Ayurveda and helped give health advice. It has a wide range of applications, including disease diagnosis and treatment, diet and lifestyle advice, personal management information systems, and text and analysis reporting tools. Nowadays, the intelligent system research of Ayurvedic medicine is still in development. The establishment of a theoretical model based on clinical treatment practice is still the future development direction of artificial intelligence.

At present, the application of artificial intelligence in the field of acupuncture research is still in its infancy [91]. In 2007, Chi Fai David Lam developed the Chinese acupuncture expert system (CAES) [92], which can provide a list of relevant diagnoses according to the symptoms and signs of patients and corresponding TCM acupuncture treatment suggestions for users. A software and hardware integration system of TCM acupuncture and moxibustion that appeared in 2012 was mainly used to assist doctors in the operation of clinical acupuncture and moxibustion, filling the

clinical needs for acupuncture and moxibustion in China at that time [93].

An intelligent meridian-assisted diagnosis and treatment system named Academician Cheng Shennong was developed in August 2017, which largely promotes AI systems for acupuncture in the trend of AI [94]. In the same year, Acubots (Digital Meridian Intelligent Acupuncture Robot System [95]), an interuniversity scientific innovation team led by researchers from the Nanjing University of Traditional Chinese Medicine in China, was unveiled. In 2019, a robot-controlled acupuncture (RCA) [96] device made the vision of robot-controlled acupuncture now a reality [97]. However, it is still a long way to deliver a practical AI system for the clinical use of acupuncture therapies.

Physical and mental therapies (e.g., meditation and yoga) have been proved to be an effective AM solution for treating a variety of diseases and improving physical and mental quality. In recent years, researchers usually combine mobile applications with psychosomatic therapy to achieve convenient and practical purposes. Collaborative research in the field of psychosomatic therapy and artificial intelligence in the future is still an opportunity and a challenge for scientific research [98]. In 2015, Vijayaragavan et al. developed an app to perform yoga and music therapy on a person by monitoring his electroencephalogram (EEG) readings; as a result, people are now able to relax and restore their peace of mind under stressful conditions [99]. In 2016, researchers developed a neural adaptive virtual reality meditation system named RelaWorld [100] to combine virtual reality with neural feedback. The system used a head-mounted display, which allowed users to float in the virtual world through meditation exercises and measure the user's brain activity in real-time through EEG. The system provided an easy-to-use tool for beginners and even provides added value for experienced meditators. In 2017, Prasanna M [101] introduced an Android app that has been connected to an Internet-of-Things-based (IoT) hardware system that monitored yoga people's blood pressure, heart-beat, and temperature; helped people perform various yoga postures; and helped sense body

responses. This Android-app-based IoT suite also provided yoga guidance to users and was easy to operate and use.

Pharmacological Applications

The typical example of the integration of artificial intelligence and clinical pharmacology is network pharmacology, which is a new cross-discipline based on multidisciplinary methodologies such as system biology, computer science, and multi-pharmacology. Network pharmacology is devoted to elucidating the action mechanism of drugs from the point of view of a biological network. It is an effective approach to discovering the active substances of TCM and revealing the pharmacological mechanism of TCM [102]. In 2007, Hopkins [103] first put forward the concept of network pharmacology, which broke the traditional concept of “one drug, one target, one disease.” Under the inspiration of system biology, it realized that drugs play a role in the treatment of complex diseases through multiple targets and pointed out that research on biological networks rather than single targets will be the direction of the new generation of drug research. In the same year, Li [104] established a biological network framework for TCM research, which was an important basis for the combination of network pharmacology and TCM. Since then, network pharmacology has rapidly become the forefront of drug research [105]. In 2011, to further solve the major problem of the unknown mechanism of TCM, Li put forward the novel concept of “network target” instead of the traditional “single target” paradigm, which became the main framework for TCM network pharmacology [106].

At present, network pharmacology is often used to help discover the underlying mechanisms of drug action and drug repurposing and the biological mechanisms of disease phenotypes in the TCM field, with various kinds of applications for many different herbal prescriptions or herbal ingredients. Here, we take a few examples for demonstration. Yu et al. [107] obtained the chemical composition and action target of TCM compound prescription in the Yinhuang Qingfei capsule through network pharmacological analysis and found eight main targets for the treatment

of chronic bronchitis. Then based on the previous drug-ingredient-target data, the active components acting on chronic bronchitis in the Yinhuang Qingfei capsule were deduced, and the known drugs with a similar structure to the Yinhuang Qingfei capsule were collected for molecular docking test, and then the active components of the drugs were verified. Taking the Liuwei Dihuang Pill as an example, Wang et al. [108] developed a new network pharmacology method to identify potential new indications of classical compound prescription by integrating drug target protein, chemical structure, action mechanism, and disease-related molecular network. It was found that the Liuwei Dihuang Pill also played a therapeutic role in immune system diseases and tumors, which further expanded the scope of application of traditional prescriptions. Ma et al. [109] integrated literature mining methods to construct a molecular network between hypertensive phenotypic genes and symptomatic phenotypic genes of hyperactivity of liver-yang syndrome. They further carried out a cluster analysis to interpret the biological mechanisms of hyperactivity of liver-yang syndrome in hypertensive disease from the genetic level. Network pharmacology has become an important tool for the development of multitarget new drugs, in particular for such diseases without cure drugs. For example, using integrative network pharmacological methods, Fang et al. [110] excavated ten potential traditional Chinese medicines, such as *Ginkgo biloba*, saw-tooth grass, and longyan, which were potentially useful for the treatment of Alzheimer’s disease. At the same time, the network-based methods of AI have also been successfully used for herb-target prediction. For example, Vanunu O et al. proposed the PRIoritizatioN and Complex Elucidation (PRINCE) method [111], which was originally used in disease-gene prediction and then was introduced into TCM target prediction by Yang et al. [112]. In 2019, Wang N et al. [113] presented an Herb-Target Interaction Network (HTINet) approach, a novel network integration pipeline for herb-target prediction mainly relying on symptom-related associations, which further reflected the increasingly prominent advantages of AI in network pharmacology.

AI also provides an alternative approach to the development of new drugs in traditional Ayurveda medicine. Ayurvedic medicine uses extracts from traditional medicinal plants to treat diseases [114]. Using a computational (in silico) approach, Fauzi [115] predicted potential targets for Ayurvedic anticancer compounds, which were obtained from an Indian plant anticancer database, with their chemical structures. The compounds can potentially be developed into potential new drugs.

Biomechanisms of Syndrome

Syndrome is the main type of clinical diagnosis for TCM. Through a comprehensive analysis of clinical information obtained through the four diagnostic TCM procedures, the nature of the disease is revealed and the syndrome type is classified [116]. AI methods have been integrated with system biology as a new route for the investigation of the underlying biological mechanisms of TCM syndrome, which has become a popular research topic.

Studies related to the biological mechanisms of syndrome have been carried out since 1950s and have made a number of significant research achievements [117], for example, the kidney Yang deficiency syndrome [118, 119], blood stasis syndrome, and spleen deficiency syndrome [120], which mainly relied on the related gene expressions and gene polymorphisms of model animals. However, these studies are still restricted by a bottleneck of problems, especially in the difference between an animal model and a human body. In 2004, related integrative text mining and network medicine studies compiled about two and half million disease-relevant PubMed citations and 1,479,630 human-gene-relevant PubMed citations in a local database. Bootstrapping techniques were used to extract Chinese disease names from the literature, and term cooccurrence was used to extract the relationships. Finally, 200,000 syndrome-gene relations were found by related shared diseases on MEDLINE [129], and syndrome-based gene networks were constructed to analyze the functional knowledge of genes from a syndrome perspective [130]. Since the publication of the classic work on disease omics in 2007

[121], network medical research on the analysis of disease mechanism by molecular interaction networks at various levels has become a hot topic [122]. Therefore, the research on the biological basis of syndrome from the perspective of molecular network has become a hot direction. The typical studies include the work from Li's group on cold and heat syndrome in 2007 [123, 124]. Furthermore, through the clinical detection of typical patients with cold and heat syndrome of gastritis, it is found that patients with cold and heat syndrome have the characteristics of imbalance of energy metabolism-immune regulation network, and the key nodes of the network can be used as potential biomarkers of cold and heat syndrome [125]. In addition, there are many studies of syndromes related to chronic diseases (such as type 2 diabetes and Qi-Yin deficiency syndrome [126], chronic kidney disease and blood stasis syndrome [127], asthma, and heat syndrome [128]). Several researchers in the field of TCM have further proposed new research ideas, such as syndrome omics [131], syndrome system biology, and network syndrome science [132, 133] to investigate the biological mechanisms of syndrome. To address the bottleneck of genetic associations of syndrome, Yang et al. curated a benchmark data set of 18,270 symptom-gene associations between 505 symptoms and 4549 genes and developed a deep-learning-based symptom candidate gene prediction algorithm [134], which have the potential to promote investigations of the molecular mechanisms of symptoms and thus provide candidate genes of syndrome (through syndrome-symptom connection) for validation in experimental settings. Obviously, the use of data mining techniques and bioinformatics approaches, the biological basis of TCM syndrome and symptom, would be further clarified in the future.

Shortcomings and Future Directions

Although AI has been used in AM to solve many practical medical problems, there still exist some obvious shortcomings compared with those of AI in modern biomedicine. Here we list several main aspects.

First, lack of high-quality data sets and shared terminological systems—although the application of AM becomes even wider to new arenas, such as telemedicine, mobile medicine, and Internet medicine [135], there is currently no substantial data sets for automatic diagnosis and treatment. Furthermore, terminological systems and ontologies that shared in the fields to help address the issues of semantic interchanges and communications are rare, which would make it difficult to accurately represent the data derived from various real-world clinical sources [23], especially in terms of symptom terminology, which traditional medicine is concerned about. For example, some patients have the sign of “limb pain,” while others have the sign of “lower limb pain.” It is clear that the information of “limb pain” covers the information of “lower limb pain” [136]. Thus, it is impossible to collect high-quality structured data if comprehensive standard clinical terminologies are not available. And more importantly, there is still lack of a knowledge graph that combines with AM and modern medicine, though the link between basic medical research and clinical treatment is crucial to the development of AM.

Second, lack of a comprehensive decision support system—although there are a number of mature systems for diagnosis prediction and prescription recommendation [71, 72], it is difficult to claim precision when it comes to personalized medicine. In fact, more and more populations actually use or are interested in AM services, such as people from South Korea, Australia (in 2005, a survey suggested that 68.9% of participants used at least one of the 17 forms of complementary medicine, <https://www.who.int/westernpacific/health-topics/traditional-complementary-and-integrative-medicine>), and the United Kingdom [137]. Herbalism, aromatherapy, homoeopathy, acupuncture, massage, and reflexology are among the most popular. However, as they become more popular, debates over the efficacy of AM have been highly polarized. Some indicate that modern medicine therapy is mostly practiced by medically trained doctors. It is not the same with AM as, for example, yoga and massage are mostly performed by patients at home [138]. Currently, information on the effectiveness of treatment is

often absent in most real-world TCM clinical data [136]. Therefore, most related TCM clinical data mining tasks only generate empirical regularities with no constraints on clinical effectiveness. This means that it is difficult to judge which discovered regularities and decision support are effective for disease treatment, in particular individualized sequential treatment decision policies.

Third, lack of substantial AI applications in AM research other than TCM—compared with TCM, there is much less research on other AM therapies (e.g., mind-body therapies), most of which focus on the treatment and safety aspect [139]. For example, a massage therapy for musculoskeletal pain can be very relaxing to the mind and relieve psychological distress [140]; mind and body practices may be of benefit in reducing stress; and hypnosis has consistently shown to have a clinically significant effect on reducing hot flashes [140]. A large amount of higher quality studies hope to determine efficacy and safety among all reviewed AM interventions for symptoms [3]. However, with the availability of large-scale big healthcare data, AM needs to give full play to the advantages that would better serve patients and society through the use of AI technology. The future direction of AI research requires multidisciplinary collaboration between different professionals, researchers, and scientists, as well as collaborative clinical practice with expertise from biomedical, bioinformatics and pharmaceutical disciplines.

Conclusion

The curation of big data makes AI technology and AM fields much closer and their development more closely interconnected in multiple clinical applications, such as intelligent diagnosis, treatment recommendation, drug discovery, and biological mechanisms of syndrome. Besides of the ontology and knowledge graph development, related AI methodologies in AM fields have transferred from production rules to data mining and now to deep learning, including applications for EMR information extraction, image-based clinical diagnosis, and integrative mining of both

clinical and biological data. Alternative medicine proposes a typical personalized medicine solution for chronic disease management, which involves various types of individualized data and biomedical research data. Many substantial challenges (e.g., data privacy, high-quality clinical data, large-scale knowledge graph, human-machine interaction) should be addressed or developed to improve the usability and actual benefits for AM practitioners. However, the large-scale real-world AM clinical practice with essential effectiveness provides a promising future and arena for both the application and research of AI in AM field to promote AM practice from empirical experiences to evidence-based personalized medicine.

Abstract

While the survival rate for cancer patients has improved from 49% in 1970 to 70% in 2020, much of this progress has been attributed to improvements in and focus on early detection. With numerous advances in cancer therapy – from leveraging genomics to immunology – the overall consensus on progress has been underwhelming. With the limited availability of cancer care specialists – even for well-resourced and high-income countries – Artificial Intelligence (AI) has the potential to fill this void and accelerate development of diagnostic and treatment options, formulation of

therapeutic plans, delivery of the treatment, monitoring, and surveillance. We describe how artificial intelligence techniques – especially machine learning – can be applied to clinical data from radiology, pathology, and electronic health records to supplement – and often optimize and automate – clinical decision making.

Introduction

English mathematician Charles Babbage conceived the idea of a steam-driven “Analytical Engine” in 1822 for computing tables of numbers.

This rudimentary machine was arguably the first one to demonstrate that machines can reliably follow, interpret, and apply logic. The question of whether machines can go beyond logic and enter the realm of “thinking” was initially conceived by Alan Turing in his seminal paper “Computing Machinery and Intelligence,” published in *Mind*, October 1950 [1]. The affirmative tone of the paper was popular and positively adopted by the wider academia. This led to substantial overselling of its practical potential that was not in sync with the available computing power of the day. Thereafter, artificial intelligence (AI)-related research entered the so-called AI winter [2]. However, the first two decades of the twenty-first century have witnessed an exponential rise of AI-powered technologies – often owing to multiple factors, such as availability of big data, cloud computing, advances in machine learning, increased investment, and immense interest from industry [3].

Application of AI to problems of health care are of particular interest because of inadequate manpower, disparate training, lack of specialists, resource crunch, and diagnostic and therapeutic errors [4]. Currently, role of AI is being explored for diagnostics (in specialties such as radiology, histology, and dermatology), therapeutics (including personalized medicine and surgical planning), rehabilitation (monitoring, biofeedback), prognostication, and research. Within the healthcare setting, it appears that oncological practice is uniquely poised to benefit from advances in AI. Global population is aging – an important contributor to increased cancer incidence. Oncological care is nearly always multidisciplinary with significant collaboration among various interrelated medical specialties. Adding to this issue is a projected shortage of cancer care providers in the immediate future, even for well-resourced and high-income countries [5]. AI can mitigate the impact of these changes by assisting clinicians in making better decisions, share workload, prevent burnout, and eventually improve patient outcomes. With this in mind, we will briefly introduce the tools for AI, current status of AI in oncology, future directions, and possible limitations.

AI Tools

The central theme of AI is to enable technologies or devices to perform tasks that normally require human intellect or capability. AI approach employs complex mathematical modeling and computer science to approximate the function of human neurons [6]. Human intellect is a very sophisticated and evolved system that utilizes the sensory system to gather data and then employ cognition, perception, logic, pattern detection, and linguistics to make sense of it. The end goal is to respond to the environment in a meaningful and beneficial manner. AI seeks to replicate this process by equipping machines with means to ingest data via cameras, sensors, historical clinical data, and give them the ability to continuously learn and refine their response to eventually mimic human understanding and actions. The armament of AI in degrees of increasing complexity is briefly discussed here:

- **Predictive Analytics (PA)** [7]: As the name suggests, PA utilizes current and historical data, data mining, conventional statistics, and machine learning – either alone or in combinations to make predictions about future events. The most well-known and oft-cited example is that of credit scoring. Banking history like payments, loans, consumer data, and current financial standing is used to predict the future likelihood of making credit payments on time. Social media algorithms determining your suggested YouTube videos and news feed on Facebook are other pertinent examples of predictive analytics. In medicine, a patient’s health records and those of a similar population cohort can be used to predict disease and treatment outcomes.
- **Computer Vision (CV)** [8]: Human beings are quite adept at analyzing visuals both still and in motion. CV is a rapidly advancing field that aims to equip computers with a human-like ability to parse through images and videos to make meaningful conclusions and respond to them. The applications range from the humble barcode-based sorting of parcels to automatic cars on the highways. In health care, CV is

- being extensively studied to aid in development of automated means of interpreting radiological scans, histological images, identifying skin lesions, and assessment of provider skills.
- **Natural Language Processing [NLP] [9]:** The fusion of linguistics and computer science to comprehend human speech in both text and spoken form as well as de novo synthesis of speech encompasses the term NLP. It is important to emphasize here that “natural” refers to everyday syntax, emotions, sarcasm, and slang. Ubiquitous virtual assistants like *Siri* and *Alexa* are good examples of how far this field has come. The applications and possibilities in health care are immense. NLP can be used to gather relevant data from patient notes that are already in the electronic health records (EHR), perform scribe duties, and possibly gather information about patient wellbeing. NLP has been used to identify markers of psychiatric symptoms and suicidal ideation in patients [10]. This may also be used to alert the system about provider fatigue and wellbeing.
 - **Machine Learning [11, 12]:** This is a subset of AI that provides computer algorithms the automated ability to improve with experience. The basic algorithm is fed training data, and it learns and improves continuously with subsequent data sets. This is especially important for complicated tasks where it is virtually impossible to code for the algorithms as innumerable possibilities exist. It makes more sense to let the machine decipher patterns, learn on their own, and refine the algorithm. The earliest examples of machine learning can be found in web-based search engines, spam filters for emails, online fraud detection, etc. ML in health care is all encompassing and can provide the structure for all the tools discussed previously (PA, CV, NLP)
 - **Artificial Neural Networks and Deep Learning [ANN and DL] [13]:** ANNs are computational systems that aim to mimic the neuronal circuitry and decision making of the animal or human brain. Just like numerous layers of neurons in the brain, ANNs have layers of nodes. Each layer extricates relevant variables from

the input data and passes it on to the next level usually in increasing orders of complexity. The variables may be weighted and passed on only when they reach a certain threshold. After passing through multiple layers, the ANNs can identify hidden and abstract information and present a meaningful output. ANNs with enough depth and layers of complexity are termed as DL networks.

Cancer Detection

Probably the most exciting avenue for AI in health care is cancer detection. Early recognition of a possibly neoplastic process is usually the number one determinant of positive long-term outcome. There is significant disparity at the provider and institution level in the ability to recognize cancer early. Diagnosis of a neoplastic process is achieved either by radiological imaging, histology, genomics, metabolites, biomarkers, and their various combinations. AI can help cancer detection by analyzing radiographic, clinical and histological images, EHR data or even by discerning hitherto unknown patterns from the vast repository of medical data that is available digitally. AI for cancer detection can be leveraged both at the screening level and the expert level to augment existing health infrastructure.

- **AI for Image analysis:** Cancer detection and follow up can be performed on three major imaging subtypes (clinical, radiological, and histological). A brief introduction and relevant limitations are discussed below.
 1. **Radiological images [14]:** The use of data characterization algorithms to extract features from radiological images is termed as radiomics. Radiological images generated by magnetic resonance imaging (MRI), computed tomography (CT), positron emission tomography (PET), and ultrasonography (US) have all been used to extract radiomic features to diagnose or prognosticate in oncology [15]. Radiomics has clearly defined steps of image acquisition and preprocessing, tumor segmentation,

feature extraction, knowledge discovery, and modeling [16]. Unlike skin images, the advantage of radiomics is that even though there is variability due to image acquisition methods, the differences are mostly concrete and accounted for. Possible variables for CT (scanner, voxel, kernel), MRI (field strength, manufacturer, protocol), and PET (grid size, iterations, breathing artifacts) images have been previously described and their mitigators suggested [17–20]. Attempts to standardize data due to differences in scanner type, institutional protocols, and radiomics software used have been made at the pre-processing level [21]. After preprocessing, the next step is segmentation, that is, separation or marking the tumor that is termed “volume of interest.” This process can be manual, semi-automatic, or automatic. The non-geometric nature of the tumors, time constraints, and interoperator variability are leading the field toward automation for this step [21, 22]. Feature extraction is the core of radiomics and is achieved manually (semantic or non-semantic) and by DL methods, for example, the question of whether a lymph node harbors malignancy may use semantic features (shape, border), non-semantic (signal intensity, uniformity), and DL (convolutional features). DL features are superior to manual features as they also incorporate the clinical outcomes rather than just descriptive nature of manual features [16]. The last phase of knowledge discovery and modeling phase refers to choosing the relevant features (avoiding redundancy) and constructing a predictive model based on it. Models can be trained in supervised, semi-supervised, or unsupervised learning modes. Finally, the model that has been developed needs to be validated, preferably on an external cohort of images. At present even though multiple proof-of-concept studies have been performed, the data is usually from a single institution. This raises questions about reproducibility, generalization, and bias in

ML outputs [23]. Future studies will need to incorporate standardized protocols and may be assessed using the recently proposed radiomics quality score (RQS) [24].

2. **Clinical images** [25]: For the most part, these are limited to dermatological applications of AI. Much work has been done at the proof-of-concept level to leverage AI for differentiating benign versus malignant skin lesions, gradation of ulcers, and inflammatory skin conditions. In one of the landmark studies, Esteva et al. used Google Inception v3 convolutional neural network (CNN) architecture pretrained on the ImageNet dataset and fine-tuned on their own dataset to classify malignant melanomas versus benign nevi. They compared the performance of 21 board-certified dermatologists to their deep CNN and found that AI could classify the lesion at a level comparable to the dermatologists with area under the curves (AUC) a remarkable 0.94–0.96 [26]. Multiple other studies have shown similar promising results [27, 28]. While much of the research is focused on melanoma detection, there have been successful attempts at differentiating premalignant vs benign vs keratinocyte carcinomas as well [29, 30]. These results remain true both for direct clinical images and those at the dermoscopic level. Due to burgeoning interest in AI and dermatology there is an annual competition “International Skin Imaging Collaboration International Symposium on Biomedical Imaging challenge” [25]. The results so far have repeatedly demonstrated that AI can improve diagnostic accuracy for dermatologists [31, 32].

Dermatological image analysis has also been used for wound assessment of diabetic and pressure ulcers [33, 34]. Cancer patients are routinely bedridden for varying lengths of time owing to treatment or the disease itself and are prone to develop pressure ulcers. These tools, provided they gain clinical acceptance, can be valuable in prevention and treatment of these ulcers. AI in dermatology has particularly widespread

implications. With approximately six billion smartphones in play by the end of 2021, mobile-based resources can dramatically expand the diagnostic care to outside of the clinic [26].

However, as with every promising idea there are certain major limitations. The AI models are only as good as the input data. Biases pertaining to age, gender, race, and ethnicity may creep into the algorithms if the input data is lacking diversity [35]. Differences pertaining to race must be factored in the models as disease presentation can be wildly divergent due to difference in skin color. Indeed, Han et al. reported that the performance of DL algorithms can be enhanced if they were trained on multiple ethnic populations [36]. Proper input dataset can help preserve the generalizability of the algorithms. Also, the quality of the images must be standardized, and the lighting, angle, background, pen marking, etc. are all possible confounders [25]. Another possible limitation is the lack of haptic feedback, and inability to elicit clinical signs in the absence of a trained provider. And if we are to look toward a future where smartphones double up as diagnostic dermatology clinics, we need to be cognizant of the fact that the camera quality on the devices may differ. We should be careful that patients from higher socioeconomic strata may have better cameras on their smartphone, and consequently, the performance of AI is also better. This may inadvertently lead AI-based applications to have poorer accuracy in marginalized patient populations that should have been the target of any such innovations [23]. In summary, future work should be standardized, use large and diverse datasets, utilize EHR information, and focus on well-designed prospective controlled trials.

3. **Pathological images** [37]: While the initial focus of AI researchers was skewed toward radiologic images, now an analogous field of pathomics has also come into being. The underlying principles from data acquisition

to modeling are same as previously described in the radiomics section. With the widespread adoption of whole slide imaging, a vast repository of pathological images is generated daily [38]. AI can be used for tissue recognition, diagnosis, and even identifying disease biology. Diagnostically, AI has been shown to be capable of differentiating benign from malignant tissue, grading of cancers, and immunohistochemical analysis [39]. As a representative example, Alphabet Inc. (Google division) researchers developed an ANN that detected breast cancer metastases with an 89% accuracy rate compared to 73% for pathologists [40]. AI can especially be useful for cancers that are notorious for interobserver bias, for example, prostate cancer and its grading (Gleason score) [41]. ANNs have been developed that were able to outperform general pathologists for Gleason grading with an accuracy of 0.70 compared to 0.61 [42]. Demonstration of these and similar capabilities has led to proposals of AI being used as a triage system to improve workflow. On the first pass digital slides could be examined by AI algorithms and they flag potential malignant ones for review by the pathologist. The threshold could be set at a value such that sensitivity is not compromised. Alternately, AI could be used as the second opinion for relatively simple cases [37]. Importantly, most of the currently used AI algorithms use hematoxylin and eosin (H&E) stained sections and no additional preparation is required.

Identification of pathological features that are ordinarily not distinguishable by human eye is another interesting application. Simple H&E stained slides were used to predict SPOP mutation in prostate cancer, similarly BRAF mutations were recognized in melanomas [43, 44]. This has the potential to supplant IHC in the future [37]. Additionally, insights into tumor biology like aggressiveness have also been gleaned from simple H&E slides, for example, in

colorectal carcinoma [45]. Taking all these capabilities into consideration, AI has been shown to consistently perform at or above the level of pathologists for cancer detection [46].

As with other image-based AI applications, there is need for standardization. There is some concern about difference in color tone of the slides at the institutional level due to differing regents, protocols, and slice thickness [47]. The variability in these parameters needs to be minimized to improve AI performance and generalizability. Lastly, composite fields like radiohistomics and histogenomics may be fields of interest in the near future [37].

- **AI Utilizing EHR and Laboratory Data for Cancer Diagnosis**

While image analysis has been the core of cancer diagnosis using AI, it must be acknowledged that newer fronts are opening and deserve attention. AI has been used for cancer diagnosis by allowing it to trawl the vast repository of EHR data and discovering hitherto unknown patterns in it. Information contained in EHR, including patient history and physical examination, in combination with laboratory findings from biomarkers and genomics, have been shown to enable early cancer detection [48–50]. Zheng et al. used self-organizing map (SOM) models to identify metabolic markers that can aid in early diagnosis of renal cell carcinoma. The same model was also efficient in monitoring postoperative recovery [51]. A similar model for detection of bladder cancer has also been proposed [50].

Genetic mutations develop over years or sometimes decades, before eventually manifesting as a cancer phenotype [52]. The last decade has seen genome sequencing cost decrease substantially from USD 50,000 to roughly USD 1,000. This newfound affordability has given rise to the possibility of utilizing genomic data as a screening test or predictive test in high risk patients. Zhou et al. developed a DL system ExPecto that uses genomic data and links mutations with disease prediction [53]. Better understanding

and validation of these methods can aid in timely diagnosis.

Cancer Treatment

The passing of the US National Cancer Act in 1971 is regarded as a major springboard in the fight against cancer. The 5-year survival rate for cancer patients has gone up from 49% in 1970 to 70% in 2020. However, most of this progress is attributable to improvements and focus on early detection [54]. While there have been numerous pathbreaking advances in cancer treatment, for example, leveraging genomics and immunology, the consensus is that the overall progress has been underwhelming [55]. AI has the potential to fill this void and accelerate development of treatment options, formulation of treatment plans, delivery of the actual treatment, monitoring, and surveillance [56, 57]. Here, we briefly discuss the current status and future direction of AI in cancer treatment.

- **Clinical Decision making** – Somashekhar et al. compared AI generated (IBM Watson) recommendations with tumor boards and found 93% concordance for breast cancer [58]. Even more significantly, in a prospective series of 1000 cases clinicians changed their decision in 14% of cases after AI suggested solutions were presented [59]. The changes were made because AI identified newer treatment options (55%), better personalized alternative (30%), and genotypic/phenotypic data or evolving clinical experience (15%). The authors have suggested that AI will be an import complement rather than replacement of traditional decision-making apparatus. The pace of literature that is generated for oncology and allied fields is increasing every year. The proportion of cancer-related entries in PubMed has risen from 6% of all entries in 1950 to 16% in 2016 [60]. And with 200,000 cancer-related articles published in 2019 alone, it is safe to say that available human resources are inadequate to keep track of it [47]. AI can tap into this data and help truly herald the age of precision

medicine. As an example, let us take a patient with metastatic gastric carcinoma who has exhausted treatment options. A newly discovered mutation that is responsive to a known drug is identified and matched with the mutation present in this patient by AI in real time. Then this patient is immediately offered this drug or given the option of an appropriate clinical trial. This contrasts with percolation of information from article to average provider that can take anywhere between months to total ignorance. This is a lag that the patient cannot afford. The role of AI in genomics itself is also well defined [61]. Patel et al. showed that AI-based systems outperformed manual systems in identifying genomic variations of clinical significance [62]. These may be used to populate existing databases like Catalogue of Somatic Mutations in Cancer (COSMIC) that is presently curated by scientists. This registry links mutations with cancer development, drug response, and drug resistance [63].

AI has the potential to guide chemotherapy both in terms of choice and dosage. AI models have been shown to predict the sensitivity and resistance of tumors to chemotherapy [64]. CURATE.AI, an AI platform, was used by researchers in Singapore to guide the dosage of combination chemotherapy for metastatic castration resistant prostate carcinoma. There was enhanced efficacy and safety when dose modulations suggested by CURATE.AI were used [65]. Similar systems that are geared toward immunotherapy for cancer (e.g., programmed cell death protein-1) inhibitors have also been evaluated [66]. Lastly, AI systems also have the potential to prevent overtreatment by accurately identifying low-risk lesions, for example, in breast or cervix [67, 68].

- **Role in Surgery:** The interaction of AI and surgery can be broadly separated into preoperative, operative, and postoperative components [69]. AI-based accurate risk scoring systems may be developed that combine population, patient, surgeon, and institutional data with disease characteristics to provide an estimate of likely surgical outcome. During the preoperative phase, AI can be used for surgical

planning by using EHR data and imaging. Promising results have been reported in construction of realistic virtual or 3D models for defining surgical planes in complicated cases [70]. During the surgery itself, physiological data from various sensors monitor analyzed by AI can give real-time feedback on patient status. Lundberg et al. developed an explainable ML algorithm to predict hypoxemia in surgical patients in real time [71]. Similarly, variables associated with surgeon's performance such as distraction and cognitive load with possible implications on patient safety can be monitored using electroencephalography (EEG) [72].

Minimally invasive surgery (MIS) lends itself very well to computer vision alerting the surgeon about danger zones and minimizing errors. AI can also aid in better 3D visualization, environment mapping, and augmented reality based visual guidance during MIS [73]. There has been a rapid shift toward adoption of robotic surgery from just 2% in 2012 to 15% in 2018 for common surgical procedures [74]. This has also spurred interest in automation of surgery. Shademan et al. demonstrated superiority of a robot (Smart Tissue Autonomous Robot) compared to surgeons for *in vivo* porcine intestinal anastomosis [75]. These advances may eventually lead to supervised autonomy for robots for removing tumors especially in routine and uncomplicated cases. AI has also shown promise in the post-operative setting by outperforming clinician judgment in triaging patients for intensive care. Also, prediction of postoperative morbidity like infections has been demonstrated [76, 77]. Surgical care is a major component of cancer care and will inevitably be a beneficiary of AI-related advances in surgery.

- **Role in Radiation Oncology:** Due to heavy reliance on digital data and computer software, radiation oncology is particularly ripe for disruption by AI-based technologies [78]. Clinical decision making can be influenced by AI systems estimating the likelihood of benefit from radiation [79, 80]. After the decision to radiate is made, next step is planning and preparation. One of the most crucial steps is image

segmentation that is performed manually by the radiation oncologist. There is significant interobserver bias in this process and may result in over or under radiation [81]. AI algorithms have been developed that perform this segmentation task with accuracy rivaling experts in select cancers [82, 83]. Successful AI-based delineation of adjacent sensitive structures especially in the head and neck, mediastinal, and abdominal region has been demonstrated [84, 85]. AI algorithms have also shown promise in accelerating the process of dose calculation and optimal radiation distribution [86, 87]. During the treatment itself, application of AI to minimize effect of motion and adapt to changes in anatomy have been studied [88, 89]. Finally, the effectiveness of treatment delivered and complication prediction including mucositis, dysphagia, and rectal toxicity have also been examined with promising results [90–92]. Despite the potential benefits, external validation of the proof of concept studies remains the biggest challenge for AI in radiation oncology.

Conclusion

Overall, AI is poised to disrupt the entire cancer care cycle. Much of the progress will depend on developing innovative frameworks that enable optimization of care delivery [35]. With better – and diverse – training datasets, improving ML techniques, and greater intellectual investment from the academic oncology community, it is entirely possible to enhance the current state – and capacity – of cancer care. Technological innovation in the artificial intelligence developers' community will not stop – the question is how willing the medical community is on integrating these innovations into routine cancer care.

Abstract

Artificial intelligence (AI) is the intelligence of a machine to perform a task. To date, with the rapid advances of machine learning algorithm, big data analytics, cloud computing, and mobile network, AI has been studied and used in radiotherapy and patient care. AI and machine learning contribute to the automation,

process enhancement, decision-making, effective resource allocation, and medical education in different aspects of radiotherapy. These, not least, include automations in the radiation treatment planning regarding auto-contouring, auto-beam setup, and prediction of dose distribution; plan evaluation and quality assurance (QA) using big data cloud and machine learning; radiation dose delivery using AI-assisted leaf-sequencing for the multileaf collimator; and chatbot for patient care and radiotherapy education. In this chapter, we review the background and basic concept of AI and machine learning, and how to implement this digital tool to automate the radiotherapy chain. We explore some recent ideas and results on the applications of AI and machine learning such as treatment planning and QA, radiation dose

delivery, and chatbot. We also discuss potential challenges related to the implementation of AI in radiotherapy and its future prospective.

Introduction

Artificial intelligence (AI) is an attractive topic. Just imagine a machine having human intelligence to complete a task. With rapid computer advances of high-performance computing, big data analytics, and machine learning algorithms in medicine [1–3], applying this digital tool in radiation treatment [4] is the way to go. Radiotherapy is a type of cancer treatment using ionizing radiations such as photon, electron, and proton beams. The therapy consists of a chain of processes including disease diagnosis and dose prescription, treatment simulation, treatment planning, plan evaluation and quality assurance (QA), beam delivery, and patient follow-up. Since most processes involve computer medical image processing, calculation, and hardware control, AI and machine learning are used in the radiotherapy chain. To date, some AI and machine learning systems have been proposed, studied, and developed to automate the treatment process, enhance the resource allocation, and increase the accuracy and speed of decision-making in radiotherapy [4–6]. The AI system facilitates the radiotherapy process, making the radiation dose delivery more accurate and precise. In this chapter, we will explore some recent results in the application of AI and machine learning in radiotherapy, focusing particularly on the treatment planning, plan evaluation and QA, dose delivery, and patient education and care.

The aim of radiotherapy is to reduce the size of tumor and kill the cancer cell. This can be helped by a radiation treatment plan aiming at maximizing the tumor target dose coverage, while sparing the normal tissues or organs-at-risk. Therefore,

highlighting or contouring the target (tumor) and organs-at-risk from the patient's anatomy three-dimensionally based on the medical image set is important. In this chapter, we will review the progress of using AI to assist auto-contouring of target and critical organs in treatment planning. Results of how machine learning can improve the accuracy and speed of contouring in the treatment planning system will be discussed. For the calculation of dose in the irradiated volume of patient in a treatment plan, AI can help to predict the dose distribution according to the previous results, provided that the radiation beam geometry and treatment site are similar. Through machine training, accurate dose distribution for a treatment plan can be predicted quickly without performing dose calculation.

Taking advantage of high-performance and parallel computing, hundreds of treatment plans can be created within minutes using a treatment planning system. These plans contain different dose-volume information of the target and organs-at-risk, radiobiological variables, beam parameters such as type, energy, field size, and angle, and delivery techniques such as intensity modulated radiotherapy and volumetric modulated arc therapy. Justifying the best plan for the patient in the treatment requires expertise and experience of the treatment team of radiation oncologist, medical physicist, and radiotherapist. Using AI and machine learning, the dose distribution index (DDI) showing important dose distribution information in the treatment plan can be predicted rather than calculated [7, 8]. From the predicted DDI, the quality of a treatment plan regarding the target coverage and organs-at-risk sparing can be evaluated. We will also explore a comprehensive AI-assisted QA system supported by Internet-of-things (IoT) [9].

Intensity modulated radiotherapy is a popular and advanced radiation dose delivery method using multileaf collimator attached to the head of a medical linear accelerator. The multileaf collimator contains individual “leaves” which are able to move independently in and out of the path of the radiation beam. The intensity of the beam can therefore be modulated by the beam segments generated by the collimator. Generally, the dose coverage of the target can be delivered by a group of beam segments at different angles or around an

arc [10]. The shape of the beam segment can be calculated by a leaf-sequencing algorithm based on a mathematical model. Using AI and machine learning, however, related beam segments can be determined without using traditional mathematical model. This makes the dose delivery process less complicated, faster, and more efficient.

For senior cancer patients who need extra care and support, maintaining good communication is a must for knowledge transfer regarding patient education and care. With the limitation of human resource, a humanlike AI-assisted chatbot would be ideal in this healthcare issue [11]. Chatbot running with natural language processing can understand the need from the cancer patients and direct them to the right path to obtain help [12]. Chatbot can also “talk” to the patient for education in radiotherapy and information acquisition such as doing a survey. Using chatbot for patient communication in radiotherapy can highly reduce resource and increase patient satisfaction. This is because the chatbot is working untiringly 24/7 with user-friendly humanlike manner on all IoT such as tablet, smartphone, and computer.

We will review the basic principle of AI and machine learning, and understand every process in the radiotherapy chain. We will explore recent applications of AI in some processes in the radiotherapy chain. Finally, we will conclude the present progress and foresee the future prospective of AI and machine learning in radiotherapy.

Basic Concept of AI and Machine Learning

AI is generally regarded as a computer system which performs functions that are normally performed by humans and is used to describe a computer or machine which can mimic human learning and problem solving [13]. The modern idea of AI was initialized by people attempting to investigate the process of human thinking as the mechanical manipulation of symbols. Still, due to various understandings of concepts and terms of AI in different fields such as business, science, engineering, music, medicine, and so on, there are different definitions and descriptions of AI. These mainly refer to software systems that provide

decision-making or think autonomously like human experts. For application of AI in medicine that clinicians aim at providing the best possible medical care to patients, AI is expected to improve clinical outcomes and reduce resource [14]. Any developments of computer hardware and software regarding AI that can help clinicians to achieve the above goals will be desired.

Machine learning is a computer algorithm which do not require traditional programming with rules to perform their functions. Machine learning is a subset of AI and its algorithms can perform a task through training themselves by analyzing a big dataset [15]. An example of machine learning in medicine is to assist the dermatologists in diagnosing melanoma [16]. The computer system is trained to distinguish between skin cancer and a normal mole after analyzing more than 100,000 patient images. Although machine learning takes many thousands more of viewing to recognize an object, while human only needs a couple of viewing, machine learning algorithms after training can detect subtle differences in millions of pixels in a dermatology image set, which is almost invisible to the human eye. Neural network are algorithms designed to mimic the functioning of the human nervous systems [17]. In human, the neural network contains neurons and synapses, while in a computer system, the network is connected by artificial neurons or nodes. To simulate the operation of human brain managing a large amount of data such as digital image, each node in the computer neural network is excited by the data from the image, then sent to the next node. The excitement transferred from one node to another is represented by a number or weight in the algorithm. The goal is to transfer the signal from the input to output through different layers of nodes as shown in Fig. 1.

Radiotherapy Chain

Radiotherapy is a cancer treatment using ionizing radiation to control or kill cancer cells. The whole treatment process can be described by the radiotherapy chain as shown in Fig. 2.

It is seen in Fig. 2 that the radiotherapy chain includes seven steps, namely, diagnosis and

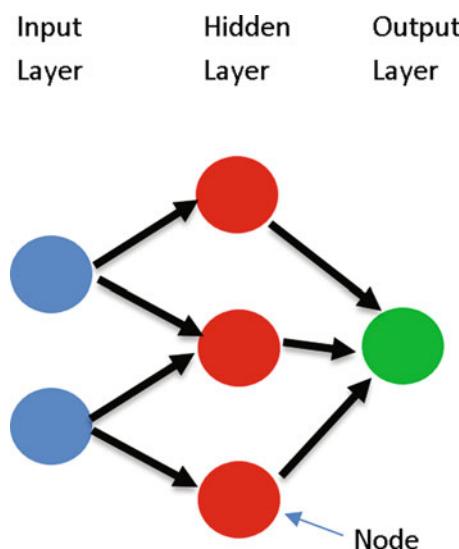

Fig. 1 Schematic diagram of a simple neural network

prescription, patient positioning, immobilization and simulation, target and organ contouring, radiation treatment planning, setup verification, and treatment delivery and completion of treatment or patient follow-up. When a patient is sent to the cancer center, various clinical tests are carried out for diagnosis of the disease. These tests include medical imaging and laboratory tests, helping the radiation oncologist to find out the stage and grade of the tumor, and whether the cancer has spread to other organs. The radiation oncologist then prescribes the radiation dose to the target (tumor), and the patient is sent to the simulation unit for treatment simulation and planning. The treatment position of the patient is set up by the radiotherapists, and an immobilization device may be used to increase the positional accuracy. A computed tomography (CT) scan is performed by a CT-simulator to acquire the 3D-anatomy information of the patient. From the CT image set, the radiation oncologist contours the target and organs-at-risk in the treatment planning system. The contoured image set is followed by a planner or medical dosimetrist to create a treatment plan using radiation beams with various type, field size, energy, and angle. Some advanced dose delivery techniques such as intensity-modulated radiotherapy or volumetric modulated radiotherapy can be used [18]. The created treatment plan is

reviewed and approved by the radiotherapist, medical physicist, and radiation oncologist, and a patient-specific quality control test is conducted by measurement. When all treatment QA procedures are done and passed, the patient is sent to the treatment unit for dose delivery. In the course of treatment, the delivery record of the patient is reviewed by a radiotherapist weekly. Patient follow-up is started after the treatment is complete to investigate the patient outcome monthly and yearly.

Applications of AI and Machine Learning in Radiotherapy

Since most processes in the radiotherapy chain involve computer control, analysis, and calculation [1], with the recent progress made in machine learning algorithm, big data processing, and high-performance computing, AI has been studied and implemented in the chain so as to automate and enhance the efficiency of the treatment [4]. In this section, we will highlight some applications of AI in various processes in the radiotherapy chain such as treatment planning, plan evaluation and QA, dose delivery, and patient care.

Radiation Treatment Planning

In radiotherapy, radiation treatment planning is the process in which a team containing radiation oncologist, medical physicist, and radiotherapist (or medical dosimetrist) plan the appropriate external beam radiotherapy or internal brachytherapy treatment technique for a patient with cancer. Implementing AI in radiation treatment planning is a long-term project requiring design of computer algorithm and infrastructure of application, set up of corresponding clinical policies, purchase and development of software and hardware, and national and international collaboration. Although such implementation process is time-consuming and complicated, some recent results are still noticeable.

In treatment planning, generating a 3D-dose distribution of a plan requires a time-consuming

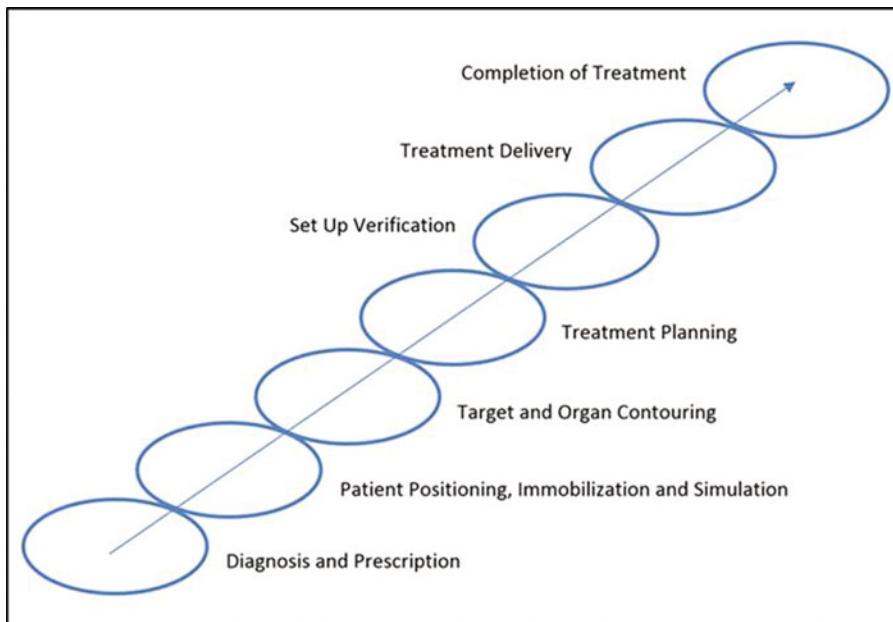

Fig. 2 Radiotherapy chain showing different steps in the radiation treatment process

calculation using various methods such as Monte Carlo simulation or convolution-superposition algorithm [19, 20]. With machine learning, the dose distribution can be determined through training associated with a pipeline of voxel-based dose prediction algorithm [21]. After machine training with previously treated patients based on multi-patient atlas selection, the system can learn to automatically select the most effective atlases for a new patient. The planning system can match the dose from those atlases onto the new patient. This AI process can avoid the time-consuming dose calculation step, and it is particularly useful when dealing with a huge number of patients having the same treatment site (e.g., breast, CNS brain, prostate, lung, and rectum), using the same delivery technique (e.g., intensity-modulated radiotherapy and volumetric modulated arc therapy) and treatment protocol.

Auto-contouring or image segmentation can be assisted by machine learning to increase the accuracy and efficiency in treatment planning. Atlas-based auto-segmentation is built and implemented to the treatment planning system [22]. This auto-segmentation is an AI-assisted process to perform segmentation on novel data using a dataset, which

consists of structures-of-interest from previous segmentation. The registration efficiency and robustness of the segmentation are improved by the registration strategy combined with the objects' shape information in the atlas. By comparing results of manual contour, atlas-based contour, and user-adjusted deep learning contour, it is found that the deep learning contour method performed the best on the lung, esophagus, spinal cord, heart, and mediastinum contours [23].

Machine learning can also help in beam angle optimization in treatment planning. In lung intensity-modulated radiotherapy, an automatic beam selection method is developed using machine learning [24]. A beam selection score function is built by considering the anatomical and beam features of the radiation beams. These include the planning target volume distribution in the thorax, the planning target volume projection shape, beam distances, and projected target volume and organs-at-risk overlap. The automatic beam selection method was tested using 149 plans with 122 for training and 26 for verifying [25]. Three to eight radiation beams were used in the plan. Results showed that the clinical acceptability criteria (e.g., planning target volume

coverage, maximal spinal canal dose, and mean lung dose) of the automatic beams are comparable to the clinical beams used as a control.

Treatment Plan Evaluation

Using the new automatic treatment planning system incorporated with high-performance computing, a large number of treatment plans can be generated at the same time that satisfied the dose-volume criteria based on the treatment protocol [1, 4]. Plan evaluation is therefore selecting the best plan for the patient. This evaluation used to be done by comparing different parameters (e.g., beam delivery, radiobiological, dose distribution, and delivery technique) and requires experts (e.g., radiation oncologist and medical physicist) to justify those parameters among plans. Machine learning simplified the plan evaluation process using a big data cloud [26]. In the following sections, we will explore an AI-assisted QA system using IoT for plan evaluation, followed by a computer system using machine learning to predict DDI from dose-volume histograms (DVHs) [27].

Treatment Plan QA

QA is a program designed to control and maintain a standard of quality to avoid and eliminate errors. This program is important in every step of the radiotherapy chain especially treatment planning, with recent implementation of large-scale clinical dose reconstruction and adaptive radiotherapy. A novel automatic QA system using machine learning for IoT is necessary to create [1, 28]. IoT refers to a network of physical devices which can interchange data. In radiotherapy, IoT includes the medical-imaging modules, treatment-planning system, image-guided system, and medical linear accelerator console. For treatment plan QA, data is exchanged among IoT to generate updated plan parameters for evaluation. This includes dose reconstruction results predicted using cone-beam CT [29]. Radiation staff are required to carry out real-time QA before every daily dose delivery in the treatment unit. This brings up two problems: (1) Many radiation experts are needed to perform

personalized QA; and (2) despite the treatment QA guidelines, evaluation results often differ among different radiation staff. To solve these problems, AI will be employed in the QA program in the radiotherapy chain with nonbiased justification.

To apply AI on IoT to automate the QA program in the radiotherapy chain, an IoT-enabled radiotherapy chain can be formed based on all clinical devices connected to the hospital network. In an IoT-enabled radiotherapy chain, the image set acquired from the CT-simulator is sent to the treatment planning system through intranet. There are five steps in the radiotherapy process: (1) A treatment plan is created with specific beam energy, geometry, and delivery technique based on the image set from the CT-simulator; (2) radiation dose is calculated based on the plan data, producing dosimetric results in form of DVHs, dose-volume points, and radiobiological parameters; (3) plan evaluation is carried out by the radiation oncologist and medical physicist; (4) when the plan is approved, treatment planning data is sent through the data network to the dosimetric QA systems for personalized treatment QA; and (5) when the QA is finished and approved, the plan data is sent to the medical linear accelerator console for radiation dose delivery. During these five steps, there is a lot of data transferred in the IoT chain involving several complicated systems, for example, from the CT-simulator to the treatment planning system and finally to the linear accelerator. Without setting them up in an IoT chain, it takes a very long time to go manually from the start to the end of the radiotherapy system.

AI plus IoT in radiotherapy can solve a huge bottleneck in the cone-beam CT. When a patient undergoes cone-beam CT, radiotherapists do a new quick calculation basing on the current physical dimensions of the patient, as the calculations done when the treatment first started may have changed, because the patient may become fatter or thinner. Thus a quick calculation at the cone-beam CT has to do with the patient lying on the couch in the treatment unit. This calculation necessarily has to be very quick with the patient's presence. All these mean, in image-guided adaptive radiotherapy, an image set of a patient is acquired by a

cone-beam CT system in the treatment unit before beam on. Then this most up-to-date anatomy information is compared to the planned CT image set in treatment planning to avoid any unacceptable deviation in the patient setup. If the calculations show deviations, the patient's physical position has to be corrected.

AI plus IoT can personalize the QA. Recent advancements in image-guided adaptive radiotherapy using cone-beam CT have made it possible for image processing/registration, high-performance computing on the dose distribution, and dose reconstruction to be carried out within 2–3 min [30]. Thus, the cone-beam CT image set done at the treatment unit can be used as the base to recalculate the dose distribution specifically for a treatment fraction. QA is therefore personalized, and we can predict the dose distribution in the patient if we proceed to finish the dose delivery. The radiation staff can then decide whether the treatment can go on.

The automation of the treatment plan QA program using AI and IoT can fit into the contemporary adaptive radiotherapy chain. With the AI-enabled IoT chain, radiation staff only need to do the approval once in a full course of treatment including multiple fractions (typically 5–30 fractions per treatment depending on the sites), instead of approving each step in the process.

Dose Distribution Index Prediction

To evaluate the quality of a treatment plan, various dose-volume and radiobiological variables are used to justify whether the created plan would satisfy the requirement of a corresponding clinical protocol [31, 32]. Among all plan evaluation variables, DDI is an effective one calculated by the DVHs from the target and organs-at-risk. This index not only provides the dosimetric estimates on the target coverage, but also spares all organs-at-risk and the remaining healthy tissue in the treated organ in a single variable [7]. DDI has been proved effective in treatment planning QA [8]. Here, instead of calculating the DDI using mathematical formulas based on the definition, machine learning is used to predict the DDI value from the DVHs generated by the treatment planning system [33].

To investigate machine learning in predicting the DDI for treatment plan evaluation, different algorithms used in machine training are investigated. These included linear regression, tree regression, support vector machine (SVM), and Gaussian process regression (GPR) [34]. Data of 50 prostate volumetric modulated arc therapy plans were used in machine training [35]. The DVHs for the targets (planning target and clinical target volumes) and organs-at-risk (rectal wall, bladder wall, and left and right femur) were pre-processed and transformed as five sampling points, namely, $D_{100\%}$, $D_{75\%}$, $D_{50\%}$, $D_{25\%}$, and D_M for the input of training. The workflow of the machine learning process (Fig. 3) included data collection, data preprocessing, model selection, training and validation, evaluation, and final justification. To compare the performance of the machine learning algorithms, root mean square error (RMSE) showing the deviation between the predicted and calculated DDI values, the prediction time of the machine learning and the training time were determined and compared.

Comparing the RMSE values among all machine learning algorithms, only the DDI predicted by the medium and coarse tree regression

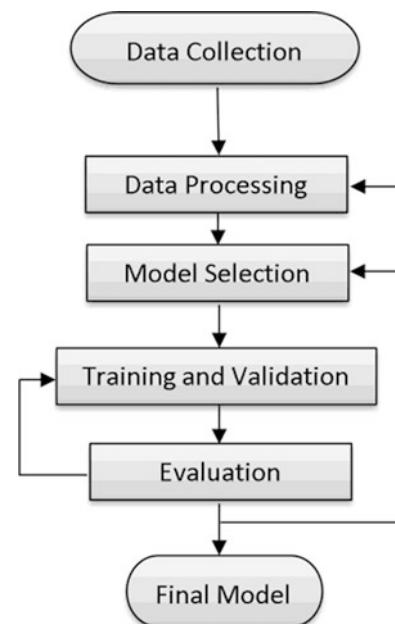

Fig. 3 Flow chart showing the machine learning workflow to determine the DDI

algorithms showed a relatively large RMSE value in the range of 0.021–0.034. These results showed that tree regression algorithms were not able to predict the DDI accurately. For other algorithms such as SVM and GRP, they all performed very well in predicting the DDI with smaller RMSE values ranging from 0.0038 to 0.0193. By considering other factors such as prediction speed and training time, the square exponential GPR algorithm had the smallest RMSE value of 0.0038, a relatively high prediction speed of 4,100 observations per second, and a short machine training time of 0.18 s [33]. This shows that the performance of the square exponential GPR algorithm is the best among others in predicting the DDI for treatment planning evaluation. It is seen that machine learning can be used to predict dose-volume variables such as DDI for treatment plan evaluation in radiotherapy.

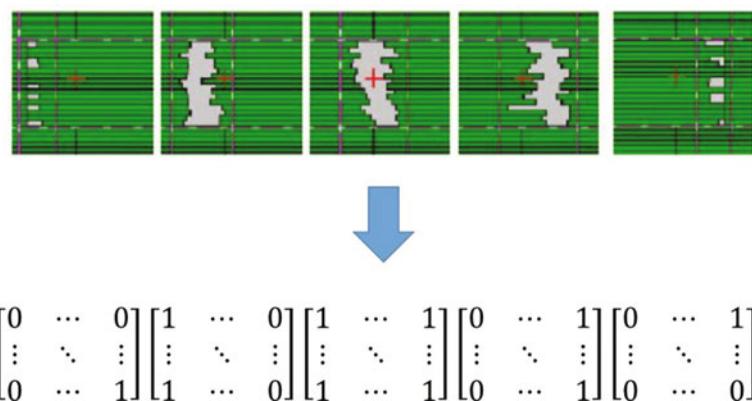

Radiation Dose Delivery Using Multileaf Collimator

In intensity-modulated radiotherapy, the tumor with irregular shape is irradiated by photon beams with various intensity-modulated profiles to achieve a dedicated dose distribution. To produce such intensity-modulated profiles, multileaf collimator is used. This computer-controlled collimator consists of a set of leaf pairs with the left and right leaves having identical size. The collimator can act as an intensity modulator to convert a given beam profile into a modulated profile or

fluence map needed in the treatment [36]. The principle is that each treatment field is divided into a group of subfields of irregular apertures (beam segments) with uniform intensity levels. These beam segments are generated by the multileaf collimator and then delivered in a stack arrangement in sequence to create the final intensity-modulated fluence map. Therefore, in intensity-modulated radiotherapy, a fluence map needs to be converted into a leaf sequence that controls the leaf movement in multileaf collimator during delivery [37]. As intensity-modulated beam techniques (static and dynamic) were developed, some leaf-sequencing algorithms were implemented in the multileaf collimator to produce beam segments of the required fluence map. These algorithms were further developed to improve the dose delivery with shorter treatment time and more accurate dosimetry [38]. Better algorithms removed more unwanted small beam segments resulting in small number of monitor unit or output produced per gantry angle in radiotherapy such as volumetric modulated arc therapy. As this small field error leading to dose distribution uncertainty can be greatly reduced, leaf-sequencing algorithm development is important in radiotherapy delivery.

Since the photon beam segment and final fluence map can be converted as graphical expressions with different intensity levels, it is possible to transform them into a grid of numbers and input them into a simple neural network. In Fig. 4, the final required fluence map was generated by five beam segments using different monitor units.

Fig. 4 Photon beam segments expressed as $m \times n$ matrices which added to become the required fluence map for intensity-modulated beam in radiotherapy

Each segment in Fig. 4 can be expressed in a $m \times n$ matrix with a constant intensity (0 or $p \times 1$), where p is related to the number of monitor units. The machine learning process is therefore carried out by feeding the beam segments in terms of graphical representations to the computer as per the targeted fluence map. The computer is trained to add the beam segments in order to produce the final fluence map required in the modulated beam dose delivery. Through machine learning, we can restrict the computer to search for the simplest combination of beam segments using the smallest number of segments, largest size of aperture, and smallest number of total monitor unit. The source of beam segments and resultant fluence map can be from the routine clinical treatment planning for the intensity-modulated radiotherapy or volumetric modulated arc therapy. There are 100,000 cases to be extracted from the treatment-planning system to a big data cloud for the machine learning process. One of the advantages in machine learning is that the leaf-sequencing process does not depend on any mathematical algorithms based on the corresponding theory and assumption. The machine learning process can find out directly the solution of the required fluence map from the beam segments with restricted condition.

Chatbot

Chatbots are the next big thing in the era of conversational services. It is a virtual person who can talk to human beings using interactive textual skills. There are currently many cloud-based chatbot development platforms such as IBM Watson, Microsoft Bot, AWS Lambda, and Heroku. In healthcare, AI-assisted chatbot is an innovative approach that can be used conveniently in health promotion and patient care interventions [39]. Conventional assistants can be deployed to IoT within different applications. Moreover, with an increased focus on the individual in health, hospital medical services have been shifting from a treatment focus to prevention and health management. The medical industry is creating additional services for health and life-promotion programs. AI-assisted chatbot is a framework

enabling a smooth human-robot interaction that supports the efficient implementation of the healthcare service. The possible ways to utilize chatbots to assist healthcare providers and support patients have been much discussed. It was concluded that chatbots will play a leading role by embodying the function of a virtual assistant and bridging the gap between patients and clinicians [40]. Moreover, AI and machine learning on chatbots can help to save healthcare costs when used in place of a human, or assist them as a preliminary step to assess a condition and provide self-care recommendation. A semistructured interview using online survey on the demographic and attitudinal variables such as acceptability and perceived utility of a chatbot was conducted [40]. Results showed that most Internet users would be receptive to using health chatbots, though hesitancy regarding this technology is likely to compromise engagement. We will focus on the recent development of chatbots for patient education and care in radiotherapy.

Background and Basic Concept of a Chatbot

When you are searching for some information about cancer treatment (e.g., what is radiotherapy?) as a member of the general public, there are many ways you can do it. You can search the information by going to the library to find some related references, look it up in some textbooks you remember placed somewhere in your study room, or calling somebody who you believe knows the answer. On the other hand, you can work otherwise using the Google search on your laptop or desktop, asking Siri on your iPhone, or posting the question to a WhatsApp group concerning the related topic and waiting for the answer. With recent rapid advances on IoT in the adoption of mobiles such as smartphone and tablet, apps are developed as specific channels for users to acquire or exchange information through the Internet. For an app providing information, the users demand instant response once they send out a question. The app should understand what the user needs immediately and provide what they are looking for accurately and precisely. This results in the innovations of chatbot powered by AI,

which is going to help the knowledge provider to automate the information transfer to the user, taking advantage of the Internet and big data.

A chatbot is a computer program designed to simulate conversation with human users through the Internet. The chatbot is an app that automates selected tasks by chatting with a user through a conversational interface. Figure 5 shows a simple workflow of the chatbot (Bot).

In Fig. 5, the user will type in a text as their enquiry or need to the chatbot interface. The chatbot will respond to the user using a question as confirmation. If the user answers “Yes.” the chatbot will process “do something” and return the information as requested by the user. If the user answers “No,” the chatbot will also carry out a task such as asking another question to further test and verify the user’s need. However, if the chatbot does not know what the user input to the interface, it will provide a guidance with some options to select in order to help the user to acquire their need.

Chatbot for Radiotherapy Education and Patient Care

For cancer patients, more than half of them receive radiotherapy as part of their treatment. The radiotherapy process is complex and complicated, as it is multidisciplinary involving knowledge in radiation oncology, medical physics, radiology, medical imaging, and medical

engineering. To make a cancer patient understand the rationale of radiotherapy is essential, because through understanding how the ionizing radiation can damage the cancer cell using the most up-to-date delivery techniques, confidence in the patient can be built up helping them to fight with cancer. The chatbot can help all the radiotherapy patients by providing them not only their appointments at the hospital, but also the necessary tailor-made information related to their treatments for patient care [41]. On the other hand, for the general public, the best way to avoid cancer should be through a healthy lifestyle and cancer screening. In this event, the chatbot can be used to promote a healthy life to avoid cancer and some cancer-screening programs. The general public will be benefited by interacting with the chatbot to acquire their needed information quickly and accurately. It is because the chatbot is humanlike mimicking a cancer professional to educate the users, whether they are cancer patients or general public [42].

An AI-assisted chatbot is a two-way communication system using a real humanlike interface. Through a warm and human touch-like communication between the chatbot and user, a friendship can be built up making the user believe the chatbot and hence makes it easier to listen to it for accepting information. It should be noted that cancer often affects seniors. Senior cancer patients

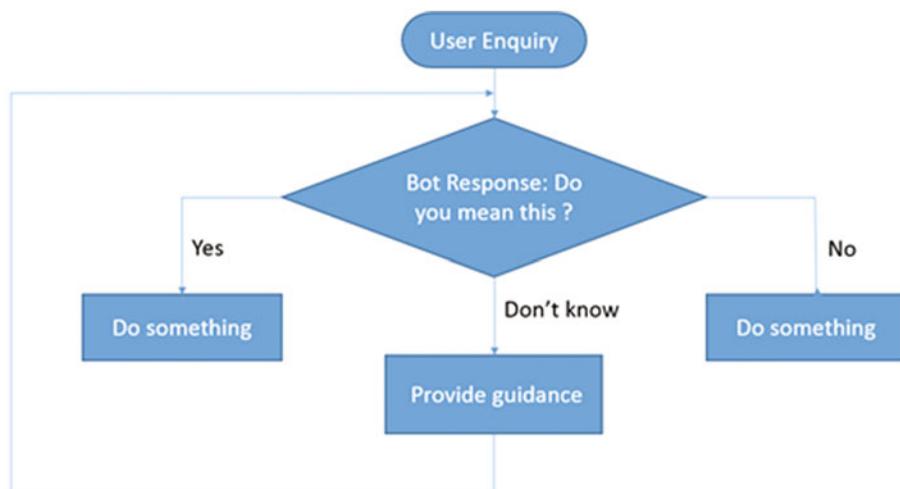

Fig. 5 The simple workflow of a chatbot

could not keep pace with the most updated computer technologies such as YouTube, Facebook, Twitter, and Instagram. They would need a relatively longer time for communication and to listen to and understand the information. The current web-based system can only provide information as per the selection made by the user on a tablet. The system cannot actually “talk” to the user like a chatbot. An AI-assisted chatbot for cancer patient is able to communicate with the user to start a conversation. Through talking with the user, the chatbot understands the background and their need. The AI system will then deliver the necessary information to the user as per their need. This dissemination of knowledge may be simple but useful, such as finding out a treatment room for appointment, the way to the washroom, patient care information, or some cancer-preventive strategies. The chatbot can solve this problem because it can predict the background and general information of the user, and find out the best way to communicate with them. The chatbot can ensure the most decent information to be acquired by the user in a warm and friendly manner.

Conclusion and Future Prospective

AI is a powerful digital tool that can benefit the advancement and automation of radiotherapy, leading to better resource allocation, more effective workflow, more accurate and faster decision-making, better patient care, enhancements of treatment plan QA, and radiation dose delivery. To date, it is seen that AI has been implemented in various components in the radiotherapy chain such as treatment planning, plan evaluation/QA, dose delivery, and patient education/care. With different AI-assisted radiotherapy processes being developed and commercialized, such as machine learning treatment planning, AI-assisted QA, AI-assisted diagnostic medical imaging, machine learning leaf sequencing for dose delivery, AI-assisted chatbot for cancer patient care, and clinical decision support and outcomes prediction, it is expected that cancer patients will be benefitted. However, there are still challenges in the application of AI in radiotherapy. These

include lack of personnel who know both AI/machine learning and radiotherapy, collaboration among multiple institutions for data privacy, security and ownership, and supports from the vendors and manufacturers for standardization of the dataset and tools and verification of results. Future directions and prospectives include focusing on the studies of data allocation and storage, because data volume will continue to grow in future with accumulation of more patient cases. Moreover, it is important to study big data management and analytics for machine learning. This involves the data-filtering technique in data-mining. Data privacy, computer security, humanlike-communication interface, and machine learning algorithm will continue to develop. Equally important is to ensure that users who do not have knowledge on the AI algorithm can still master the virtual machine easily to produce useful results.

Abstract

Breast cancer incidence has increased in the past decades. Extensive efforts are being made for early detection to reduce the mortality rate. As one of the leading field in artificial intelligence, deep learning algorithms have been widely used in breast cancer research in recent years, ranging from detection, segmentation to classification. To provide insights and development in this field, we review and summarize the popular datasets and deep learning methods used in breast cancer detection, focusing on mammography. We provide a summary of the state-of-the-art deep learning methods in mammography breast cancer detection and its performance. We discuss the challenges in

breast cancer detection and provide some new insights to advance the field.

Introduction

Breast cancer is one of the leading death causes of women. Over the past years, researchers proposed computerized techniques with the intention to aid the computer-aided diagnosis. However, many did not share their datasets and codes, which have become the main barriers in advancing the field. With the advancements in computer technology and data sciences, there has been a lot of research effort in exploring deep learning methods for various tasks. Deep learning methods based on Convolutional Neural Networks (CNNs) have also gained importance in the field of medical image analysis and the efforts are laid to develop modern computer aided detection systems.

This chapter provides an overview of publicly available mammography datasets and its most commonly used deep learning methods. For deep learning methods, we review the state-of-the-art deep learning algorithms for mammograms, compare the performance of the deep learning methods, and explore recent advancements in CNN to facilitate the development of automated deep learning method in detection of breast lesions. We discuss the challenges and future directions of deep learning in breast cancer detection.

Datasets

One of the major barriers in medical image analysis is the limited availability of datasets. Despite recent initiatives in sharing large-scale dataset in natural images [41], public datasets in the field of medical imaging and breast cancer in particular are still scarce or nonexistent. This can be explained by the difficulties to obtain ethical approvals to share the patients' data but also to the need of obtaining accurate data annotations and ground truth, which often requires gathering complex sources of information such as clinical data (i.e., electronic patient records), tests (i.e.,

biopsy results), and specialists (i.e., radiologists), therefore being both complex technically and time-consuming.

Nevertheless, public datasets need to be encouraged and developed as they allow the advance on the state-of-the-art methods on a particular field, providing a common platform to train machine learning methods but also, and more importantly, to compare and evaluate different methods. However, in order to be useful, these public datasets need to be of clinical relevance for the particular medical field or topic and need to include ground truth as accurate as possible, minimizing the effects of intra and inter reader variability.

There is a number of publicly available datasets for mammographic images: DDSM [33], CBIS-DDSM [44], INbreast [52], MIAS [63], and BCDR [29]. In addition, there are other initiatives that, although not publicly available, provide access to large datasets of mammographic datasets including clinical and patient data, subject to application. Those projects include the OMI-DB project in the UK [19] or the recent Cohort of Screen-Aged Women (CSAW) dataset from the Stockholm region in Sweden [20]. In addition to obvious aspects such as the number of patients, imaging views (CC, MLO), variability of lesions (benign and malign), and clinical information, an important aspect about a mammographic dataset is the nature of the images themselves, as older datasets [33, 44, 63] contain digitized screen film mammograms (SFM), where more recent databases include full field digital mammograms (FFDM) and, in some cases, even mammograms in raw format (also known as for processing) in addition to the mammograms post-processed for visualization (also known as for presentation). This chapter does not cover other modalities closely related to mammography such as Digital Breast Tomosynthesis (DBT), magnetic resonance imaging, or ultrasound. In those modalities, the number of publicly available datasets is even less common compared to mammography, although some initiatives can be found, such as the MRI dataset used in [30], the breast ultrasound in [73], or the recent DBT lesion detection challenge in [6].

MIAS

The Mammographic Image Analysis Society (MIAS) dataset [63] was one of the first public datasets. It was published in 1994 and contains 322 SFM, initially digitized at 50 microns but resized to 200 microns with a common resolution of 1024×1024 pixels. The database includes 209 normal mammograms and 113 abnormalities with radiologist annotations, indicating the type of abnormality (calcifications, well-defined/circumscribed, spiculated, ill-defined masses, and architectural distortions and asymmetries) and the position and extent of the lesion. The database also includes a classification of each image according to their density pattern using three classes: fatty, fatty-glandular, and dense-glandular.

DDSM

The Digital Database for Screening Mammography (DDSM) dataset contains approximately 2,500 studies. It contains SFM compressed with lossless JPEG encoding. The Curated Breast Imaging Subset of DDSM (CBIS-DDSM) [43] is a newer version of the mammographic dataset, containing a subset of the original DDSM images in the standard DICOM format. It was curated by a trained mammographer. The dataset can be downloaded from CBIS-DDSM website [17]. It contains 3,061 mammograms of 1,597 cases. In total there are 1,698 masses in 1,592 images from 891 cases which includes both CC and MLO views for most of the screened breasts. Figure 1 shows two mammographic views of the same case (CC and MLO) from the dataset.

INbreast

The INbreast [52] dataset is composed of FFDM acquired using a Siemens MammoNovation mammography system (Siemens Healthineers, Erlangen, Germany). The images were acquired from 115 cases with CC and MLO breast views, leading to a total of 410 images available in

DICOM format. From these, a total of 116 masses can be found in 107 mammograms from 50 cases. Several types of lesions (masses, calcifications, asymmetries, and distortions) are included. Accurate contours made by specialists are also provided in XML format. Figure 2 shows two views of an FFDM (CC and MLO) of the same case in the dataset.

OPTIMAM Mammography Image Database (OMI-DB)

The OMI-DB [32] is an extensive mammography image database of over 145,000 cases (over 2.4 million images) comprised of unprocessed and processed FFDM from the NHS Breast Screening Programme of the United Kingdom, which also contains expert's determined GT and associated clinical data linked to the images. As this is a relatively new dataset, Agarwal et al. [2] were the first to implement a deep learning algorithm on a subset of this dataset, comprising of 4,750 cases. These cases are images captured from four different manufacturers including Hologic, Philips, General Electric (GE), and Siemens, containing a total of 2,419 cases with 4,217 masses and 946 cases without any mass. Figure 3 shows sample FFDMs from the scanners of different manufacturers in the OMI-DB dataset. This is a much richer dataset as it also contains clinical, surgical (i.e., biopsy related) and pathological information about each patient, in addition to the mammographic images.

BCDR

The Breast Cancer Digital Repository (BCDR) [29] dataset contains 1,734 patients with mammography, clinical history, lesion segmentation, and various precomputed image-based features. The dataset is divided into two different repositories: a digitized SFM Repository and a FFDM repository both obtained from the Centro Hospitalar São João, at University of Porto, Portugal. BCDR provides normal and annotated patients cases of breast cancer including

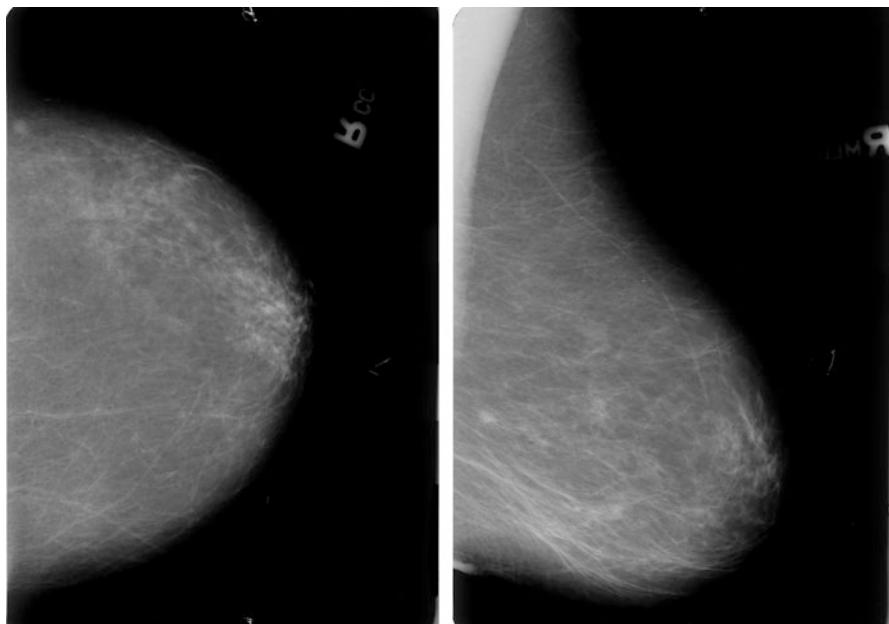

Fig. 1 Sample SFM from CBIS-DDSM [43] showing two different views of the same case, left: CC and right: MLO

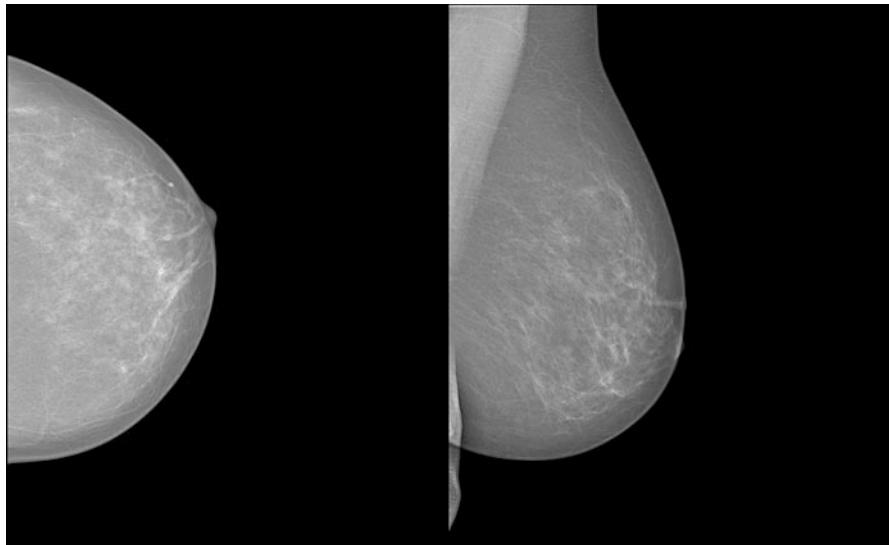

Fig. 2 Sample FFDM from INbreast [52] showing two different views of the same case, left: CC and right: MLO

mammography lesions outlines, anomalies observed by radiologists, precomputed image-based descriptors, as well as related clinical data. The digitized database is composed of 1010 patients (998 female and 12 male) with ages between 20 and 90 years old. From those patients,

there are 1,125 studies with 3,703 mediolateral oblique (MLO) and craniocaudal (CC) images and 1,044 lesions manually segmented and classified using the BIRADS standard for malignancy assessment. Images were digitized and converted to TIFF format with a resolution of 720×1168

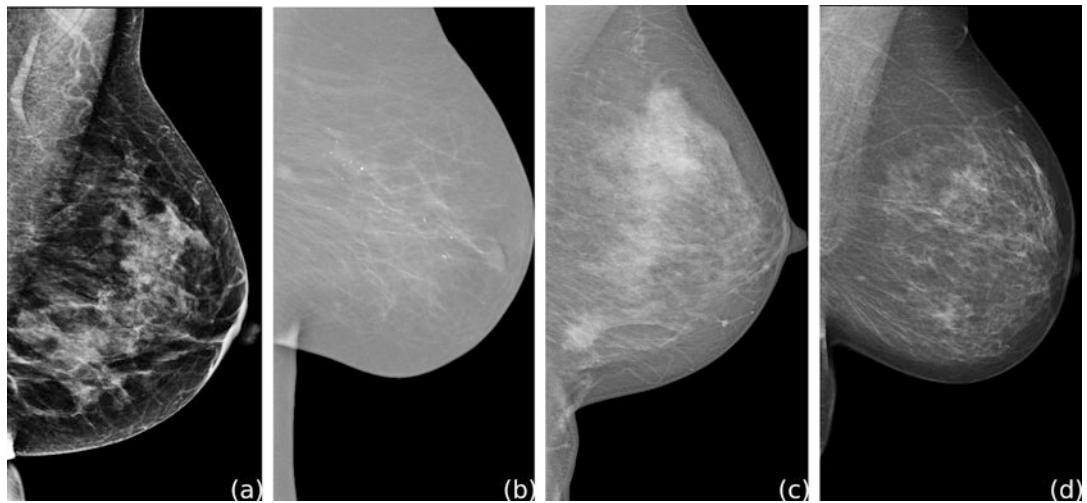

Fig. 3 Sample FFDM from OMI-DB dataset from different manufacturers. Here mammograms are from (a) Hologic, (b) GE, (c) Siemens, and (d) Philips

pixels and a bit depth of 8 bits per pixel. The FFDM dataset is composed of 724 patients (ages between 27 and 90 years old) with 1042 studies, 3612 MLO/CC images and 452 lesions with manual segmentation. The resolution of the images is 3328×4084 or 2560×3328 pixels (depending on the acquisition parameters) and saved as TIFF format using 14 bits per pixel.

Deep Learning Methods

Following the recent developments in computer technology and data science, there has been a lot of interest in exploring deep learning methods for breast cancer [1, 37, 70, 73]. The term “Deep Learning” can be defined as a subtopic of machine learning methods that learn data representations using multiple levels of representation [42]. They are obtained by composing simple but nonlinear models that transform the representation from one level (starting with the raw input) into increasing levels of representation. Deep learning strategies have recently gained a lot of interest in various fields including object detection [12, 27, 42, 57, 65], image recognition [24, 27, 41, 57, 64–66], natural language processing [13, 18], and speech recognition [34, 50]. In Deep Learning, Convolutional

Neural Network (CNN) is most commonly used to analyze images.

This section outlines the recent deep learning methods for breast cancer in mammography. Table 1 presents a summary of the state-of-the-art deep learning methods on mammography mass detection by year, dataset used, image resolution, and performance measures.

Several authors have proposed the use of traditional machine learning and content-based image retrieval techniques to classify masses and microcalcifications [25, 54]. The feature exploitation of deep learning frameworks in the field of breast imaging has been relatively limited, as only a small number of public datasets are available (as seen in the previous section).

In this regard, one of the first works was the work of Dhungel et al. [21] in 2015, who proposed a multiscale deep belief network (m-DBN) classifier, followed by a cascade of Region-Based CNN (R-CNN) and cascades of random forest classifiers for mass detection, obtaining True Positive Rate (TPR) of 0.96 ± 0.03 at 1.2 False Positives per Image (FPI) on INbreast and 0.75 at 4.8 FPI on DDSM-BCRP dataset. Later, Carneiro et al. [15] proposed the use of CNN models pretrained using a computer vision database (ImageNet) for classifying benign and

Aly et al. [9] (2020)	INbreast (410)	YOLOV3	832 × 832	0.98	0.92 at 0.086

malignant lesions obtaining an Area Under Receiver Operating Curve (AUROC) of 0.91 ± 0.05 on INbreast and 0.97 ± 0.03 on DDSM dataset.

In 2017, Lotter et al. [48] trained a patch-based CNN to classify lesions in the DDSM dataset and subsequently used a scanning-window approach to provide full mammogram classification

achieving an AUROC of 0.92 on the DDSM dataset. In the scanning-window approach, the image is partitioned into set of patches (with minimal overlap) and each patch is the input of the CNN and classified as being normal or lesion. Posteriorly, Dhungel et al. [22] used a deep learning approach for mass detection, segmentation, and classification in mammograms and evaluated on the INbreast dataset. Detection results had a TPR of 0.90 ± 0.02 at 1.3 FPI on testing set.

Regarding the use of private mammography datasets, Becker et al. [11] used a multipurpose image analysis software and an internal database from 3,228 patients to train the Artificial Neural Network (ANN). The model was then tested on the BCDR dataset [47] of 35 patients to obtain AUROC of 0.79. In other works, Kooi et al. [39] used a larger private database of 45,000 FFDM to provide a comparison between traditional mammography CAD systems relying on hand-crafted features and the CNN methods. It was shown that the CNN model trained on a patch level with a large database outperformed state-of-the-art CAD systems, obtaining an AUROC of 0.929 compared to 0.906 obtained for the CAD system.

Researchers have used Faster R-CNN in medical imaging [28, 67], but a very small amount of literature is available in the field of breast imaging. For instance, Akselrod-Ballin et al. [4] used a modified version of Faster R-CNN model to include information from the finer bottom levels during classification stage. Results were then evaluated on an internal database of 850 images to obtain AUROC of 0.78. Later, in [5], the results were evaluated on a subset of the INbreast dataset (with masses) obtaining a TPR of 0.93 at 0.56 FPI. Similarly, Ribli et al. [58] trained a Faster R-CNN on the DDSM database composed of 2,620 SFM and then evaluated the performance of the network on the INbreast database of malignant lesions, obtaining a TPR of 0.90 at 0.3 FPI and AUROC of 0.95.

Jung et al. [38] proposed a mass detection model based on RetinaNet [46] and used a new loss function called focal loss to address the problem of extreme class imbalance between foreground and background. The performance of the network was evaluated on the INbreast to obtain

the best TPR of 0.97 ± 0.05 at 3.0 FPI and 0.94 ± 0.02 at 1.3 FPI. Morrel et al. [53] presented a neural network based on region-based fully convolutional network (R-FCN) and deformable convolutional nets. The network was trained using the OMI-DB [32] dataset, achieving AUROC of 0.867 for breast-wise detection in the DREAM challenge on 13,000 images from Group Health.

Al-masni et al. [8] adopted the You Only Look Once (YOLO) deep learning method [56] for the detection and classification of masses in mammograms. The results showed an overall mass detection accuracy of 96.33% and a classification accuracy of 85.52% on the DDSM dataset. Authors showed that enhanced accuracies were obtained when using an augmented DDSM database created by rotating each mammogram multiple times. However, they used images of the same patient for both training and testing instead of splitting training and testing datasets at a patient level, thus giving potentially biased results. In other works, Al-antari et al. [7] presented a fully integrated CAD system adding lesion segmentation to the framework proposed in [8]. The results were presented on the INbreast dataset, but again the augmented dataset is used and the distribution is made based only on the images raising issue on overlap between training and testing patients.

Agarwal et al. [1] presented an automated mass detection framework using CNNs, where small regions of the mammograms (patches) were extracted using a sliding window approach and used for training different CNNs. The framework obtained results comparable to the state-of-the-art on the INbreast dataset. However, the high computational cost was a limiting factor for its clinical use. In 2020 [2], a Faster-RCNN-based framework was proposed to detect masses in the large-scale OMI-DB dataset consisting of approximately 80,000 FFDMs, obtaining a TPR of 0.93 at 0.78 FPI on FFDMs from the Hologic scanner. The framework was also used to analyze the state-of-the-art INbreast dataset, obtaining a TPR of 0.99 ± 0.03 at 1.17 FPI for malignant and 0.85 ± 0.08 at 1.0 FPI for benign masses. Figure 4 depicts the overall framework for the detection of lesions using the Faster-RCNN algorithm.

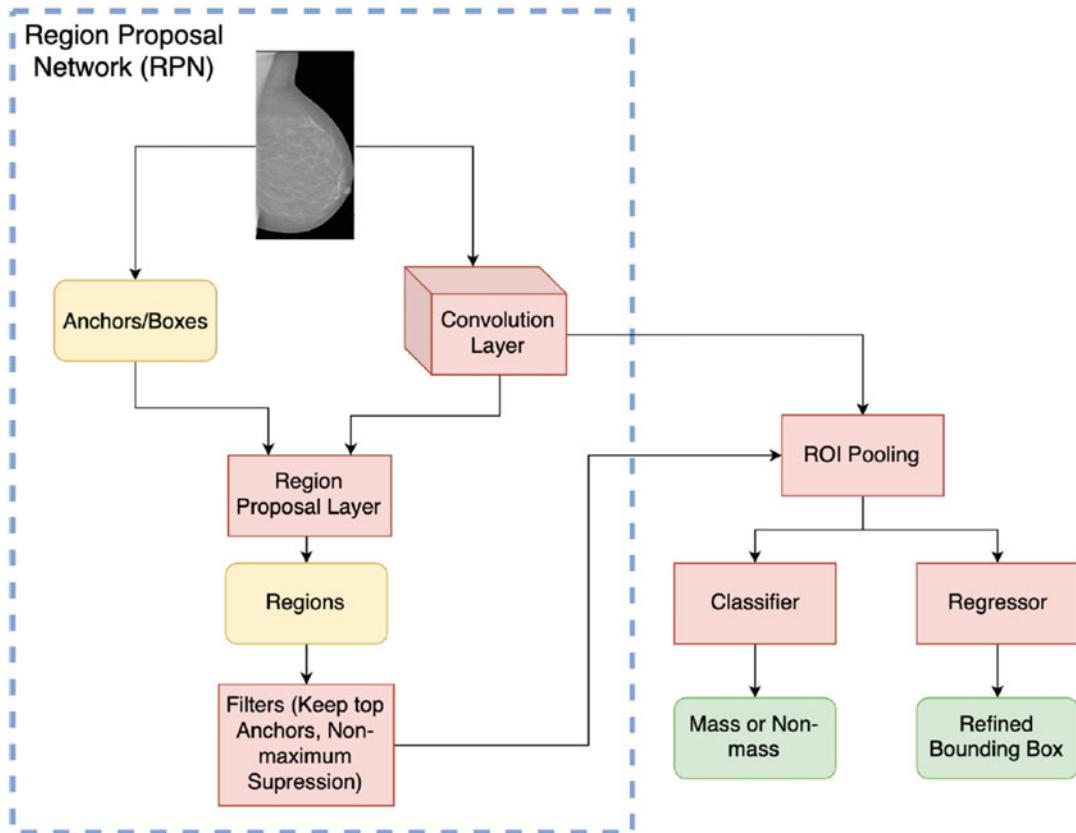

Fig. 4 Diagram of Faster-RCNN for lesion detection in mammography [2]

The latest developments in this field include the work of Shayma et al. [61] and Aly et al. [9], where a framework based on AlexNet and YOLO has been used for the classification and detection of breast masses, respectively.

Despite the limited availability of datasets, researchers have successfully implemented deep learning algorithms with data augmentation and two strategies: (i) by using image patches as inputs rather than full sized image and (ii) use the concept of transfer learning, in which the knowledge obtained by training for one task is used for another related task (also known as domain adaptation). In this regard, firstly the CNN trained on a very large dataset of natural images is adapted to classify between mass and nonmass image patches in the Screen-Film Mammogram (SFM), and secondly the newly trained CNN model is adapted to detect masses in FFDM. The following section describes some popular

performance metrics, which are commonly used to evaluate the performance of breast screening.

Performance Metrics

Different measures are commonly used for the evaluation of lesion segmentation methods. Usually the terms segmentation and detection need to be differentiated in medical image analysis. A detection method aims at obtaining the position and extent (i.e., with a bounding box if possible) of a lesion but without an accurate boundary delineation. On the other hand, a lesion segmentation method is designed to obtain an accurate outline, region, or contour of the lesion for subsequent analysis (i.e., diagnosis). Segmentation algorithms are often applied after the detection of the lesion is performed, although some methods (i.e., U-Net) provide both segmentation

and detection simultaneously. One should note that this chapter focuses on lesion detection; hence, evaluation measures for this task are discussed below.

Most measures take into account the elements of a confusion matrix: true positives and negatives (TP, TN) and false positives and negatives (FP, FN). In that sense, the definition of what is considered a TP needs to be clearly stated for the methods to be comparable. Usually the criteria of overlapping with the ground truth bounding box region is used at a given threshold criteria (i.e., > 50% of overlap is considered a TP). However, in the literature, one can find more loose definitions, such as defining a detection as a TP if the algorithm finds a lesion in an image which has been labeled as containing a lesion, regardless of its correct localization. In any case, from a given definition of TP, several evaluation measures can be derived. True Positive Fraction (TPF) and False Positives per image (FPs/image) are the most commonly used measures [23, 60, 69]:

$$TPF = \frac{\text{number of TPs}}{\text{number of actual lesions}} \quad (1)$$

$$FPs/\text{image} = \frac{\text{number of FPs}}{\text{number of images}} \quad (2)$$

TPF measures the sensitivity of the method. Some of the algorithms are capable of detecting multiple lesions while some are only capable of detecting a single lesion. The TPF allows a fair measurement as it is measuring the total detected lesions to the total number of actual lesions. Thus, if a method can detect only one lesion in an image with multiple lesions, the TPF of this methodology will be lower than the method that is capable of detecting multiple lesions.

In addition, Receiver Operating Characteristic (ROC) analysis can be used, as a graphic plot that illustrates the performance of a classifier system as a function of its discrimination threshold (i.e., probability of being a lesion). It is created by plotting the fraction of true positives out of the total actual negatives (FPR) for various thresholds. The Area Under the Curve (referred to as *AUC* or A_z) can be computed from the ROC curve

as an quantitative indicator of overall performance of a classifier. Often detection algorithms are also evaluated using free-response ROC analysis (FROC), a variation of ROC analysis, where the X-axis is replaced by the number of false positives per image. FROC gives more importance to the correct localization of the lesion rather than just analyzing the false positive rate.

In addition to TPF and FPs/image, the F-measure (the weighted harmonic mean of recall and precision) [55] is computed as:

$$F\text{-measure} = \frac{2 \times \text{TP}}{(2 \times \text{TP}) + \text{FP} + \text{FN}} \quad (3)$$

Discussion and Future Challenges

As mammography is the gold standard for breast cancer screening, there is a growing trend adopting deep learning for real-world applications. A recent study in nature [49] showed an artificial intelligence system is capable in breast cancer prediction, surpassing human performance. The work is based on a combination of OPTIMAM database and a private dataset – which makes it difficult to replicate and compare against.

In specific patient populations (i.e., young women or women with dense breasts), mammography is often nonconclusive and other modalities are needed. For instance, ultrasound is used as a complementary tool for breast screening. Breast ultrasound examination is a safe procedure as it is noninvasive and does not use ionizing radiation. Researchers in breast ultrasound are facing the similar challenges of small datasets available for research. The earlier works in using deep learning for breast ultrasound were in 2016 by [37], but particularly motivated by Yap et al. [73] in 2017 when they shared a dataset. Although this is a small dataset, it has provided the researchers a common ground to compare the performance of their algorithms. With transfer learning and inspired by the success of fully convolutional network and U-Net, researchers have experimented deep learning methods in segmentation [14, 70, 72] and region

of interests detection [71]. As breast ultrasound is widely used alongside with mammography in clinical practices, future challenge is to develop deep learning methods to work on several modalities.

In recent times, tissue stiffness-based biomarker is emerging with enormous potential for differentiating between benign and malignant breast lesions because of the fact that malignant tumor tissues are harder than normal and benign ones [31, 36]. Ultrasound elastography is the imaging modality being currently used for measuring the stiffness of the tissue along with morphology. Among the variants of elastography, strain elastography and shear-wave elastography are the two well-studied techniques for breast imaging. The diagnostic performance of deep learning-based shear-wave elastography has been demonstrated to be very promising compared to conventional ultrasound [75]. However, combining complementary information from ultrasound B-mode and elastography can provide even better diagnostic decision in computer-aided diagnosis of breast lesions [35]. In particular, elasticity imaging may help early detection of breast cancer as the changes in breast tissue elasticity may result earlier than its morphological changes [10]. Though substantial advances have been made, the elastography imaging still requires further attention for improving the image quality [3]. Fusion of mammography, ultrasound, elastography, and photo acoustic imaging may be the next generation technology for computer-aided diagnosis of breast cancer.

With the advancement of 3D technology and hardware capabilities, magnetic resonance imaging (MRI) is used as a supplemental tool for mammography and/or ultrasound. It may be used to screen women at high risk for breast cancer, evaluate the extent of cancer following diagnosis, or further evaluate abnormalities seen on mammography. Typical breast MRI is performed on a 1.5 Tesla magnet with a dedicated multichannel breast coil. In breast imaging, dynamic contrast-enhanced MRI (DCE-MRI) is used and is a noninvasive process. Contrast agents play a crucial role in DCE-MRI and should be carefully selected in order to improve accuracy in DCE-MRI examination [68]. Breast MRI is

expensive and produces false positives; therefore, it is not recommended for screening general population.

In mammography, there are some efforts over the past few years in expanding the capacity of mammogram to improve breast cancer detection. A new imaging tool, pseudo-3D digital breast tomosynthesis (DBT), was developed to reduce the masking effect of overlapping fibro-glandular tissue [26]. Although DBT is gradually being adopted, x-ray mammography is still the gold standard imaging modality used for breast cancer screening due to its fast acquisition and cost-effectiveness. Moreover, DBT is relatively new and its availability at the hospitals is limited. So, it is not yet considered to be a standard method for breast cancer screening.

The latest 3D technology proposed for breast screening is Automated Breast Ultrasound (ABUS), which produces a 3D volume of a full scan of breast tissues [62]. ABUS can overcome the issues of hand-held ultrasound screening in two aspects: operator dependent and lesion localisation. The challenge of ABUS is that the radiologists have to analyze each slice of the 3D volume to identify suspicious lesions, which is very time-consuming and laborious. Currently, researchers are working on developing deep learning methods for computer-aided detection [45, 51] to overcome this issue. However, there are no publicly available dataset of ABUS and lack of collaborative works to overcome this challenge. A larger publicly available ABUS dataset is required to improve the accuracy and the repeatability of the developed deep learning framework.

The deep learning methods have the potential to be adapted to detect lesions in 3D volumes such as ABUS and DBT, which are currently being adopted in the clinical practice. In this regard, an extensively large database composed of slices of 3D volumes would be required for training and testing of the CNN. This would require higher computing resources and may require using multiple GPUs for the purpose of training the CNN.

Another barrier for the adoption of deep learning methods in CAD is human acceptance. Developing a fully automated breast cancer detection algorithm is not meant to fully replace the

radiologists. As mammography requires a second reading or consensus opinion often in complex cases, the computer algorithm can step in to help in this process and reduce the workload and improve efficiency. For instance, in [59], authors published a study on the use of a CAD system to independently read around 50% of screening cases (2,600 cases, 650 of which contained cancer) and make radiologists focus only on the most complex and malign cases. The study showed no reduction on the overall detection performance compared to reading all cases by radiologists, but reducing their workload by almost half. Additionally, if CAD systems are able to incorporate all available modalities in the diagnosis process this will surely help to improve the accuracy. Fusion of modalities is a complex task due to the different nature of the different images and requires new methods to integrate this information. Other issues include trust in AI, data protection, accountability, which have open the door for researchers and policy makers to work together on the explainability of AI and establish new law/policy for using AI effectively and safely.

Conclusion

This chapter has presented an overview of the development of deep learning in mammography breast cancer detection. First we review the datasets, and then we summarize the performance of deep learning methods in mammography breast cancer detection. The emergence of data-driven deep learning has revealed the important of data sharing in medical imaging, more than ever, which has been a known challenge for many over the past decade. Although recent research shows promising results in using deep learning on mammography, we recommend to explore the potential fusion of multimodalities to improve the performance of breast screening. Finally, we discuss the challenges and provide some new insights for future work to advance the field.

Abstract

The use of Artificial Intelligence (AI) in medicine has increased in the recent years due to its ability to aid the clinician for better clinical decision. AI solutions could play a critical role in the growing need for health care access and low clinician to population ratio. Breast cancer incidence rate is rising every year and there is an urgent need for scalable and low-cost solutions for breast cancer detection, especially for low

and middle income countries. Breast thermography has been used as an adjunct modality for breast cancer detection since 1980s. Breast thermography has advantages of being low-cost, non-invasive, radiation free, and privacy aware. However, subjectivity and high expertise required for interpretation of breast thermograms are major challenges for its poor adaptability and equivocal results in the literature for its effectiveness of breast cancer detection. To overcome these challenges, AI solutions have been proposed to automate different steps involved in breast thermography. The recent explorations have suggested that automated breast thermography can play a potential role in breast cancer detection, risk estimation, and hormonal status prediction. In this chapter, we discuss breast thermography and different AI applications in automated breast thermography.

Introduction

Cancer, a frequently used term for malignant neoplasms, can be described as uncontrolled growth of abnormal cells in a body. It occurs when normal cells in the body lose their specific functional behavior (*differentiation*), begin to multiply uncontrollably (*proliferation*), invade their host cellular matrix (*invasion*), and finally spread out into other adjacent or distant parts of the body (*metastasis*). Cancer is a medical condition that could permanently destroy the normal functioning of affected organs if not treated in the early stages. Breast cancer is a malignancy that develops in the cells of the breast (human mammary glands) tissue. It is typically formed either in the lobules that produce milk (lobular carcinoma) or in the milk ducts (ductal carcinoma) that carry milk towards the nipple [1].

Breast cancer is the leading cause of cancer deaths among women all over the world. According to the World Health Organization (WHO), nearly 627,000 women lost their lives to this disease in 2018 [2, 3]. The incidence rate has been placed at 2.1 million every year [2], thus averaging to approximately one woman being diagnosed with breast cancer out of every 17 women in her lifetime. It is estimated that the incidence and mortality of breast cancer could

increase to 3.06 million and 0.99 million, respectively, by 2040 [4]. These incidence and mortality rates further vary with countries and their economic status [2, 3]. Breast cancer can be caused through genetic mutations that could be hereditary or acquired during the lifetime, either randomly or induced by exposure to carcinogens such as certain industrial chemicals and excessive ionizing radiation like X-rays [1]. As summarized by Feng et al. [1], obesity, hormonal replacement therapy, use of contraceptives for birth control, alcohol consumption, early menarche, and late childbirth are other significant risk factors for breast cancer [1]. It has approximately a hundred times higher incidence among women compared to men, and the risk of breast cancer increases with age [1].

It has been shown in various research studies that early detection of breast cancer can improve the chances of survival significantly [5]. The conventional imaging modalities for breast cancer detection include mammography, ultrasound, and Magnetic Resonance Imaging (MRI) and are discussed in detail in section “[Conventional Breast Imaging Techniques](#).” However, high cost equipment, need for high skilled personnel, dependence on infrastructure, use of ionizing radiation, among others, are major hurdles for their implementation, as discussed in section “[Challenges with Conventional Breast Imaging Modalities](#).” Expected increase in the incidence of breast cancers in the coming years [4] calls for acute need for early breast cancer detection techniques that are automated, affordable, and portable to improve accessibility.

Infrared breast thermography, which measures breast surface temperatures, has been used for breast cancer detection as an adjunct modality (section “[Infrared Thermography for Breast Imaging](#)”). Breast thermography can address some of the potential challenges faced by the conventional imaging modalities. However, subjectivity and high expertise required for interpretation of breast thermograms are major challenges for its poor adaptability. With the advances in Artificial Intelligence (AI) and improved infrared detectors in the last two decades, breast thermography is emerging as a mainstream imaging modality for breast cancer detection. In this chapter, we take a critical look at manual thermography (section “[Challenges with Manual Interpretation of Breast Thermography](#)”) and recent

advancements of automated thermography with Artificial Intelligence (section “[Artificial Intelligence for Breast Thermography](#)”) and discuss the potential use of automated breast thermography for breast cancer detection (section “[Discussion](#)”).

Conventional Breast Imaging Techniques

X-Ray Mammography

Mammography is considered as the gold standard technique for breast cancer detection. It uses planar projection X-ray images to visualize the internal structure of the breast. The cancerous cells generally are high-density regions and appear as white or enhanced regions in the mammographic images. Mammography uses low doses of X-rays to study two main types of breast changes such as high-density regions and calcifications. There have been many randomized trials in the literature that show the effectiveness of mammography for breast cancer detection [5]. There are also various studies that report the role of mammography in reducing the mortality of breast cancer [5, 6]. In general, the sensitivity and specificity of mammography reported in these studies for breast cancer detection vary from 64% to 90% and 82% to 98%, respectively, across different populations [6–8].

Unfortunately, mammography has some disadvantages. The use of ionizing radiation for breast imaging can increase the risk of secondary cancer. This led to the restriction of repeated usage of mammography, and the United States Preventive Services Task Force (USPSTF) and the European Commission have regulated the usage of X-ray mammography to once in every two years (on an average) across different age groups. According to some studies [8–10], mammography has sensitivity less than 70% and a high false positive rate of 56% in young women who generally have high density breast tissues. Since the breast tissue surrounding the lesion is also highly dense, it would be significantly harder to detect the cancerous lesion in these women. Also, to image the entire breast region, 15 to 20 pounds of pressure is applied onto a breast to flatten it against an imaging receptacle, which can be very uncomfortable and often painful for women.

A survey by Forbes et al. [11] stated that physical pain, embarrassment, inconvenience, and physical discomfort involved during breast compression are among the reasons why women may defer mammography or prefer to avoid mammography.

Ultrasound

Ultrasound is a commonly used breast imaging modality to characterize a mass or an abnormality inside the breast region. It uses sound waves well above the frequency range of human hearing to investigate the structural properties of soft tissue such as muscle and fat. The invasive nature of cancer cells to spread to the surrounding host tissue makes their structure particularly unusual compared to smooth oval and circular structures expected of healthy breast tissues. One can also observe the microscopulations on the host-tumor boundary region indicative of tumor aggressiveness [28]. The sensitivity and specificity of standalone ultrasound from different studies for breast cancer detection varies from 53% to 75% and 89% to 98%, respectively [7, 8]. The new advances of ultrasound imaging are further aiding in improving the accuracy of ultrasound imaging.

In clinical practice, ultrasound imaging is typically used for corroborative findings alongside mammography and/or clinical examination by manual palpation of the breasts. It is found to increase sensitivity by more than 20% in detecting small cancers and tumors in dense breasts when used in conjunction with mammography than mammography alone [7, 8]. However, high technical and clinical expertise is necessary to interpret the ultrasound images [8, 12], along with a dedicated mean examination time of 10 to 20 min from a clinician [12].

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) captures detailed anatomical information of the body using strong magnetic fields and nonionizing radio waves. The nuclei of hydrogen atoms in the body emit very weak radio waves when excited in a strong magnetic field. The frequency of these emitted radio waves is indicative of the immediate

physico-chemical environment of the water molecules. Radio wave pulses from an external transducer are used to synchronize and trigger the emission of the nuclear radio waves, such that an image can be progressively reconstructed from the frequency of the emitted radio waves.

Several studies showed that breast MRI can result in very high sensitivity (over 90%) for detecting cancerous abnormalities [12]. However, it has high false positive rates with low to moderate specificity ranging from 37% to 72% [13]. This could also be the reason why MRI is not used as a routine screening test for breast cancer detection in an otherwise asymptomatic or low risk population. In general, women with particularly higher risk of breast cancer and high breast density are recommended for MRI examination along with mammography to monitor the variations over time in the breast tissue [13]. However, MRI scanners are expensive and require dedicated infrastructure and skilled staff for their usage. Furthermore, lying still for extended periods inside the physically constrained environment of the MRI scanner imaging bore may not be suitable for body habitus or may cause claustrophobia.

Challenges with Conventional Breast Imaging Modalities

The diagnostic and screening implementations with the above conventional imaging modalities have demonstrated a reduction in mortality rates due to breast cancer [5, 6, 8], especially in high income countries. However, there are some challenges with their implementation especially in low- and middle-income countries. Some prominent reasons [6, 8] being:

1. *High equipment cost and high maintenance cost* of conventional screening and diagnostic facilities limits their availability to very few specialist clinics in developing countries. Non-portability of the equipment and the dependence on infrastructure further limits their usage to conduct screening camps.
2. Need for *high skilled* technicians to operate machines such as mammography, ultrasound, and MRI and for *experienced radiologists* to

interpret the imaging data generated. In India, for example, there are less than 10,000 radiologists for a population of 1.3 billion, that is, a single radiologist per 100,000 people [14].

3. Restrictions on usage of mammography and ultrasound. Mammography is not recommended for frequent imaging due to the use of ionizing radiation. Ultrasound is restricted in some countries since it can be used for fetal sex determination.
4. Lack of *awareness* among women to go for breast cancer screening.
5. *Privacy or embarrassment* during the breast imaging is found to be one of the major reasons why women, especially from South and South East Asian countries, do not prefer to attend routine breast cancer screening [11]. A survey conducted by Forbes et al. [11] found that 59% of Indian women reported embarrassment as a barrier for screening.
6. *Social or cultural barriers* such as stigma, fear, and cancer fatalism [6].

Infrared Thermography for Breast Imaging

Breast infrared thermography is considered as a low-cost imaging modality that has found its usage for breast cancer detection since the 1960s [15]. The high metabolism required for the growth of cancer cells is promoted by the increased resources to the vicinity of the tumor region. To facilitate the high resource consumption, new blood vessels are formed, large volumes of blood is circulated through the existing blood vessels, and dormant blood vessels are recruited [15]. The increased metabolic activities generate more heat and the generated heat is transferred to the breast surface through tissue conduction and venous convection. The high temperatures associated with cancerous regions and blood vessel regions were validated experimentally in various studies [16]. Therefore, it might be possible to detect the cancerous lesions by investigating the surface breast thermal patterns. Breast thermography allows a noninvasive and noncontact way of breast imaging which further enables a privacy aware imaging. Further, thermal imaging

equipment is affordable and portable, addressing the infrastructure and affordability issues with the conventional screening modalities such as mammography and MRI.

In the literature, there have been various studies that show the effectiveness of breast thermography conducted under controlled settings for breast cancer detection [15]. In different independent studies [15–17], it was also observed that thermography was able to identify cancerous lesions before they show positive signs in conventional imaging. As the metabolic changes occur from the onset of cancer, it might allow thermography to detect cancers in early stages even before a mass is formed. Based on this hypothesis, some studies [15–17] validated if thermography can be used as a risk indicator to identify women who are at high risk. Anbar et al. [18] found that dynamic thermography, videos at high frame rate, can be used to differentiate cancer types such as invasive, *in situ*, and inflammatory cancers. In a recent exploration, Zore et al. [19] observed that thermal imaging shows different heat patterns for hormonal positive and negative tumors, a biomarker used for prognosis, and treatment planning. This could be due to the dependence of hormones on the increased heat response.

Appreciating these potential implications in breast imaging, the Food and Drug Administration (FDA) approved the usage of thermography as an adjunctive diagnostic imaging modality for breast cancer detection in 1982. The significant advances in infrared detectors involving uncooled microbolometer Focal Plane Arrays (FPA) over the last two decades have led to the development of low-cost infrared imaging devices that can detect minute temperature variations up to 20 mK. This has further aided in improving the performance of breast thermography in breast imaging as discussed in [15, 20].

Breast Thermal Imaging Protocol

As summarized in [15], imaging protocols for breast thermography can be broadly categorized into continuous and discrete imaging protocols. Continuous imaging protocols involve analyzing the thermal signatures over time by capturing

videos at high frame rate. On the other hand, discrete imaging protocols involve analyzing a set of views captured at different view angles. In the literature, discrete imaging protocol is prominently used for breast thermography. Typically, five views at 0° (Frontal), $+45^\circ$ (Left Oblique), $+90^\circ$ (Left Lateral), -45° (Right Oblique), and -90° (Right Lateral) are captured to image the 180° of the breast region as shown in Fig. 1.

Challenges with Manual Interpretation of Breast Thermography

As discussed in the previous section, breast thermography can be used to detect breast abnormalities. However, interpretation of thermograms requires high expertise and is therefore subjective. Since thermography captures the temperatures emitted from a surface, the captured thermal data would comprise of real-valued temperature measurements with a precision dependent upon the thermal sensitivity of the infrared device. Therefore, pseudo color palettes like Rainbow, Iron, Gray, etc., are used for visual interpretation [21]. A lower and upper temperature limits need to be set to convert the captured thermal data into a pseudo color image for visualization. Any change in the temperature limits could change the pseudo color image, as illustrated in Fig. 2, and hence, might affect the interpretation of thermal images. This could introduce subjectivity in interpretation and the visual inspection of different color shades representing minute temperature variations could be a high cognitive load for the clinician. Further, it is not trivial to classify malignancy by observing the color shades of the pixels with naked eye though thermal abnormalities appear as hot or high intensity regions. This is due to evidences that some of the benign conditions like duct ectasia, fibroadenoma, fibrocystic, abscess, and high hormonal response could cause high metabolic heat generation and appear as high intensity regions on breast thermal images [22]. These factors might be a reason for the existence of contradicting results about the use of thermography for breast cancer detection.

The Breast Cancer Detection Demonstration Project (BCDDP) [23], a breast cancer screening

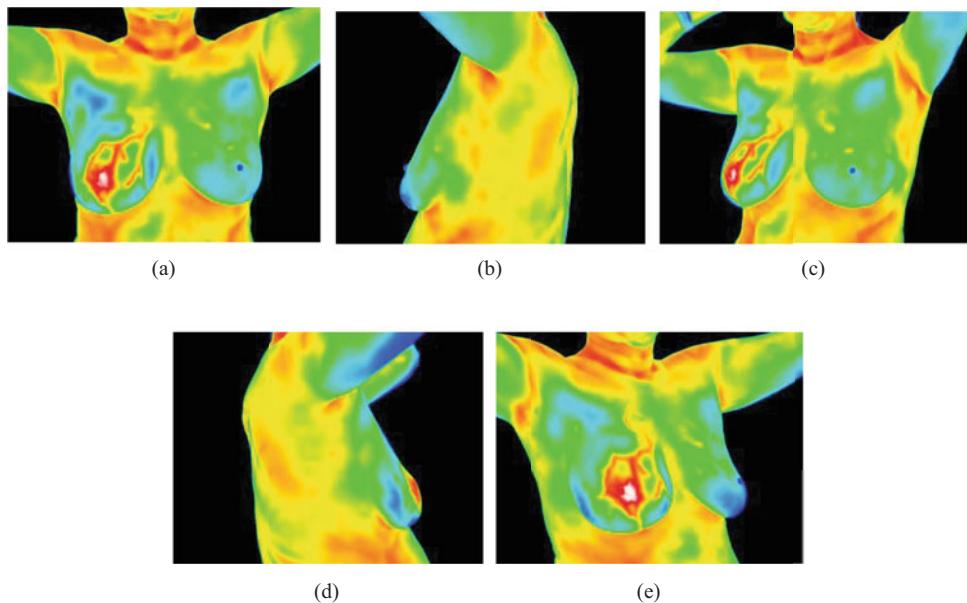

Fig. 1 Thermal images of a subject in Meditherm color palette captured at (a) frontal, (b) left lateral, (c) left oblique, (d) right lateral, and (e) right oblique views

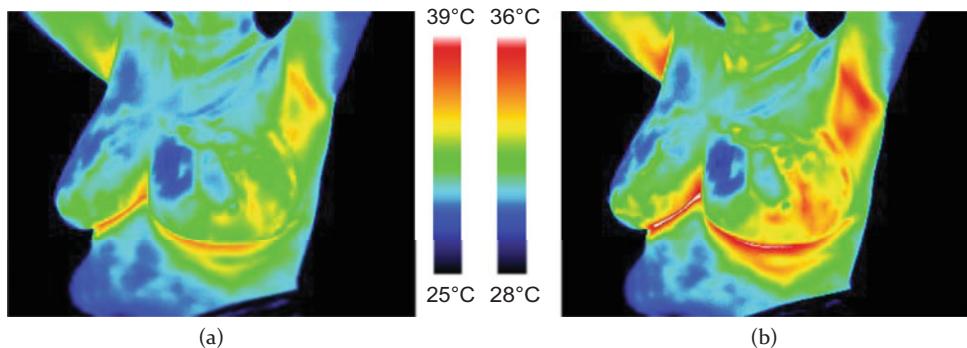

Fig. 2 Thermal images of a participant with different temperature ranges. (a) 25 °C to 39 °C. and (b) 28 °C to 36 °C

program conducted between 1973 and 1980, and few more studies [24] reported poor performance of standalone thermography for breast cancer detection. According to Gautherie et al. [16], Keyserlingk et al. [25], Kennedy et al. [26], and Gonzalez et al. [20], these poor results could be due to the lack of adequate quality control, technical skills, training for using infrared equipment and high expertise required to interpret breast thermograms. According to Keyserlingk et al. [25], the low sensitivity could also be attributed to the failure in the image capture of oblique views, which could have led to missed cancers

in the outer quadrants of breasts. As discussed by Gonzalez et al. [20], some of the low accuracies reported in the studies could be due to low sensitive cameras used for the study and the accuracies could have been improved with the latest advances in the infrared thermal cameras that can measure minute variations up to 20 mK. The detection of minute variation in temperatures would allow for better visualization and discrimination of vascular and nonvascular heat patterns and could improve thermographic category grading [25]. Further, most of the studies that reported low sensitivities were performed during 1970 and

1990 [20]. Overall, from these observations, the accuracy or resolution of thermography seems to be benefited from the advances in infrared detectors; however, the accuracy obtained with thermography seems to be subjective and requires high expertise for interpretation of breast thermal images. This may be a key reason for its poor adoption in the clinical practice.

These reasons have led the Food and Drug Administration (FDA) to impose restrictions and stringent warnings [27] on the use of breast thermography as a standalone imaging modality for breast cancer detection. In order to reduce these false thermal interpretations and subjectivity, we need a robust computer aided system that can learn expert domain knowledge and help in automating the interpretation of breast thermal images. The high resolution data from recent highly sensitive thermal cameras help the computer-aided algorithms in analyzing minute heat variations that might be difficult to interpret with the naked eye.

Artificial Intelligence for Breast Thermography

Artificial Intelligence (AI), the ability of computer systems to perform tasks that typically require human intelligence, has emerged significantly over the recent years and has started playing a pivotal role in various sectors. Specifically, there has been a tremendous increase in the investigations of AI applications for healthcare [28] in the last decade. Though there were many speculations regarding the implications of AI on patient care in the beginning, the recent regulatory clearances for AI based medical devices from regulatory boards such as the US FDA indicate its strong role in the future of healthcare [29, 30]. In breast radiology, there have been several AI algorithms in the literature for automated analysis of conventional imaging to reduce subjectivity and improve accuracy. Some of these AI applications such as Quantx [31] and Transpara [32] are cleared by FDA for analyzing MRI and mammography images, respectively. Overall, the use of AI in radiology is receiving appreciation and seems to alleviate the need for high expertise required to interpret the images and

helps in reducing the overall time required by a radiologist for examination.

Breast thermography has many challenges starting from image capture to interpretation of thermal images. Like many other imaging modalities, breast thermography captures multiple thermal images at different view angles, as described in section “[Infrared Thermography for Breast Imaging](#).” This could lead to subjectivity in thermal imaging capture and mislabeling of captured views. As discussed in the previous section, manual interpretation of thermograms is difficult and subjective and might be a reason for the controversial results observed with manual analysis of breast thermography. Therefore, AI can help in addressing the interpretation issues with manual thermography and might help in automating, scaling and standardizing the thermal image interpretation for breast cancer detection.

Subjectivity with manual thermography, availability of low-cost infrared camera equipment coupled with the recent advances in the infrared technology, and the radiation-free benefits of thermography have led to the sparked interest in the machine learning community on automated breast thermography from the 2000s. As summarized in recent review papers [33, 34], and a PhD Thesis [63], there are various studies in the literature that show the effectiveness of AI in various phases of automated interpretation of breast thermal images. These AI applications for thermography can be categorized into five key tasks, which are detailed in the following subsections.

AI for View Labeling

Image capture plays a crucial role in obtaining accurate results with any computer-aided diagnosis/detection solutions. As mentioned in section “[Breast Thermal Imaging Protocol](#),” breast thermography involves the capture of multiple images of the subject at five different view angles. Thermographer or technician needs to manually save these captured images corresponding to their view angles to enable automated analysis. Manual saving of the images could be erroneous due to the presence of the right/left breast on the left/right

side of the image and might result in inaccurate analysis. To deskill this process, there has been a recent approach [35] that uses ResNet 50, a 50-layer convolutional neural network (CNN) with residual skip connections, to automatically predict the view from the thermal image. The results of 97% accuracy for 5-class classification corresponding to the five captured views and 99.5% accuracy for labeling into left, right, and frontal views show the potential of AI in automated view labeling of thermal images. This automation can help in decreasing the overall time for image capture and also to flag any errors in cases of wrong or improper view capture.

AI for Breast Segmentation

Breast segmentation is essential for automated analysis of thermal patterns inside the breast region. The manual segmentation of a breast region is laborious and is subjective due to the lack of strict breast boundaries. The minimal variation in thermal intensities between the breast and the nonbreast regions and amorphous nature of the breast make the automated segmentation of thermal images a challenging problem. In the existing literature, there have been many automated and semi-automated approaches for breast segmentation [33–37]. These techniques typically use traditional image processing approaches to segment the breast regions by using heuristics from inframammary fold region, axilla region, and

breast silhouette boundary [33–37]. The sensitivity, accuracy, and dice index reported in the literature were greater than 90%. Most of these techniques work either for a frontal or a lateral view. A recent approach shows that an encoder-decoder CNN can be used to segment the breast region in multiple views [38]. Specifically, authors propose the use of V-Net and showed that a Dice index of 0.92 can be achieved for segmentation of breast region. They further explain that the obtained Dice index is 1% higher than the interobserver dice correlation. This shows that AI has potential to perform similar to a human expert. To further refine the AI predicted segmentation with human intelligence, some authors suggest an elliptical or polygon user interface on the AI output [38] for manual adjustment, as shown in Fig. 3. Overall, these advances in AI are transforming the laborious and time-consuming breast region segmentation into a simple and fast process.

AI for Malignancy Classification

Malignancy classification involves classification of breast thermal patterns into two classes: malignant or benign. As discussed in section “[Infrared Thermography for Breast Imaging](#),” breast heat patterns are affected by the increased vascularity and metabolic activity of the cancerous region. However, the increase in the heat patterns can be observed with some of the benign conditions as well. This makes the manual interpretation

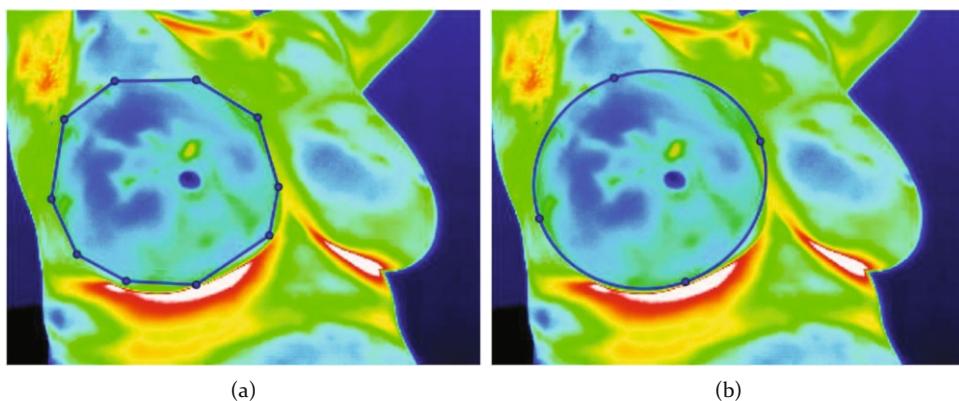

Fig. 3 Manual adjustment of the predicted breast region with (a) polygon, and (b) ellipse

challenging and error prone. Automated classification of malignancy from the heat patterns could help in alleviating the subjectivity and reducing the false interpretations that were earlier reported with manual thermography. The problem of differentiating the malignant and benign heat patterns with AI is well explored in the literature and there are many AI approaches to classify the heat patterns. The sensitivities and specificities reported in the literature vary from 79% to 100% and 79% to 100%, respectively [20, 33, 34], showing the feasibility of automated interpretation. These AI solutions differ in the features used for classification and broadly can be divided as below:

Textural and statistical features: These methods extract textural and statistical features describing the overall heat patterns on the breast region and classify using Machine Learning (ML) classifiers such as Support Vector Machines (SVM), Random Forests (RF), Artificial Neural Networks (ANN), Multi-Layer Perceptron (MLP), etc. These features involve mean, contrast, moments, energy, homogeneity, entropy, etc., of the heat patterns inside the breast region [33, 34]. Some approaches use Histogram of Oriented Gradients (HOG) features of the breast region for classification [39] into benign and malignant.

Hotspot features: These techniques first identify high thermal regions (hotspots) and extract features from these regions to characterize malignant heat patterns. Clustering techniques such as

fuzzy c-means and k-means [40], active Contours [41], adaptive histogram thresholding [22], and CNNs [42] have been explored in the literature to automatically segment the hotspot regions. From these hotspots, domain knowledge features [22, 43] such as irregularity, symmetry, temperature increase, etc., for differentiating between benign and malignancy are proposed for classification using ML classifiers. The detection of hotspots helps in localization of tumor region, whereas extraction of domain knowledge features from hotspots might improve semantic interpretation by a clinician. Figure 4a shows the high and warm thermal regions detected by the approach proposed by Madhu et al. [22] for a sample thermal image.

Vascular features: Vascular deformations are the initial changes that are associated with the abnormal growth of cancer cells [15]. Thermal imaging can be used to study these vascular deformations. The heat generated from the blood vessel activity might be diffused during its transmission to the breast surface, and therefore, the captured heat pattern might have diffused vessel boundaries. Therefore, automated vessel extraction techniques in other imaging domains might not work well for breast thermal images due to these diffused vessel boundaries. Due to this reason, authors in [44–46] propose multiple structural and intensity enhancement techniques to identify the blood vessel structures, as illustrated in Fig. 4b. From the detected vessels, authors [44, 45] suggest the use of domain features such

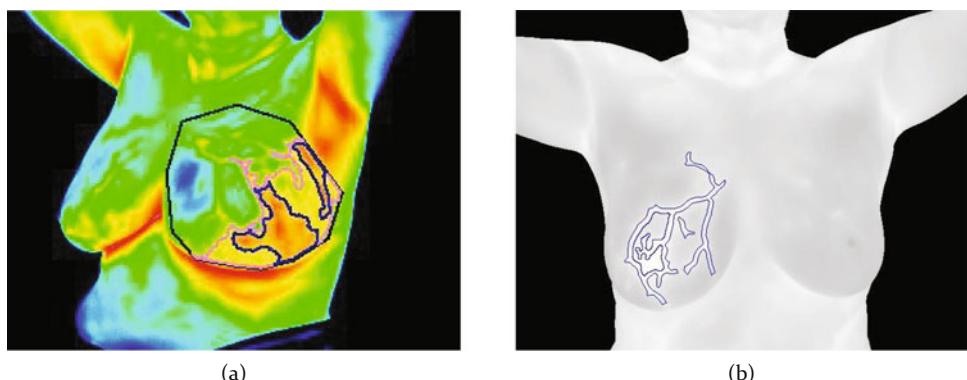

Fig. 4 (a) High and warm thermal regions detected by the approach proposed in [22]. (b) Vessel like structures detected by the approach proposed in [44]

as tortuosity, symmetry, number of blood vessels, etc., for classification of malignancy with ML classifiers. In [46], authors compare thermal minutiae points of detected vessels before and after the application of cold challenge for classification of malignancy.

Pixel level classification: This class of algorithms classifies each pixel or block of pixels in an image as malignant or normal. In [47], authors use statistical features such as signal complexity and signal mobility of the heat variations at each breast pixel on the image over time. In [48], authors propose a split and merge approach using a multifeature fusion algorithm to detect the tumor automatically. Since each pixel or block of pixels is being classified, these set of algorithms can be used for localization of malignancy.

CNN-based features: CNNs eliminate the need for hand-crafted features by learning the representation between the input images and their corresponding output labels. In the literature, authors [49–52] have used deep learning architectures such as ResNet, VGG, Inception, GoogLeNet, DenseNet, MobileNet, and ShuffleNet to predict the malignancy from thermal images. These deep learning architectures are showing promising results for prediction of malignancy from thermal images. However, interpretation of the predicted outcome is a known challenge with deep learning. In a very recent exploration [52], authors propose the use of activation maps to identify focus areas of deep learning architecture for predicting malignancy. However, the validation of focus areas is not performed. Overall, these results are encouraging, and significant research is being conducted to further improve the interpretation with deep learning.

AI for Risk Estimation

Breast cancer risk estimation can help in identifying women with high risk of breast cancer and thereby aiding the clinician to create a personalized care for women tailored to their level of risk. The identification of high-risk women can be extremely beneficial in creating awareness

among women and to divert the limited resources for those who would need them the most in rural camps. As breast thermography captures the metabolic information in the form of heat patterns in the breast region of the subject, it might be used for breast cancer risk estimation. A clinical study conducted by Gautherie et al. [16] with manual interpretation reported that approximately one-third of 1,245 women who had an equivocal thermogram and a normal examination by conventional means in their first visit had developed breast cancer in the next five years. In the literature, there are both automated and semi-automated AI approaches to evaluate the use of thermography for breast cancer risk estimation. In [53], authors used a semi-automated assessment criterion called BIRAS (Breast Infrared Assessment System) to categorize the thermal images into five cohorts with BIRAS 1 being low risk and BIRAS 5 being high risk. This approach considers 10 images (5 before cooling and 5 after cooling) and uses automated nonvascular criteria such as symmetry, areolar temperature, isothermia in each quadrant, temperature decrease due to cooling and hotspot parameter and vascular criteria described by the clinician. In a recent exploration [45], a completely automated risk estimation called Thermalytix Risk Estimation (TRS) is proposed using vascular features, non-vascular features, age, and symptoms for pre-screening of breast cancer. Authors suggest that the estimated TRS can then be used to categorize women into four risk cohorts. In both these approaches, the proportion of malignancies has increased with increased risk showing the potential role of automated breast thermography for risk estimation.

AI for Biomarkers Prediction

Biomarkers involving estrogen (ER), progesterone (PR), KI67, and HER2 play an important role in the prediction of prognosis and treatment procedure for breast cancer. Typically, histopathology of tissue samples that are extracted through a surgical procedure is used for assessing the biomarkers. Obtaining these biomarkers

would be costly and time consuming for the patient due to the limited pathology labs in the developing countries. In a study conducted by Zore et al. [19], it is observed that tumors with positive hormonal (estrogen/progesterone) status have a different thermal signature compared to hormonal negative tumors. To automate the hormonal status classification with AI, authors [54] propose the use of machine learning features such as symmetry, Jensen Shannon Divergence (JSD), relative hotness, thermal distribution ratio, and textural features. This automation can make biomarkers estimation an automated, fast, and non-invasive approach.

Discussion

The advanced machine learning solutions, as discussed in the previous section, are aiming to generate an increasingly consistent and accurate interpretation of breast thermograms. The use of AI in medical imaging can allow continuous learning through retraining of the machine learning models from a new variety of data. This could be essential to accustom the AI solution to different cancer types and to the changes in the cancer mutations over time. The improved accuracies in the literature for automating breast thermography with the advancements of AI over the recent years are showing a promising role of breast thermography in breast cancer care.

The lack of publicly available large datasets with curated ground truth seems to be a major challenge for research in automated breast thermography. The availability of PROENG [55] dataset helped the machine learning community to experiment on breast thermography for segmentation and classification. However, the small training dataset has limited most of the existing approaches to use traditional image processing and machine learning for different problems in breast thermography. In the presence of large datasets [35] and with the techniques of transfer learning of weights from one domain to other domain [49–52], a transition has seen in recent years from traditional image processing and machine learning approach to deep learning.

While the former might require a small amount of data, it might not be generalizable. On the other hand, deep learning can produce better results but they might overfit to the input distribution in presence of smaller training datasets. This brings a trade-off between these approaches and evaluating of these techniques would be critical in measuring the real effectiveness. In general, evaluation of results on independent test sets rather than the validation datasets is commonly used to compare the approaches. The ground truth for training and validating the ML models is another important factor in measuring the effectiveness of these ML classifiers. In many studies, the ground truth for classification is not described in detail. Since thermography is not a standalone modality, comparison with manual labeling would not result in actual sensitivity and specificity of automated breast thermography for breast cancer detection. Biopsy is considered to be the ultimate ground truth for breast cancer detection. However, it is not ethical to perform biopsy on all the subjects without any strong suspicion from malignancy. To tackle this, a combination of conventional imaging modalities such as mammography, ultrasound, and MRI can be used to confirm the negative ground truth, whereas biopsy can be used to confirm the positive ground truth.

Most of the existing AI approaches for different tasks in breast thermography considered breast thermal images of women who had no prior history of breast cancer. This might limit the applicability of these approaches on women who had surgical procedures like mastectomy, breast augmentation, breast reduction, lumpectomy, etc. Segmentation and tagging that rely on boundary features might not work on these women as the breast contours would be significantly modified. Also, the heat patterns might be disturbed due to surgery and might interfere with the classification of heat patterns into benign or malignant. Screening of these women with prior breast cancer is important due to the chances of recurrence of breast cancer either in the same or contralateral breasts. As mammography might not be recommended for mastectomized or recently lumpectomized women, it would be interesting to see if breast thermography can be effective in

these women. Similarly, the ML approaches should also consider male population distribution during training of the ML models as 1 in 1000 men have a chance of breast cancer.

Further, the adaptation of automated thermography in clinical practice is still in its initial stages. Currently, most of the evaluations of AI solutions for breast thermography are done retrospectively and there are only a few studies [56–59] that have evaluated the automated AI solutions in clinical settings. In a recent study [60], authors evaluated the effectiveness of an AI tool called Thermalytix on symptomatic asymptomatic cohorts at multiple sites, where they reported a sensitivity of 91% for detecting breast cancers. However, most of these existing studies involved small cohorts with similar demography. Therefore, it is important to validate breast thermography AI solutions on large-scale diversified populations for their clinical effectiveness in various stages of breast cancer care continuum before its clinical usage. Specifically, the role of breast thermography in screening, diagnosis, and prescreening needs to be evaluated through randomized clinical trials. Though the cost of breast thermography equipment is low compared to conventional screening, specificity ($1 - \text{false positive rate}$) of breast thermography with AI solution is found to be low in some studies. A detailed health technology

assessment needs to be conducted to understand the real cost effectiveness of breast thermography.

Interpretability of a predicted outcome is another crucial factor for clinicians as it could play a critical role in patient care [61, 62]. There has not been any literature that talks about the interpretability and user/clinician studies for the existing automated breast thermography systems. As observed in a study conducted by Bratko et al. [61], clinicians do not want to rely solely on the predicted outcome but would be interested in simplified and sensible qualitative interpretation. According to Vellido et al. [62], visualization can aid a perfect conduit for the interpretation of algorithmic data. In addition, a cyclic feedback through an interactive visualizer could aid in dealing with detected outliers, anomalous data, or data artifacts. From these studies, it is evident that a computer-aided thermographic system that could estimate quantified qualitative thermal parameters with a supported visual interpretation in addition with a cyclic feedback is necessary for better and quick clinical acceptance. Figure 5 shows a possible cyclic feedback for integrating different modules of breast thermography for better clinician interaction. It is essential to experiment and study different cyclic integrations of automated thermography systems for its implications on clinical adaption and improving the overall accuracy.

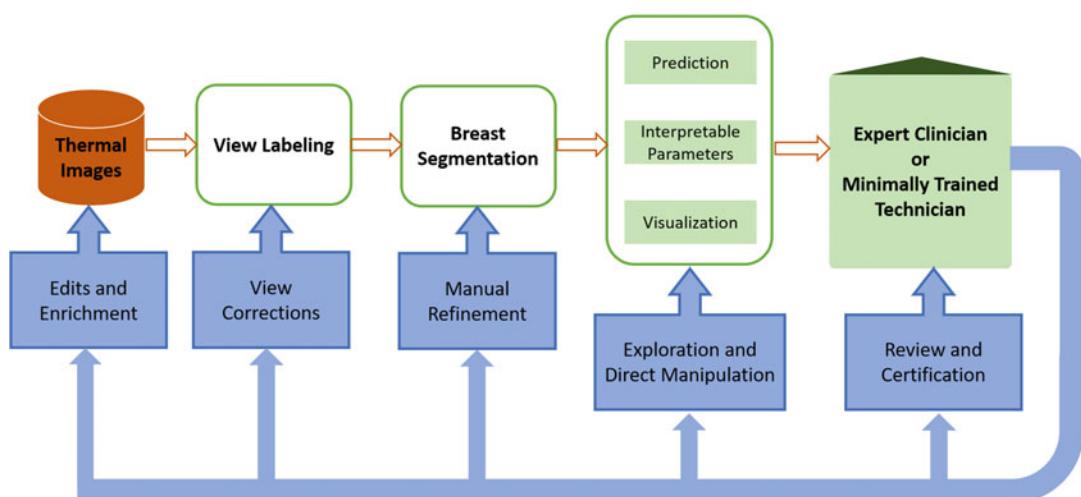

Fig. 5 A block diagram showing different AI modules with cyclic feedback in automated breast thermography for improving clinical interpretation

This need for interpretation also questions the usage of deep learning as it might be difficult to explain the predicted outcome. Though the activation maps, as discussed in [52], are improving the interpretability of deep learning, proper validation needs to be done for their accuracy and implications on interpretation.

In addition to the potential applications of AI for breast thermography as discussed in section “[Artificial Intelligence for Breast Thermography](#),” breast thermography was used for treatment monitoring [25], bio-heat simulation [20], and cancer subtype determination [18]. However, the results are preliminary and there have not been any clinical studies validating these applications. Further, transfer learning can be explored to check if ML classifiers trained with breast thermography data can be used to validate the feasibility of automated thermography for the detection of other cancers such as oral cancer, thyroid cancer, and skin cancer. At last, there is still a long road ahead for automated thermography; much improvement, validation, and large-scale clinical studies are needed before its implementation into clinical practice.

Conclusion

Breast infrared thermography has benefits of low-cost, radiation-free, noninvasiveness, privacy awareness, and portability. These advantages could become a boon especially to low- and middle-income countries. Subjectivity and potential misinterpretation with breast thermography have led to stringent restrictions on its usage and poor adaptability in the medical community. However, the advancements of infrared detectors when combined with the recent developments in Computer Aided Diagnostics (CAD) on thermal images show promising improvements in generating consistent and accurate results. There are a few systematic clinical studies that show the effectiveness of such an end-to-end automated CAD system for breast cancer detection. For clinical adaptation of such automated tools for assisted interpretability, it is important to evaluate these CAD systems on a large-scale diverse population.

Abstract

Computer-assisted diagnosis has yielded disease prognosis and other clinical results for early diagnosis in a rapid manner. The applications of artificial intelligence for contributing immensely toward the automated diagnosis of cervical cancer including its staging have also come through many breakthrough development phases. Evidence in computer-assisted cervical cancer diagnosis has shown encouraging outcomes and warrant categorization of the pap smear images into its relevant classes based on The Bethesda System of Classification. Both advanced machine and deep learning techniques

have been explored to yield promising results in this subject. Instance and semantic segmentation, in-depth feature analysis based on shape, color, texture features, deep ensemble model classification, etc., are some of the prominent application areas using Pap smear images. The state-of-the-art techniques reveal 99.6% highest accuracy for Pap smear image classification. In a recent study, advanced simultaneous instance segmentation and classification have been achieved on Pap smear image using a proposed deep learning model.

Introduction

Cervical Cancer and the Role of Pap Smear Test in Early Detection

Cervical cancer is one of the many types of cancer which when detected early can be successfully cured at its initial stage. It is known to be the second most prevailing cancer among women because of its high incidence rate. Researchers have found that the human papillomavirus (HPV) plays the primary role of a cancer-causing agent in most of the cases. Early diagnosis through

periodic screening tests or HPV vaccination can thus reduce the increased risk of cervical cancer to a great extent. Very often women having early-stage cervical cancer do not undergo any symptoms and only the symptoms such as vaginal bleeding after sexual intercourse or menopause or after periods, pelvic pain after intercourse, etc., are experienced in advanced stages. This is the most common reason why cervical cancer is not detected in early stage in most developing or underdeveloped countries. Lack of awareness of screening tests is also a major reason. It is also a challenge to bring about an awareness of cervical cancer and early diagnosis among women belonging to developing countries like India, where personal fear and social taboo still prevails in the economically weaker section. Some of the associated risks factors include multiple sex partners, early sexual activity, multiple miscarriage or abortion, sexually transmitted infections (STI), taking birth control pills, etc. It is very important to have a routine Pap test and receive HPV vaccination to prevent the risk of cervical cancer. Prognosis treatment generally includes chemotherapy, surgery, or radiation therapy. Cervical cancer is of two types, namely, adenocarcinoma and squamous cell carcinoma based on types of cells in the endocervix and ectocervix. Endocervix involves glandular cells while ectocervix includes squamous cells. A schematic view is shown in Fig. 1.

The Papanicolaou or Pap smear test is one of the cervical screening techniques that facilitate the identification of precancerous cells in the cervix, which can be treated before they progress into

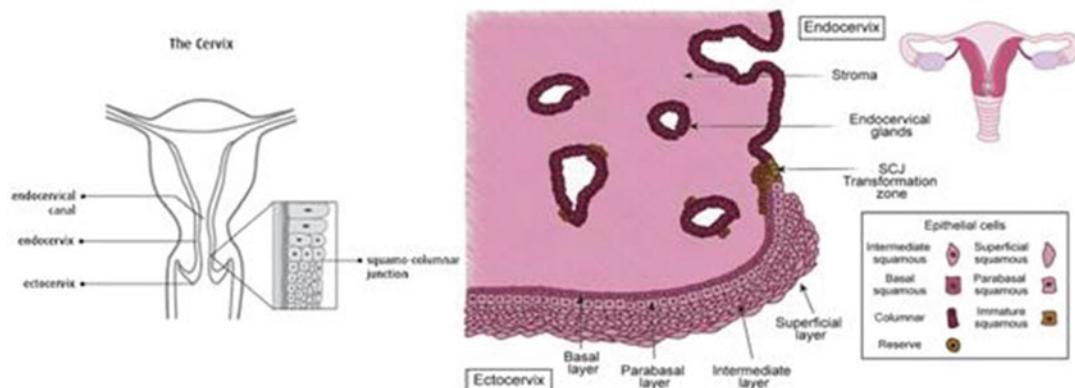

Fig. 1 Anatomy of human cervix highlighting ectocervix and endocervix regions

cancerous cells. Pap test is normally recommended for all sexually active women having age not less than 21 years. The specimen for smear is collected with the help of a speculum targeting the cells from the transformation zone, which is the highly sensitive region for abnormal cells to develop. The transformation zone features the location in the cervix where squamous epithelium cells meet columnar epithelium cells. The collected specimen is then transferred to a slide where the cells are spread over a certain small region. This region is then observed under a microscope by a pathologist, and any suspected cases are referred for a biopsy test for confirmation.

Conventional and liquid-based cytology (LBC) are the two available methods of the Pap smear test. The sample collection and technique for the preparation of the slides differ slightly for both the methods. Conventional Pap test involves taking the sample from the vagina with the help of a brush or spatula and then preparing and staining the smear on a glass slide manually by a technician who is trained for the same, with hematoxylin and eosin. The cell nuclei appear blue due to Hematoxylin stain whereas the extracellular particles and cytoplasm appear as pink as a result of eosin stain. The rest of the cellular structures take different shades, hues, or combinations of these colors. In the LBC method, the slides are prepared by a kit. It involves more steps such as the collected sample will be initially kept in a container having some additive fluids. This fluid helps in evacuating different types of debris such as mucus, blood cells, etc. The sample then

undergoes sedimentation and centrifugation at 2500 rpm for 5 min to break mucotic or blood molecules. This is again followed by staining using hematoxylin and Eosin (H&E) after which a uniform slide is obtained. An example related to sample preparation using LBC kit is shown in Fig. 2.

The two methods have their pros and cons. Whereas the LBC method is more efficient than conventional smears in providing more uniform and cleaner slides [1, 2], it involves a more elaborate and costly setup. In any underdeveloped or developing country, the economic viability of providing a certain type of medical test plays a pivotal role in its actual implementation, especially when it is utmost necessary to reach out to the prospective candidates as a screening method. However, apart from precancerous lesion detection, the LBC specimen can be used further for Human Papilloma Virus (HPV) testing, which is found to have the cancer precursor linking. Due to the manual method of preparation, conventional slides include many “debris” such as inflammatory cells, red blood cells, etc.

When adopting AI-driven automated methods for diagnosis, the choice of screening methods do not produce any diagnosis error but may require additional preprocessing and segmentation algorithms for removing the debris in case of conventional smears. Figure 3 illustrates the two cervical screening techniques schematically.

Based on the Pap test report, Squamous Intraepithelial Lesion (SIL) is reported following The Bethesda System (TBS) of Classification related

Fig. 2 (a) sample collection from patient (b) pap smear slide preparation using LBC kit (c) LBC kit

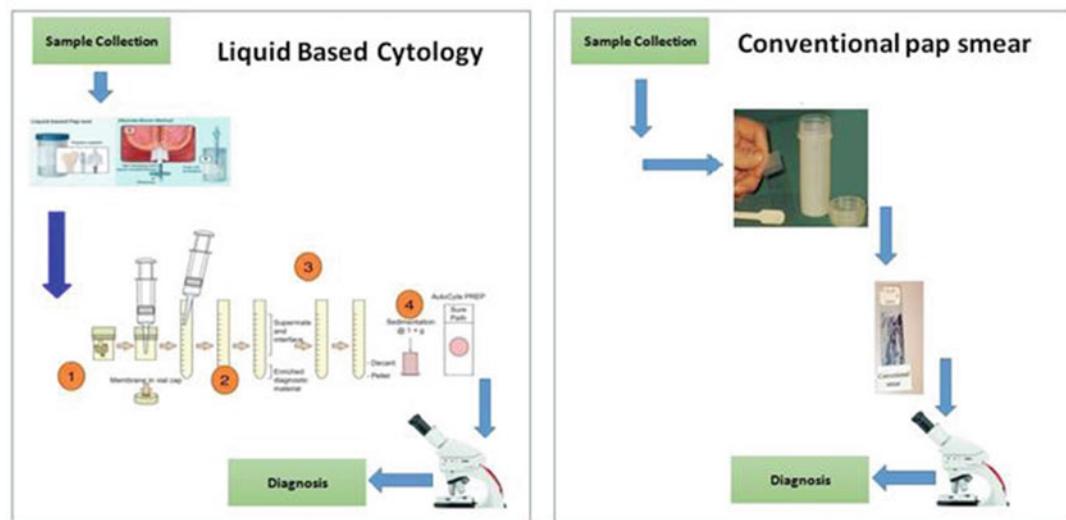

Fig. 3 Overview of Liquid-based cytology and Conventional Pap test

to cervix cancer [Nayar and Wilbur]. The system classifies SIL into the following:

1. Negative for intraepithelial malignancy (NILM)
2. Low-grade squamous intraepithelial lesion (LSIL) and
3. High-grade squamous intraepithelial lesion (HSIL)
4. Squamous cell carcinoma (SCC)

Apart from nuclear enlargement among the cervical cells, there are numerous cytological descriptions related to LSIL, HSIL, and squamous cell carcinoma (SCC) classes which are discussed well in the reference book by Gray et al. [3]. It has been established that 57% LSIL cases regress to normal while 32% LSIL cases progress to HSIL or carcinoma-in-situ and only 12% to invasive carcinoma cases.

Pros and Cons of the Automated System of Diagnosis Concerning the Manual Diagnosis

Class identification and quantification of cervical cancer by an experienced pathologist needs

rigorous observation of the individual cells, which is very tedious, time-consuming, and error-prone [4]. Considering the highly skewed ratio of pathologists/patients in most underdeveloped or developing nations, usually mass-screening following manual system involves huge processing and analysis time where the majority of cases come out to be under normal class. As an answer to this challenge, artificial intelligence (AI) via machine and deep learning have ushered into a much-needed automation aspect. Pap smear is one of the image-based screening tests, which can be integrated into automated image analysis or disease diagnosis software. Such an automated system may assist pathologists for rapid diagnosis. There are two commercially available cervical screening systems, namely, the Focal Point GS Imaging System by BD [5] and Thin Prep Imaging system by HOLOGIC, Inc. [6]. But such systems require skilled manpower and hence are not cost-effective and feasible during the mass-screening program. An automated system in such case which is more portable, robust, and low-cost can significantly contribute toward prognosis treatment. Pap smear test has helped to reduce the incidence rate of cervical cancer, so it is believed that the automation strategy will lead to a much better and rapid diagnosis.

Challenges and Advances in Automation of Pap Smear Images

Necrotic debris removal, poor staining quality or poor contrast images, and overlapped cytoplasm in Pap smear images are some of the prime research areas. Conventional pap smears often contain unwanted debris or artifacts such as inflammatory cells, red blood cells, etc., which require to be removed before automated classification. This is so because the shape, color, and texture features of individual cervical cells need to be studied and hence unwanted debris must be removed. There are some computer algorithms that address the solutions for debris removal. One such technique based on Maximally Stable Extremal Region (MSER) algorithm has been described by Bora et al. [7] for Pap smear images.

The unavailability of an indigenous dataset on pap smear images is also a major challenge for a researcher [8]. AI-driven methods delivered on indigenous dataset prove the consistency of real-time data. Another research challenge is to address overlapped cytoplasm or clustered nuclei problem for Pap smear images. Plissiti [9] and Song [10] have discussed techniques for tackling overlapped cytoplasm issue based on morphological reconstruction and graph cuts algorithms. Figure 4 illustrates general pipeline steps for automated diagnosis of cervical cancer.

Line of Action or AI-Driven Approaches for the Automation Task Using Pap-Smear Images

Pap Smear Image Database Generation

An image database plays the main role in image recognition. A well-curated image database serves as the strong pillar for any AI-based automation task. There is already a lack of indigenous medical image database in cervical cancer detection task and hence it is of concern area to prepare one manually and make it accessible to the research community. Among the very few available databases of conventional pap smear images include

the Sipakmed database by Plissiti et al. [11] and Pap smear benchmark database by Jantzen et al. [12]. Among LBC database include the liquid-based cytology pap smear dataset by Hussain et al. [13] and Cervix93 by Phoulady et al. [14]. All such database can be useful for AI or computer-assisted diagnosis, which requires interpretation of the images for different algorithms under computer vision and artificial intelligence. Figure 5 highlights pap smear sample images belonging to different classes.

In the case of Pap smear specimen, the whole slide images are first acquired using a digital microscope normally under $200\times$ or $400\times$ magnification. A minimum overlap of image sections is considered while capturing the images from the Pap smear slides. Ethical clearance has prime significance for conducting such studies.

Ground Truth Labeling

Ground truth labeling by an expert pathologist holds a key aspect for Region-of-Interest (ROI) selection. The ROI is manually confirmed by the expert, which is mandatory for accurate object recognition or image classification task. LabelMe and Icy are few existing software best suited for the ground truth labeling task.

The Region-of-Interest in a Pap smear image is mainly the cervical cells, namely, superficial, intermediate, basal, parabasal belonging to squamous epithelium layer. Apart from nuclear enlargement, numerous in-depth features related to these cells are analyzed for the final automation task.

Automated Cell or Nuclei Segmentation from Whole Slide Image

A segmentation algorithm plays a key role in extracting the Region-of-Interest. Any computer-assisted diagnosis system is significantly supported by accurate cell or nuclei segmentation. An efficient segmentation algorithm needs to consider the ROI in a whole slide pap smear image

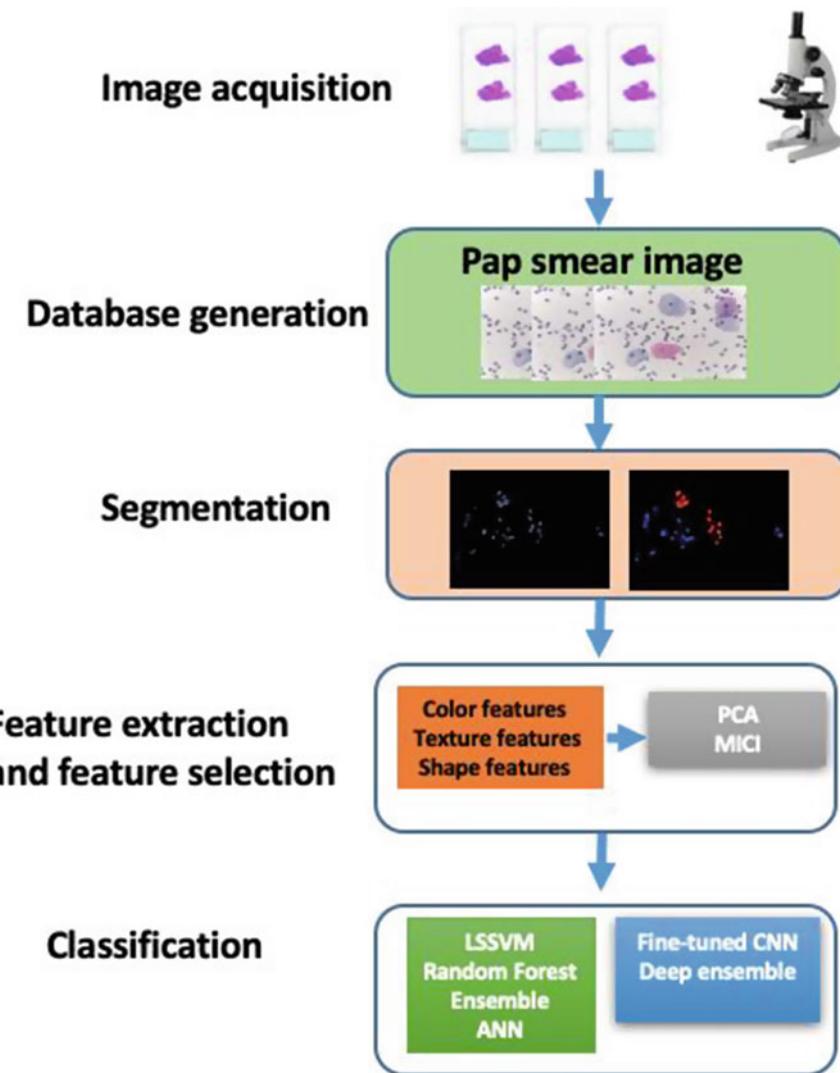

Fig. 4 General Steps in AI-driven applications for automated diagnosis

thus considering the removal of overlapped cytoplasm or background artifacts, etc., issues too.

The literature on automated segmentation using pap-smear images highlights few algorithms such as Adaptive Gradient Vector Flow [15], circular shape guided graph-based segmentation [16], Radiating Gradient Vector Flow Snake model [17], fuzzy c-means clustering [18], Particle Swarm Optimization algorithm [19], and modified Maximally Stable Extremal Region [7]. Further, there are algorithms for tackling overlapping cytoplasm issue along with segmentation

task on pap smear images such as integration of nuclei intensity or shape and texture feature by Song et al. [10] and Plissiti et al. [9]. However, all these algorithms follow different thresholding criteria often in pipelined structures. There are also some deep learning-based segmentation algorithms that follow pixel-wise classification. Deformable Multi-Path Ensemble Model based on a convolutional neural network by Zhao et al. [20], Mask_RCNN followed by conditional random field by Liu et al. [21], morphological convolutional neural network by Lin et al. [22],

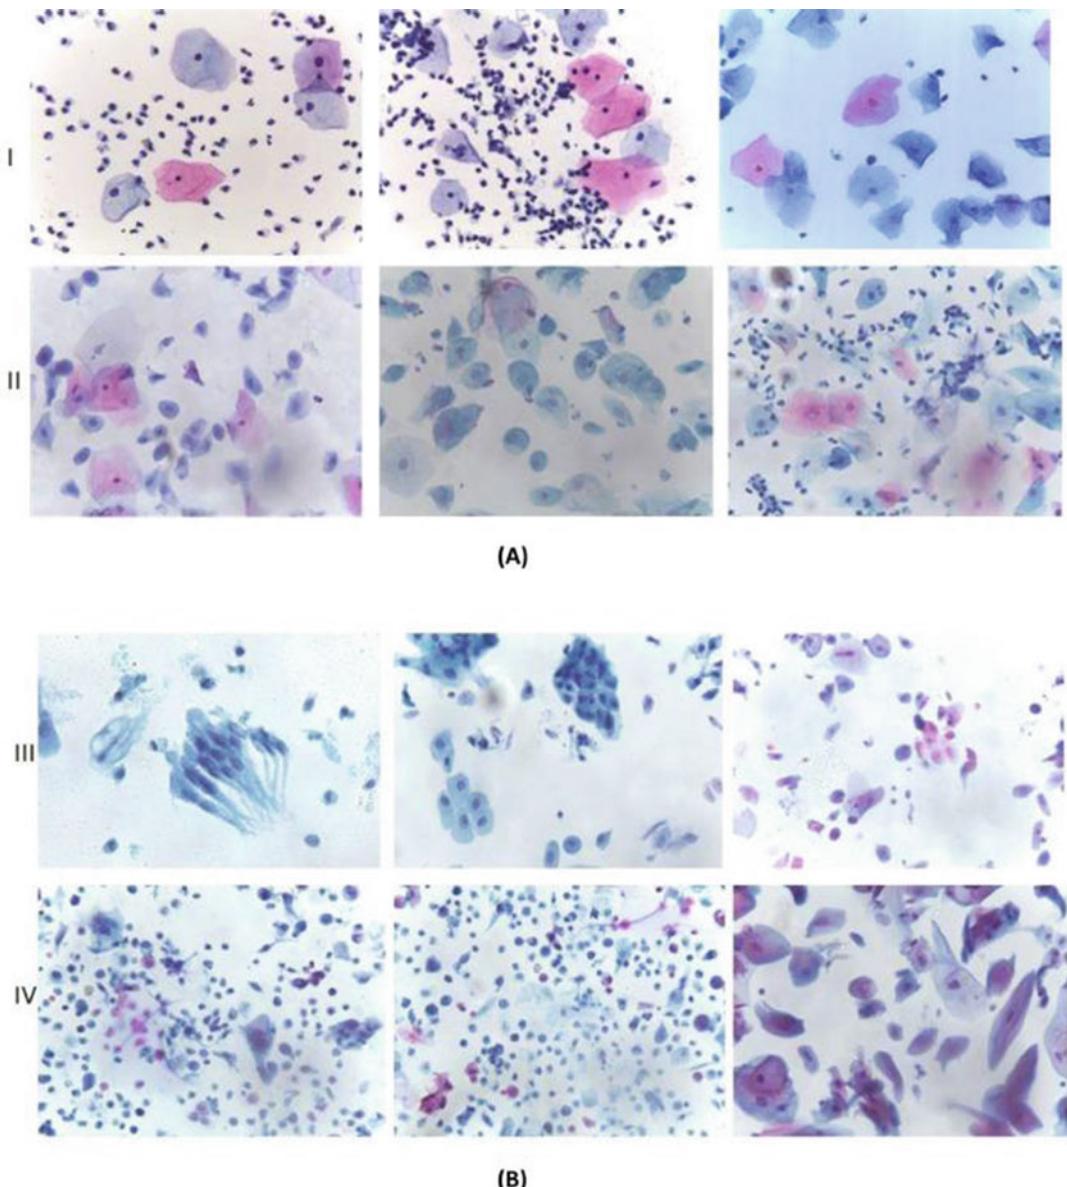

Fig. 5 Examples of whole slide Pap smear images belonging to (I) NILM, (II) LSIL, (III) HSIL, and (IV) SCC classes

Hussain et al. [23], and Song et al. [10] have addressed overlapping cell issue on pap smear images based on deep learning segmentation algorithms. Recent techniques such as simultaneous instance segmentation and classification have been explored by Hussain et al. on pap smear images. While conventional segmentation algorithms do not require input mask labeling, deep learning-based segmentation is solely dependent

on the input image and its associated mask. They require hard annotations for preparing the masks and may not be reliable for bulk computation tasks. In other words, the performance of segmentation algorithms is usually evaluated by Jaccard index or Zijdenbos Similarity Index to name a few, which compares the ratio of similarity between predicted segmented output and manual segmented output.

Feature Extraction and Feature Selection Methods

Feature extraction serves a main role for quantifying the dysplastic changes as well as differentiating the classes in whole slide Pap smear image. For this, in-depth analysis of both low-level and high-level clinical features related to the images are followed. Feature selection on the other hand involves selecting relevant feature for an increase in the classification accuracy. Generally, feature extraction and feature selection are core techniques under machine learning. While traditional machine learning classification models supports hand-engineered features, deep learning models can bring end-to-end classification outcome by learning both low-level and high-level features without selective feature engineering. The machine learning models rely on the extracted features to be fed as input parameters for the final classification task.

For quantification of pap smear images based on clinical features, one such work has been proposed by Bora et al. [7] based on cervical nuclei shape, color, and texture features. They have extracted the shape features using the MSER algorithm for quantifying the area, perimeter, eccentricity, and circularity of the cervical nucleus. The remaining texture and color features were extracted using Gray Level Co-occurrence Matrix (GLCM) and Ripple transform analysis. The literature on feature extraction process for Pap smear images highlights categorization based on different features used for quantifying the dysplastic changes. Work by Chen et al. [24] explains extraction of 13 features representing nuclear size, nucleo-cytoplasm (N/C) ratio, shape, and texture. Genctav et al. [8] have also performed in-depth feature analysis based on shape features. However, these two works failed to include color features. The color features using DFT and MPEG descriptors have been studied on pap smear images by Guan et al. [25] and Camargo et al. [26], respectively. But DFT can obtain frequency information and not time and has a bad convergence rate. MPEG descriptors neglect correlation from the pixels of neighboring blocks thus

producing the resultant image with undesired blocking artifacts. Ripple Type 1 transform proves to be a superior color feature extraction method than DFT and MPEG.

Feature selection enables reduced computational time and complexity by selecting a smaller subset of features thus retrieving the optimal characteristics of data. It also helps in the development of an efficient and compact classifier model. Bora et al. [27] have attempted one such unsupervised feature selection techniques on Pap smear images. The technique is based on measuring the similarity index using Maximal Information Compression Index among the feature vectors. The method proved to be better than Principal Component Analysis (PCA) as it is fast, do not require any search, and the feature subsets are not transformed. Initially, a feature set is partitioned into smaller clusters, which are having high similarity features but low inter-cluster similarity. Selection of a single feature from each cluster is done thus forming the resultant reduced subset.

Automated Binary or Multi-Class Classification of Pap Smear Images

Most of the machine learning models using the Pap smear images are reliant on pipelined segmentation or preprocessing algorithms, whereas deep learning model gives better classification output without segmentation. Literature works based on deep learning highlights binary and multi-class classification using single-celled (cropped-out single-cell images) as well as whole slide smear images. An accuracy of 99.6% has been achieved by Nirmaljith et al. [28] using a proposed deep convolutional neural network (CNN) for binary classification. There are many deep learning approaches for single-celled pap images such as patch-based CNN model by Gautam et al. [29], which reported 90% accuracy on binary classification and ConvNet architecture by Zhang et al. [30], which reported 98.3% accuracy. Based on experimental findings from such works, it can be observed that single-celled classification does not tackle real

problems arising from overlapped cytoplasms or clustered nuclei and hence cannot be applied to the whole-slide image. Work by Hussain et al. [31] reports an accuracy of 98.9% based on whole slide image using proposed deep ensemble models for multi-class classification. Among machine learning classifier models, Bora et al. [7] reported 96.5% accuracy using ensemble model (weighted majority voting scheme), Marinakis et al. [32] reported 96.8% accuracy using genetic algorithm-nearest neighbor, and Changkong et al. [18] reported 99.3% accuracy using artificial neural network. However, deep learning models require large-scale database for training the networks, which are not abundant in case of medical images. In such cases, data augmentation plays a crucial role in increasing the size of the image database. Inadequate data may cause overfitting or class-imbalance problem. Data augmentation supports predefined functions such as rotation, shearing, scaling, translation, cropping, zooming, flipping, etc.

Before starting the classification phase, it is very important to split the image database into training, validation, and testing sets. Strategies such as k-fold cross-validation, train-split strategy in the ratio of 80:20 can be followed here. For machine learning-based classifiers, the input feature sets extracted from feature analysis will be used whereas deep learning models prefer directly the image as input. Concepts such as sliding window protocol or image patch generation can be applied for reading the image initially. Classification using deep learning either involves transfer learning or building a CNN model from scratch. Such techniques do not require hand-engineered feature extraction. But the latter supports abundant large-scale database for training the model. Transfer learning using fine-tuned models can give promising results by pretraining a network on a large-scale natural database and then transferring the knowledge on our target domain. One such work on pap smear image analysis has been reported by Hussain et al. [31] where six fine-tuned deep learning models, namely, Alexnet, Resnet (resnet-50 and resnet-101), VGG-net (vgg-16 and vgg-19), and Googlenet have been explored.

Summary

Pap smear screening allows routine examination of the cervical lesion. A patient having low-grade or high-grade squamous epithelial can rapidly progress into squamous cell carcinoma if not detected early via routine screening tests. With the highly skewed ratio of pathologists to patients, it is very difficult to give rapid diagnosis result during mass screening campaigns. Artificial Intelligence can play a significant role in curbing out early diagnosis scenario and can ease the overall screening protocol.

Abstract

The management of infectious diseases lends itself to the application of artificial intelligence. The treatment of infection is complex, requiring the consideration of a large number of dynamic variables to inform decision-making. This includes considering organism, host, and drug factors in the context of local disease epidemiology and potential long-term consequences of anti-infective use, such as the development of antimicrobial resistance. The heterogeneity of clinical presentation caused by the same pathogen means that in many cases there is a paucity of data available to guide decision-making in real time, with individualized decisions made based on the individual patient and available data. Within this chapter we explore current applications of artificial intelligence in (i) the laboratory detection of microorganisms, (ii) the clinical diagnosis and management of infectious diseases, and (iii) the surveillance of infection. This chapter will not address other potential areas for the application of AI in infectious diseases that include anti-infective drug development, targeting infection prevention activity, and public health decision-making. We highlight potential future directions for AI in infectious diseases within the areas explored by this chapter and current barriers to wider adoption of such systems.

Keywords

Infectious disease · Microbiology · Antimicrobial resistance · Supervised machine learning · Unsupervised machine learning · Clinical decision support systems

Introduction

The management of infectious diseases is practiced ubiquitously across medicine in all countries and health economies. Infection can be the primary reason that someone is admitted to hospital or can complicate other diseases, for example, postoperative wound infection, *Clostridioides difficile* (*C. difficile*) infection following antimicrobial exposure, or neutropenic sepsis following chemotherapy.

Infectious disease management lends itself to the application of artificial intelligence (AI). Management of any infectious disease requires a large number of dynamic variables to be considered. During the course of an infection these variables are constantly changing and interacting in different ways. The clinician must consider individual patient factors, such as their age, physiological status, the site of the infection, their comorbidities, previous infections, and other medical treatments that they are receiving. They must consider the causative organisms characteristics, such as its susceptibility to antibiotics, its pathogenicity, and its ability to evade the immune system. They must consider the characteristics of any treatment that they recommend, such as the ability of an antimicrobial to penetrate the site of infection, the concentration that certain doses will achieve following the pharmacokinetics and pharmacodynamics (PK/PD) of the drug, and potential side effects to the patient. Additionally, infectious disease specialists must consider the impact of the infection and its treatment on the wider population, through the potential transmission to other individuals and the propagation of antimicrobial resistance (AMR).

Often, limited research and clinical data are available to support the evidence-based diagnosis and management of infection. Consequently, the use of antimicrobials for the treatment of infection is often inappropriate, which includes delays in appropriate antimicrobial use and overuse. Inappropriate use of antimicrobials is a key modifiable driver of AMR.

Adoption of electronic clinical decision support systems (CDSS) and the integration of hospital datasets have enhanced clinician decision-making by providing person-specific and population-level data at the point decisions are made. When used, CDSS improve the quality and safety of healthcare provided [1]. Global uptake of electronic health record (EHR), computer prescribing order entry (CPOE) systems, and mobile technology are generating greater volumes of data to support clinical decision-making in infection management. The development of new diagnostics, powerful processing capabilities, and AI provide opportunities to utilize available data in a more precise manner. This may facilitate better decision-making in infection management through the delivery of individualized, evidence-based recommendations.

Within the field of infectious diseases, a number of AI-based systems have been developed, evaluated, and reported. These range from AI tools to support laboratory diagnosis of pathogens to empirical antimicrobial selection, and to the better use of data for surveillance of healthcare-associated infections [2, 3].

Figure 1 outlines some of the potential applications of AI technology to the field of infectious diseases. Training AI to perform data cleaning functions and to deal with missing data presents exciting opportunities to improve the use of routine EHR data for decision-making. Advances in computer processing capabilities and AI algorithms could facilitate real-time prediction. AI may enhance our ability to make individualized treatment decisions for the management of infection, even when there is a limited evidence base to support decision-making. AI may also facilitate surveillance, including for the unintended

consequences of decisions, such as side effects and the potential propagation of AMR, making healthcare safer. However, many barriers still also remain in the development, implementation, and adoption of AI technologies in infectious disease management.

Within this chapter, we explore the rationale for AI use in infectious diseases. We report the current state-of-the-art AI supporting (i) the laboratory identification of microorganisms, (ii) the clinical diagnosis and management of infection, and (iii) the surveillance of diseases. We also highlight future potential applications of different types of AI and provide examples of successes and challenges to date.

Applications of Artificial Intelligence in Infectious Diseases

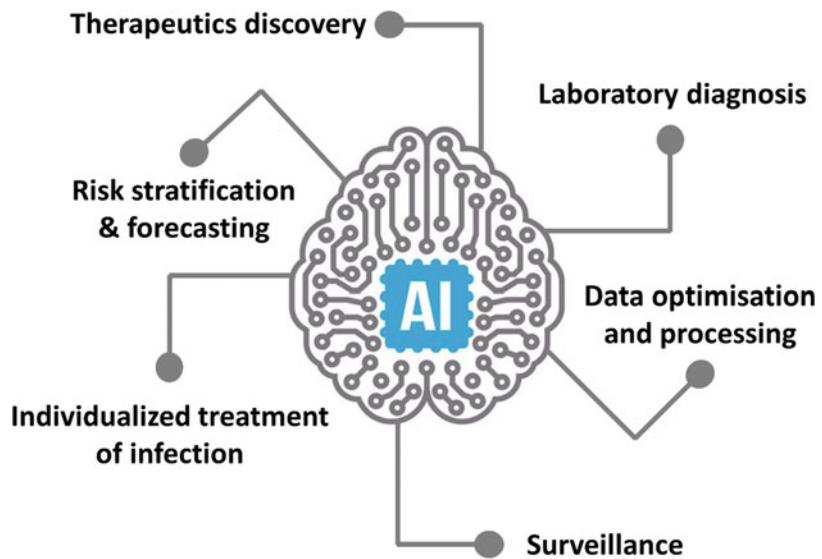

Infectious disease management is a complex process, requiring consideration of a large number of variables (Fig. 2).

Optimal treatment of the individual with infection must consider host, organism, and drug factors. This must be balanced against potential future impact on other patients and future populations through the transmission of infection and propagation of AMR.

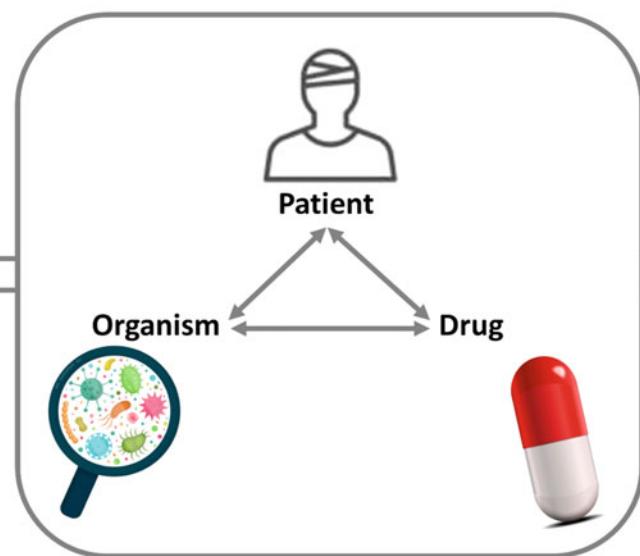

Current data available to support clinical decision-making must be carefully interpreted. For example, the microbiology laboratory can only provide in vitro data on drug susceptibility that must be contextualized to the infection that the clinician is treating. Whole-genome sequencing may provide a genotypic picture of an organism, but the phenotype being expressed in vivo may be different. Drug PK-PD in the context of the individual patient must also be considered, with different target site concentration and risk of resistance development taken into account.

Despite infectious diseases being managed across all specialities of healthcare, training in infectious diseases is limited at the undergraduate and postgraduate level [4, 5]. For example, primary care physicians in the UK who are

Fig. 1 Potential applications of artificial intelligence technology in the field of infectious disease management. Artificial intelligence can be applied to a large number of fields within infectious diseases including the laboratory diagnosis of infection, clinical management of disease, and surveillance. Furthermore, AI can support the discovery of new antimicrobial agents, better sorting of routine healthcare data and forecasting at individual and population levels

Future, global impact

Fig. 2 Interactions that must be considered when making decisions for infectious disease management. The management of infection requires consideration of a large number of variables that are constantly changing and interacting in different ways. This includes consideration of the individual patient, pathogen, and antimicrobial therapy that is

being prescribed. Additionally, the clinician must take into account factors such as local epidemiology of disease and drug resistance, the evidence available to support decision-making, risk of transmission of infection to others, as well as the potential long-term consequences of prescribing therapy on antimicrobial resistance

responsible for approximately 75% of all antibiotic prescribing are only expected to complete 2/1368 (0.14%) curriculum learning points on

antibiotic prescribing and its consequences (e.g., AMR) during their postgraduate training [4]. The application of AI to low-middle income settings

may also support decision-making in settings where infections are managed by nonphysician healthcare professionals, such as nurse-led clinics, which rely on syndromic algorithms to guide decisions on the diagnosis and management of infectious diseases.

Given the limited amount of formal training and the complexity of decision-making, the ability to provide a greater level of decision support in infectious disease management is crucial. The application of AI offers potential solutions to this broad challenge. Within this chapter, we will explore how AI has been applied to support decision-making in the diagnosis, management, and surveillance of infectious diseases. We will describe some of the current barriers to implementation and adoption and outline recommendations for the future development and evaluation of AI platforms in infectious diseases.

Artificial Intelligence for the Identification of Microorganisms

The identification and characterization of microorganisms is a cornerstone of infectious disease management. Until recently, the laboratory process had remained unchanged for nearly 100 years relying on traditional microbiology techniques to identify and characterize microorganisms causing infection. Within the last decade, advances such as matrix-assisted laser desorption ionization–time-of-flight (MALDI-TOF) mass spectrometry (MS), whole-genome sequencing (WGS), and the access to microbiota data by next-generation sequencing has driven a shift in processes within the laboratory [6]. This has generated greater amounts of clinically relevant data to support clinical decision-making during the diagnosis and management of infectious diseases. The application of AI in the microbiology laboratory provides the opportunity to better harness data from other technologies, to reduce the time between sampling and microbiological diagnosis. AI can also improve the use of traditional methods, such as microscopic imaging and bacterial culture [3, 7].

The application of AI in the laboratory can support the diagnosis of infection, the identification, and quantification of micro-organisms, and the analysis of antimicrobial susceptibility. A recent review identified 97 AI applications designed to support microorganism detection, identification, and quantification, evaluate antimicrobial susceptibility, help target diagnosis, and support disease classification and prediction of clinical outcomes [3]. Most of these AI technologies focused on diagnosis of bacterial infection (85%). Diagnosis of parasitic, viral, and fungal infection has also been reported.

Current AI technology in the microbiology laboratory often aims to facilitate the automation of repetitive tasks with the clinical microbiologists required to validate their results. Future applications for AI in this setting aim to provide systems capable of analyzing complex and high-dimensional data, such as that generated by next-generation sequencing. They also may support the development of lab-free, point-of-care technologies.

Microorganisms Detection, Identification, and Quantification

Microbiology laboratories are moving towards (semi-) automated systems. AI can be used to optimize the identification of bacteria by direct analysis of clinical samples, using volatile organic compounds for diabetic foot infection or tuberculosis, 16S ribosomal DNA PCR on respiratory samples for lower respiratory tract infections (LRTI), or fluorescent microscopic images in tuberculosis [3]. Recently, the use of Raman optical spectroscopy of a single bacterial colony in suspension coupled with a convolutional neural network (CNN) was used to identify a single species among 30 bacterial and yeast species within hours after clinical sampling [8]. This technology could support much more rapid turnaround times for organism detection and reporting than current methods employed in routine practice.

For parasitic disease, image recognition software coupled with algorithms such as artificial neural networks (ANN) and k-nearest neighbor

classification (KNN) have been applied to microscopic images of blood smears to detect *Plasmodium* species and microscopic images of fecal samples to identify intestinal helminths [9, 10]. This approach can be used to support diagnosis in settings where skilled laboratory staff are not available and also support screening of large volumes of samples in settings where staff are present.

In the virology laboratory, the application of ANN and random forest analysis has been used to analyze metagenomics sequences with classifiers prespecified to identify new putative viral sequences and support taxonomic classification from large datasets [11].

Evaluation of Antimicrobial Susceptibility

Determination of antimicrobial susceptibility is a core function of the microbiology laboratory. In vitro antimicrobial susceptibility is used to guide appropriate treatment choices for infectious disease management. It can also be used to identify patients with potentially transmissible healthcare-associated infections (HCAI), such as MRSA and carbapenemase-producing Enterobacteriaceae (CPE). While a range of methods are used to screen for and determine significant antimicrobial susceptibility patterns, the mainstay of most laboratories remains the disc diffusion method [12]. Newer methods of determining organism resistance, such as whole-genome sequencing and real-time PCR, are available. However, these only provide an organism genotype. As organisms, such as CPE, do not always express their mechanism of resistance, the reliance of genotype alone can be misleading.

Inferring the phenotypic antibiotic susceptibility pattern of microorganisms from genomic data is one of the main areas that can be supported by the application of AI [13]. AI can be applied when knowledge of the precise mutational event associated with antibiotic resistance is not complete and therefore cannot be used in genotype-to-phenotype studies [13]. Support vector machine classification (SVM) has been used to analyze *Pseudomonas*

aeruginosa gene expression (RNAseq) and the presence or absence of resistance genes demonstrating a high accuracy for predicting resistance to the broad-spectrum antibiotics meropenem and tobramycin [14]. However, worse performance for predicting resistance to other antibiotics, such as ceftazidime (81% for predicting resistance and 83% for predicting susceptibility), was observed [14]. Similar approaches have been described for *C. difficile*, *Escherichia coli*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, and *Elizabethkingia* species [3]. One study looked at combined genotypic and phenotypic data to rapidly identify the susceptibility profile of bacterial pathogens from RNAseq data directly from positive blood cultures, developing a random forest model classifier to support analysis [15]. Another study conducted a supervised classification and regression tree analysis with clinical outcome data from 58 patients to determine the optimal pyrazinamide MIC for *Mycobacterium tuberculosis* susceptibility breakpoint [16]. Similar application of AI technology has been used in the field of HIV to explore mutations associated with antiretroviral agent resistance. This could help to find unexpected mutations associated to the evolution of viral sequences in HIV and thereby pave the way for new diagnostic markers that could replace standard genotypic analyses [3].

Improving the speed and cost of current laboratory techniques has also been addressed through the development of AI technology. Using Raman spectroscopy and CNN, it was possible to differentiate methicillin-sensitive and methicillin-resistant *Staphylococcus aureus* strains (MSSA and MRSA) with high accuracy a few hours after sampling [8]. The development of amplification and melting curve analysis (AMCA) using intercalating dyes as part of a digital PCR is one novel approach to this problem [17]. Supervised machine learning can be applied to the analysis of real-time amplification data and thermodynamic melting profiles to accurately classify genotypic resistance patterns, such as colistin resistance in multidrug resistance gram-negative bacteria [17]. Further application of AMCA, supported by supervised machine learning approaches, is driving the development of point-of-care

diagnostics that do not require traditional laboratory capacity and facilities available.

Diagnosis, Disease Classification, and Clinical Outcomes

To support the diagnosis of infectious diseases, one group combined microbiological and host transcriptome data in tracheal aspirates using a rules-based model (RBM) to differentiate patients with proven LRTI ($n = 26$) and patients with noninfectious acute respiratory failure ($n = 18$) with a 100% sensitivity and 87% specificity [18]. ANN have been developed to analyze the odor (volatile organic compounds) of various clinical samples in order to diagnose urinary tract infections, acute chronic obstructive pulmonary disease exacerbations, or active tuberculosis [3].

AI technology linked with microbiology laboratory data has been used to predict the severity of disease such as respiratory syncytial virus infection. Indeed, analysis with AI identified a 84-gene expression pattern that could discriminate between children with mild respiratory syncytial virus (RSV) infection from those with severe RSV disease [19]. The identified signature was independently validated in other cohorts and could serve to develop prognostic tests for the management of RSV disease. Other similar AI technologies have been evaluated to predict the recurrence of *C. difficile* [20] or the severity of tuberculosis from WGS data or gut microbiota data.

Extreme gradient boosting has been used to analyze urine microscopy, culture, and sensitivity reports over one year in a single microbiology laboratory and develop a method of screening urine samples and classifying those that can be discarded because of a low probability of significant microbiological growth. Using 212,554 urine sample reports, including clinical and epidemiological data, the authors stated that such an application could reduce the workload by 41% [21]. However, the implementation of the system and the evaluation of its actual impact are still in progress.

Artificial Intelligence for the Clinical Diagnosis and Management of Infectious Diseases

The clinical diagnosis and management of infectious disease is challenging. It requires the combination of laboratory microbiology, clinical information, and a wider understanding of patient and regional trends in disease and epidemiology. Given that most infections are managed by healthcare professionals who are not experts in infection management, there is a need to provide expert clinical support for decision-making. Currently, support for decision-making takes the form of guidelines, clinical prediction rules (determined using traditional statistics), and clinician experience. This leads to wide variations in practice, many of which are often not evidence based.

AI offers dynamic, individualized methods of supporting decision-making for infection management based on the individual patient. Current AI technologies have been developed to focus on a range of clinical outcomes, such as the prediction of sepsis in critical care, the diagnosis of TB or surgical site infection, the prediction of virological success of antiretroviral therapy, and the selection of an antibiotic regimen.

One review identified 60 unique AI tools designed to support decision-making for clinical diagnosis and management of infection [2]. AI was used to support the diagnosis of infection (20/60; 33%), the early detection or stratification of sepsis (18/60; 30%), the prediction of response to antimicrobial therapy (13/60; 22%), the presence of antibiotic resistance (4/60; 7%), and the choice of antibiotic regimen (3/60; 5%).

Early Detection and Management of Sepsis

Sepsis is defined as a dysregulation of the body's immune response to an infective trigger that often drives multiple organ dysfunction. Steps critical to reduce mortality require early detection, determination of the probable source of the infection (e.g., urinary, central nervous system, and chest), and commencement of appropriate treatment. In

particular, delay or inappropriate prescription of antibiotics in sepsis is associated with higher rates of death and long-term morbidity [22]. The application of AI for the diagnosis and management of sepsis may be able to improve outcomes by providing tailored, evidence-based decision support to clinicians.

For development of AI to support decision-making in sepsis, critical care datasets such as the Medical Information Mart for Intensive Care (MIMIC) have provided rich data from which algorithms can be developed and tested [23]. Many AI tools designed to support the diagnosis and management of sepsis include a large number of variables, often richly measured and stored electronically within critical care databases. These include individual patient vital signs, laboratory data, demographic information, medical history, therapeutic data, and radiology plus specialist investigations. In some cases, unstructured clinical data is also added to these models.

Markov decision processes have been applied to intensive care data as part of the “AI Clinician” to explore whether AI can make individualized treatment decisions in the context of sepsis [21]. In a large validation dataset, sepsis treatment decisions matching those recommended by the AI clinician were associated with superior outcomes to divergent treatment decisions [21]. This supports the hypothesis that AI can be used to compute large volumes of data, rapidly accumulating experience that is greater than individual humans can acquire, and apply these to real-world situations to support optimal decision-making.

Diagnosis of Infection

Beyond sepsis, supporting the appropriate diagnosis of infection remains a significant challenge for clinicians. While blood stream infection and sepsis will often present with recognizable signs and symptoms, infections such as urinary tract infection or postoperative complications can often be difficult to differentiate from non-infectious signs and symptoms. These tend to drive overprescribing of antibiotics, which has a significant impact on the selection of AMR.

AI to support the diagnosis or exclusion of infection has been widely explored in a range of conditions. These range from the diagnosis of tuberculosis (TB) in outpatient settings to the diagnosis of bacterial infection in hospitalized patients, or the distinction between bacterial and viral meningitis [2].

Supervised and unsupervised machine learning has been explored for the prediction of events. This has predominantly focused on predicting the likelihood of infection using clinically available data. For example, TREAT explored the ability of causal probabilistic networks to predict the likelihood of blood stream infection and causative organism [24, 25]. Other examples include the use of decision tree classifiers using binary classification applied to blood test parameters to predict the diagnosis of *Chlamydia pneumoniae* [26] and hepatitis B/C virus [27]. SVM have been used to predict the likelihood of a patient having a positive microbiological result within 48 h of routine blood tests, which successfully inferred the likelihood of infection in a prospective evaluation of a cohort of patients admitted to a hospital in London, UK [28].

Prediction Tools

Wide variation in host, organism, and drug factors plus traditional delays in the determination of infection type and susceptibility profile mean that antimicrobial therapy is often empiric during the initial phase of therapy. Once targeted therapy can be confidently delivered, the large number of remaining unknown factors mean that confidence in outcome, determination of length of therapy, and final outcome/long-term sequelae cannot always be predicted. Wide heterogeneity and lack of experimental data means that the clinician will often rely on experience or unsupported, but widely accepted “clinical rules,” such as treatment for 5, 7, 10, or 14 days.

In the outpatient setting, ANN have been applied to predict treatment success including the virological response to HIV and HCV therapy [2]. These tended to analyze treatment history, viral genotype, and medical history. Treatment

history was limited to previous HIV or HCV therapies but not to other drugs that the patient might have been taking. SVM, random forest, and least absolute shrinkage and selection operator (LASSO) regression have been used to predict treatment outcome in TB using demographic data (e.g., education level and homelessness), TB history including constitutional symptoms, treatment, and structured data from the chest radiograph (e.g., size of cavity) [29].

In the hospital setting, *C. difficile* colitis and disease recurrence have been predicted [2]. AI including decision trees and regression techniques have been explored for personalized prediction of baseline antibiotic resistance in UTI [30] and treatment history of patients with positive blood cultures to predict baseline susceptibility to ampicillin, ceftriaxone, and gentamicin [31].

Antimicrobial Selection

Antimicrobial selection is traditionally guided by local prescribing policy. This is determined using local antibiograms, clinician experience, and probable causative organisms for the type of infection. AI can provide individualized recommendations, taking into account a much greater number of factors than the ones currently used to determine antimicrobial guidelines.

Current AI systems for antimicrobial selection have focused on choice of the optimal individual antibiotic regimen in bacterial infections and anti-retroviral treatment for HIV [2]. To date, these systems only focus on selection of the optimal antimicrobial agent, but have not explored route, dose, or duration of treatment. These systems have tended to use data routinely available in the hospital setting.

A notable example of AI used in clinical infectious diseases, with high-quality data to support its application, is the TREAT system. TREAT used causal probabilistic networks [24, 25]. A cluster randomized control trial was undertaken across three hospitals with the primary outcome measures of appropriateness of empirical prescribing. A secondary analysis of 180-day

survival following treatment was also explored. For influence of AI on the appropriateness of empirical therapy compared to detected organisms' sensitivity, TREAT demonstrated a 9% improvement in appropriateness of prescribing. However, once findings were adjusted for medical ward clustering and site, using multivariate regression, the findings did not reach significance. This may have been partly due to under powering of the study, or financial and time constraints. Furthermore, assessment of 180-day survival demonstrated a significant benefit from the use of AI on per-protocol analysis (6% increase in survival, $p = 0.04$). Statistical significance was not reached on intention-to-treat analysis. These findings suggest that clinical uptake of interventions may have been a contributing factor, along with appropriate powering of the cluster RCT.

Causal probabilistic networks, or Bayesian networks, are an attractive option for the utilization of machine learning in medicine. They facilitate the incorporation of qualitative and quantitative variables to model uncertain knowledge [32]. However, a major problem of these types of knowledge-based systems are that they require the construction of large, complex decision trees. In the case of TREAT, this comprised over 6000 nodes [24, 25]. The complexity of these type of system leads to problems transferring them into clinical practice as there is wide heterogeneity in infrastructure and data availability [32]. Therefore, at present these types of tool are challenging to develop, implement in practice, and require large amounts of information and technical skill to maintain [34].

Alternative methods have been explored to support antimicrobial selection in practice. Case-based reasoning (CBR) uses knowledge-based systems. CBR aims to solve a new problem by adapting a previously successful solution to the current problem encountered [34]. CBR aims to address many of the challenges associated with knowledge-based systems, including:

1. CBR does not require a defined model like causal probabilistic networks. Therefore, data collection simply relies on the extraction of case histories.

2. Implementation of CBR requires the identification of significant features within a case, as opposed to creating an explicit model.
3. CBR facilitates large volumes of information to be managed by applying database techniques. Furthermore, it provides greater flexibility when working with sparse or incomplete datasets.
4. CBR learns through cases that it acquires, which makes maintenance of such systems easier than model-based systems.

CBR has been used widely in the field of medical decision-making including antibiotic decision-making in intensive care [33, 35–37], radiology, psychiatry, chronic disease management, hepatology, and cancer.

CBR for infectious diseases has been applied and prospectively tested in clinical practice [38]. The use of a CBR CDSS recommended narrower-spectrum antimicrobials, while maintaining a similar appropriateness of prescriptions recommended by clinicians in practice [38]. Experimental evaluation of this type of approach is yet to be described.

Future applications of AI in clinical diagnosis and management of infectious disease must be developed in diverse health settings, including primary care and low-middle income (LMIC) settings that are currently underrepresented. Developed tools must be embedded and integrated with current electronic health record technology specific to the clinical setting that is it deployed within. Future studies should aim to report clinical outcomes following sustainable use in routine clinical care and focus on both patient outcomes (i.e., mortality) and long-term benefits on AMR and HCAI.

Artificial Intelligence in Surveillance and Infection Prevention

Infection prevention and control (IPC) is as important as the laboratory diagnosis and clinical management of infection in promoting optimal patient outcomes and preventing long-term consequences of AMR and HCAI. The use of AI in IPC has generally been applied to surveillance and diagnosis/detection of infections and outbreaks. The use of AI in the microbiology laboratory

have already been described above. With the application of point-of-care technology, this provides a mechanism for leapfrogging many of the current barriers to the application of surveillance in low-middle income settings [39].

Surveillance of infection, such as HCAI, lends itself to the application of AI. Surveillance of HCAI requires the analysis of data from multiple different databases to prospectively monitor trends, identify outbreaks, predict future events, and detect networks of transmission [40]. For common HCAI, such as *C. difficile*, AI has been applied to EHR data to predict the risk of infection and respond to the dynamic nature of healthcare [40].

To support screening for potentially transmissible diseases, deep learning image recognition has been applied to the analysis of chest radiograph to support the diagnosis/detection of pulmonary tuberculosis (TB). Automated systems may greatly support current mechanisms of IPC. Furthermore, their application to screening of images in settings where there is limited specialist radiologist input may facilitate the streamlining of cases to those only where there is diagnostic uncertainty/a high likelihood of TB being present.

Current challenges in the application of AI to surveillance systems involves the lack of standardized data being collected for a wide range of infections. This data is often not rich enough for significant systems to be applied outside of individual institutions or regions making translatability challenging. Moreover, variations in microbiology laboratory practice make standardized tools that work across different regions difficult to develop.

Challenges and Limitations in the Development and Application of Artificial Intelligence in Infectious Disease Management

While AI has the potential to enhance infectious disease management, a number of barriers remain to its adoption. These can be classified at the micro (individual health professional) and macro (health system and beyond) barriers. A common concern with AI is the widespread, unregulated training of these systems during their development, as well as

the potential of unsupervised learning upon implementation. Insufficient attention to the human-computer interface as part of clinical decision support at the design phase means systems are ergonomically weak.

At the macrolevel, there is currently very little guidance and regulation governing the training and development of AI in infectious diseases and medical microbiology. As with many other fields, dataset size, generalizability of training sets, and evaluation of systems before deployment are often left to the discretion of the developer, with safety and translatability to other clinical situations often unclear. This lack of regulation has led to concerns about adoption of such tools, providing a major barrier to successful implementation. At the microlevel the unsupervised nature with which systems can potentially continue to learn in the absence of human oversight means that errors input into the system may be propagated and go unnoticed unless supervised and curated, leading to patient societal harm. Currently, there is little thought to how these potential unintended consequences of AI will be monitored for and how systems will respond to them when they are identified.

Current media attention around the use of AI has attracted some strong opinions in terms of safety in healthcare. From the patient perspective, confidence in computer-driven decisions regarding healthcare is mixed. In a recent study exploring public confidence in computer-driven decisions, citizens reported that while computer-supported decision-making had potential benefits in improving accuracy, interaction and oversight from a medical professional remained important [41]. This was reported by participants to be based on the realization that human interaction cannot simply be based on evidence, but must also take the social and cultural context in which the decision is made into account. For antibiotic prescribing, many potential end users are currently uncomfortable about the way that decision support will be implemented [41], especially when the system may tend towards a more societal perspective than that of the individual, as is often the case when decisions are made for infection management.

Development, Implementation, and Adoption

Many of these described barriers can be addressed through the engagement of healthcare professionals, patients, and carers early in and during the development of such tools. AI development emphasizes participatory approaches because, in essence, it aims to simulate capacities of human intelligence. However, while codesign of the system to improve design and the functionality aspects are important, it may not be enough. Codesign must also alleviate concerns and help to promote greater transparency in how the recommendations being made by the system have been developed and are utilized to augment human decision-making. This will promote better understanding of the role of these tools in healthcare and help foster the realization that although human subjectivity can be removed from prediction, it cannot be removed from the practice of evidence-based medicine. This is because the individual, social, and microbiological context in which a decision is made requires the human decision-maker.

For the clinical decision-maker, AI tools remain notoriously difficult to interpret. While visualization tools may highlight the combination of variables that led an algorithm to make a particular prediction, healthcare professionals must be aware that, like humans, AI can easily be affected by systematic biases (e.g., scanning device, patient's age, etc.). Special pedagogical efforts must thus be made in both scientific reports and in the clinics to keep a healthy skepticism when it comes to AI results. Second, the lack of large healthcare, clinical, imaging, and genetic public repositories leads each institution to locally develop its own analytical pipeline on its own small dataset, which significantly limits the generalizability of the results. While this issue is not specific to AI technology, the ability of modern algorithms to encompass heterogeneous datasets should drive us to both share the de-anonymized raw data used in each clinical study and favor the development of large cohorts from which AI technology can be applied. Furthermore, AI technology must be evaluated using randomized control methodology using clear outcome

measures such as mortality to further support their application in practice.

Conclusion and Recommendations for Artificial Intelligence in Infectious Diseases

AI technology has great potential to support better decision-making in the management of infectious diseases. This ranges from enhancing the ability of the microbiology laboratory to better and more rapidly identify pathogens to helping clinicians make optimal, individualized treatment decisions for specific infections. To recognize the potential of AI in infectious diseases many of the general limitations in the development and implementation of AI, discussed elsewhere in this book, must be addressed. Additionally, for infectious diseases, the development of AI technology must take into account the application of tools in low-middle income settings and utilize datasets that allow the system to control for many of the systemic biases that are observed in current approaches. Implementation of AI technology must be supported by robust, randomized control trial evidence that looks at hard outcomes, such as the impact of AI on patient mortality, taking into account the behavioral and nontechnical factors that play a large role in the diagnosis and management of infectious diseases. Finally, with the ever-expanding generation of electronic data and methods of being able to utilize this to support decision-making, we must also consider the ethics of failing to use this data to support decision-making if a clear benefit from the application of AI technology is demonstrated.

John Last defined epidemiology as “The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems.” It underscores that epidemiologists are not concerned only with disease but with health-related events, and that ultimately epidemiology is committed to control of disease. Initially focused on the disease, the objects of investigation in epidemiology now correspond to any

factor that may influence the state of health of the human being, i.e., biological, clinical factors, in relation to the physical, mental, and social environment. Regardless of the field considered and the type of epidemiology (clinical or population based) referred to, the basic brick of epidemiology remains the data. The data must be as valid and precise as possible to ensure validity and reliability of results. The use of artificial intelligence and its methods can occur at different levels and in several areas of epidemiology. At present, we can consider three main use cases. First, AI can add to a long tradition of using more or less sophisticated observational data analysis methods. It has a role to play in causal inference. Second, AI can intervene at the stage of reconciling and structuring siled and varied data sources. Finally, AI can simply bring new ways of exploring and using data, such as sentiment analysis applied to social media. These three use cases are found, in practice, often intermingled and do not necessarily meet in isolation from each other. The private sector (intermediation platforms) and policy makers are the two other actors involved in the forms that AI uses in epidemiology will take.

Introduction

The origin of epidemiology lies in the idea first expressed more than 2000 years ago by Hippocrates that environmental factors can influence the occurrence of diseases [1]. The word epidemiology comes from the Greek word “epi,” meaning on or over, “demos,” meaning people, and “logos,” meaning the study of. In other words, the word epidemiology has its roots in the study of what happens to a population. Multiple

definitions have since been proposed. John Last, in the *Dictionary of Epidemiology* [2], has defined epidemiology as “The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems.” Last’s definition underscores that epidemiologists are not concerned only with disease but with “health-related events,” and that ultimately epidemiology is committed to control of disease. As such, epidemiology constitutes a basic discipline of public health since it aims to quantify the health status of populations in order to identify its causes and to propose interventions to improve the health of the population concerned and to evaluate them. Depending on the population concerned, a distinction can be made between clinical epidemiology (“clinical research”), which is concerned with populations of “patients” with a view to improving the medical management of these patients, and population epidemiology (“classical” epidemiology), which is concerned with the general population with a view to developing public health strategies.

The different fields of epidemiology are characterized by the nature of the questions to be answered and the methods used to answer them. Classically, a distinction is made between: i) descriptive epidemiology, the purpose of which is to describe the frequency and distribution of health phenomena or health determinants in populations, according to human, spatial, and temporal characteristics. The purpose here is to estimate surveillance indicators such as prevalence, incidence, and survival; ii) analytical epidemiology, the purpose of which is to identify and estimate the link between exposure to certain factors and the subsequent occurrence of disease (or health event). The object here is the search for determinants, to study the patterns, the “causes”; and iii) evaluative epidemiology, which aims to test the effectiveness of a health program or policy intervention on the disease or health condition under study.

Initially focused on the disease, the objects of investigation in epidemiology now correspond to any factor that may influence the state of health of the human being (i.e., biological, clinical factors,

in relation to the physical, mental, and social environment).

Regardless of the field considered and the type of epidemiology (clinical or population based) referred to, the basic brick of epidemiology remains the data. The data must be as valid and precise as possible to ensure that they measure what they are supposed to measure (validity) and limit measurement error (reliability).

Whether it is to describe a phenomenon, to understand mechanisms, or to make inferences, evidence in epidemiology is based on the protocolized/standardized production of data. Protocols specify the volume and the scope of the data to be collected. The logic consists of working with a limited set of data that are precisely characterized and traced, and even certified. It is therefore the quality of the data, and what it allows for an increase in generality, that is prioritized. It is a question of specifying a set of criteria upstream of the investigation in order to characterize the population studied, the values investigated, and to ensure that the measures are likely to respect its characteristics.

In clinical epidemiology, these data most often come from clinical and biological data collected routinely in medical records, for example, or ad hoc through the implementation of specific studies (clinical trials, cohorts), or from specific systems that ensure the validity and exhaustiveness of the data, such as cancer registries. In population epidemiology, data can also come from trials, registries, or cohorts, which have the advantage of including all the desired data but for a restricted population (the one included in the study) and from data routinely collected in different systems, such as medico-administrative data (reimbursement of expenses/medical acts), administrative data (civil status, taxes, family allowances, retirement, etc.), and environmental data (air pollution), which are likely to provide information on the living conditions of a very large part of the population (or even the entire population). The limitation of these data is that they have not been constructed to study the health of populations, which raises questions about their validity and reliability, and these different databases were not constructed with the intention of being

interoperable with other databases. Access to these databases, particularly at the regulatory level, is also an issue.

Once these data have been collected, they are then modeled. Epidemiology has always used numerical methods to produce results, whether to help describe, understand, or evaluate parameters hidden from observation, and to help with experimentation [3]. Concerning the modeling used, we can distinguish classical regression methods such as multiple linear, logistic regression, and survival models, and also more sophisticated methods (causal approach), some of which are now labeled “machine learning” (hierarchical classification, factorial analysis, component analysis, canonical correlation analysis, and Bayesian networks). The definition, collection, and analysis of data is therefore at the heart of epidemiology, which makes it a discipline particularly concerned by the development of what is called massive data and artificial intelligence.

The development of data digitization, including in the field of health (biology, clinical, and imaging), connected tools, and social networks, opens a new era of availability of massive, varied data, never known before. The term big data is thus used, which is classically associated with the 3Vs, namely volume (which accounts for the massive use of data), variety (which relates to the heterogeneity of content), and velocity (which is associated with the speed of data processing) [4]. Big data may therefore be defined as the rapid processing of massive heterogeneous data that calls upon approaches, some of which are part of what is known as artificial intelligence (AI).

These massive data are opportunities to better describe, understand, and intervene on the health of populations, and therefore a tool for epidemiology and its development. As stated by Flahault et al., the main objective of the data science “is to develop mathematical models and computational solutions able to reason and interpret massive amount of data where typically the information sought is quite sparse” [5] and to make it possible to apprehend and make intelligible an ever-increasing amount of information that humans cannot condense and understand in a meaningful way [6].

But AI's immediate usefulness is not guaranteed, however: Electronic health records were predicted to transform primary care for the better, but led to unanticipated outcomes and encountered barriers to adoption [7, 8]. AI could also harm, for example, by exaggerating racial, class, or gender biases if models are built with massive but biased data that are not representative of the entire population, or used with new populations for whom performance may be poor [9].

Present Advances

The use of artificial intelligence and its methods can occur at different levels and in several areas of epidemiology. At present, we can consider three main use cases:

- Epidemiology has a long tradition of using more or less sophisticated methods of observational data analysis. The so-called AI methods extend and enrich this tradition, and can be compared to more classical methods, when they are used to pursue the same goals, for example, to identify associations between an exposure and a health outcome.
- The profusion of data, as well as the diversity of their collection format (voice, text, sound, etc.), and also the real-time nature of the collection of this data mean that AI methods can impose themselves as natural reference methods, for uses or analyses significantly different from what epidemiology has produced until now.
- Finally, epidemiology is often seen as intervening at the stage of the analysis of data and their interpretation. This same diversity of sources and types of data, their heterogeneity, and their distribution in many more or less partitioned systems require methods upstream of the analyses. These methods are typically AI methods, and make it possible to collect, extract, and structure data according to different models, so that they can then be used by epidemiologists.

These three use cases are found, in practice, often intermingled and do not necessarily meet in isolation from each other. We present the

illustration through several examples below: the use of AI for the organization of data, the surveillance of diseases and health outcomes, pharmacovigilance, sentiment analysis of social networks, and finally the use of data and model-driven approaches [10].

Collecting Data for AI Development and Developing AI for Data Collection

Data are the building blocks useful for epidemiology, but also for any learning of an AI or a model in general. Thus, it is necessary to be able, on the one hand, to collect and annotate data to train the AI algorithms which will be useful for epidemiology, and on the other hand, the AI algorithms will also be able to be used to help this data collection.

AI to Collect, Classify, and Structure Data

AI can be used to match data with each other from separate databases, especially when the data is anonymized and a probabilistic matching needs (data linkage) to be performed. This may be the case, for example, between cohort databases, electronic health records (EHR), medico-administrative databases, or even open data. A particular use of AI named federated learning is developing more and more, in order to overcome a double problem: that of the distributed nature of data and that of the robust learning of algorithms.

Thus, AI can intervene to reconcile heterogeneous sources or formats toward a single and shared structured model: This can be the case from electronic health records, for example [11].

The use of interoperability standards as an intermediate or complementary solution, overlaying already available data sources, is developing to allow a shared research framework. This is the case with the common data model from the OMOP initiative (Observational Medical Outcomes Partnership [11]). Finally, a third possibility, that of not bringing together the data in one and the same database, for reasons of properties, rights, and privacy: It becomes possible to carry out the training of AI algorithms useful for epidemiology by “distributing” these algorithms to the different sources (for example: in each

participating hospital). These techniques are called federated learning. They have already been used in several cases, such as the prediction of side effects related to drugs, apart from electronic health records [12]. Xu et al. define federated learning as “a mechanism of training a shared global model with a central server while keeping all the sensitive data in local institutions where the data belong, provides great promise to connect the fragmented healthcare data sources with privacy-preservation” [13]. This emerging technique seems to be able to overcome the majority of the obstacles encountered when learning AI from distributed sources, and the performances of the algorithms thus obtained seem to be able to be almost similar to those obtained from a centralized database: The Sheller et al.’s experience showed that federated learning based on the exploitation of data from ten establishments made it possible to obtain models of quality similar to those obtained by centralizing the data (99% of the model quality with centralized data) [14].

AI to Reconstruct or Virtualize Experimental Designs

The use of multivariable models in epidemiology, applied to observational data, tends to neutralize as much as possible the influence of confounding factors, and therefore to approximate a controlled experimental design, as in clinical trials. What we could not impose at the time of data collection, we try to recover by the sophistication of the analyses and models used. One promise of AI is to go even further, by recreating from massive amounts of data, databases that virtually reproduce the conditions of a controlled experimental design. We are talking about virtual randomized controlled trials [15, 16]. These approaches remain for the moment essentially theoretical.

Disease and Health Outcomes Surveillance

Public health surveillance may be defined as the ongoing systematic collection, analysis, and interpretation of data, closely integrated with the timely dissemination of the resulting information

to those responsible for preventing and controlling disease and injury [17]. Multiple sources of data have become usable for public health surveillance, for example, mobile phones, online searches, social media, credit card transactions, wearable and ambient sensors, electronic health records (EHRs), medico-administrative records, and pharmacy sales.

It can be expected that the “rapid development of data science, encompassing big data and AI, and the exponential growth of accessible and highly heterogeneous health-related data should enable health authorities to respond readily to health crises” [18]. By using traditional approaches (for example, from paper-based medical records), it could take weeks to find out that an infection was emerging somewhere in the world. The access and use of data now generated almost continuously from hospitals or other medical facilities and devices constitutes theoretically an opportunity to understand, predict, and combat diseases at unprecedented speed.

Some studies have already shown the interest of using a large number of queries on Internet search engines to detect earlier influenza epidemics in the USA [19]. The pandemic of COVID-19 is an ongoing example of the importance of data to face the epidemic. This pandemic shows us how much data on mobility via cell phones, use of public transport, leisure facilities, and social networks can be used to control the epidemic. The same is true for wastewater data, which can be used to locate places that are more exposed to the virus. All of these data enable the development of more accurate prediction models, which in turn can be used to better guide public decisions.

We can be confident that public health surveillance will use this type of approach in addition to the systems currently in place for the surveillance of infectious diseases but also chronic diseases. However, it is important to keep in mind that these tools will not replace existing surveillance systems. It has been shown that Google Flu Trends, which estimated prevalence from influenza-related Internet searches, drastically overestimated peak flu levels compared to traditional surveillance data, leading Google to finally close

their website in August 2015. Other experiments, still on influenza, relating more generally to syndromic surveillance, were carried out based on the analysis of social networks, for example, Twitter, with apparently better results, which remain to be replicated and confirmed [20]. These methods can thus complement, but not replace, traditional epidemiological surveillance networks [5].

The unprecedented development of connected health tools and applications already offers the possibility for those who benefit from these tools to know and monitor certain elements of their health status (weight, blood pressure, heart rate, glycemia, calories ingested and expended, etc.), and therefore in theory to be able to detect abnormalities and disturbances before the disease sets in. We can anticipate that the development of this type of tools will increase in the next years, allowing us to know more and more elements of our health. The already preponderant role of this type of tools in health surveillance was highlighted by the COVID-19 epidemic for which several applications have been developed to know its status with regard to infection and exposure to contact cases.

The question of the validity of these tools to measure what they are supposed to measure, of their access for all, of the storage and secondary use of the information coming from these tools most of the time developed by private companies is a major issue.

Pharmacovigilance

Pharmacovigilance may be defined as the collection of information useful for monitoring drugs, including information on suspected adverse reactions when a drug is used. It is classically based on the careful analysis of reports by doctors to public health authorities and/or pharmaceutical companies. In normal practice, it takes time after a medication has been put on the market before the medication is found to have caused an undesirable event. The current pandemic underscores the need and importance of accurate, up-to-date information to enable us to judge the safety and risk of vaccination against

COVID-19 almost in real time. The use of a variety of databases, from electronic medical records to medico-administrative databases and Internet, can constitute an opportunity to achieve this goal and to identify potential side effects more quickly.

Previous studies have already shown the ability of using AI approaches to detect evidence of unreported prescription drug side effects. For example, White R et al. were able to find evidence, by using automated software tools to examine queries handled by six million Internet users taken from Web search logs in 2010, that the combination of an antidepressant, paroxetine, and a cholesterol lowering drug, pravastatin, caused high blood sugar [21].

The application of such methods requires extensive expertise in computer science and statistics that was not required by standard adverse event monitoring. It is difficult to imagine that these methods and associated tools are not destined to be used more and more in the future development of pharmacovigilance. However, these tools will not replace human pharmacovigilance, but they could be of considerable help.

Sentiment Analysis and the Use of Social Media as Alternative Data Source and Data Processing Method in Epidemiology

Virtually, the development of AI makes it possible to process any form of digital data, especially if it comes in large volumes. A new use in epidemiology is therefore to take advantage of new sources of data: in theory, any data from the Web, in practice, data from forums or, more generally, from social media. These networks can be used and their content analyzed in different ways: They can allow the active or passive recruitment of people for the constitution of e-cohorts, or syndromic surveillance.

Another approach to using AI in epidemiology is the analysis of content combined with volume and uses linked to social media. In particular, sentiment analysis is increasingly used.

Recruitment of E-cohorts and Online Syndromic Surveillance

Faced with the cost and the necessary logistics linked to the constitution and then to the maintenance of traditional cohorts, which are increasingly large in number of people, and also because of the evolution of the means of access to people and uses, alternative strategies or complementary products are developing in epidemiology, aiming both to reach and maintain as many people as possible in the cohorts, and to reduce maintenance costs. Electronic cohorts, or e-cohorts, have therefore developed, to complement or replace, for example, cohorts based on the sending of paper questionnaires or face-to-face evaluations. Of course, the profile of the populations recruited by traditional approaches and by “2.0” approaches, as well as the way of answering the questions (and of asking them), cannot be strictly superimposed.

It is possible to go further than substituting a paper form for a Web form, for example, by recruiting people directly via social networks. Facebook is one such example [22]. Either actively: creation of a page and call to participate via the media; or passively, by analysis and selection of content and profiles obtained by data collection (for example, on patient forums).

Social Media Content and Sentiment Analysis

Textual data, especially in large volumes, are particularly suitable for analysis by AI, in the sense that a certain amount of information, the quality and relevance of which must be carefully considered, can be extracted automatically where a human operator would not have enough of a life to read everything and then synthesize. Text mining therefore consists of the analysis of textual data, from the simplest to the most sophisticated. A particular use of text mining and social media is sentiment analysis. It can be defined as follows: determine whether the feeling given off by a sentence is positive or negative [23]. The main difficulty of analysis lies at the very heart of the use of language. Among other factors, the feeling of a sentence depends on context and language, as well as on the person who wrote it. Sentiment

analysis can be based on two approaches: lexical analysis and analysis based on machine learning. In both cases, AI is strongly associated with it. Both methods can be combined [24]. Lexical analysis will use semantic analysis, based on a classification of the sentence studied against dictionaries, for which words or sentences deemed to be similar have been annotated in terms of negative or positive polarity.

Several examples of social media analysis can be mentioned. For example, in order to better understand the representations and behaviors vis-à-vis vaccination. Authors used Twitter to update the semantic web of positive, negative, and neutral feelings about vaccines [25]. Beyond this static representation, it is possible to study the relationships between getting vaccinated and epidemic dynamics (Disneyland measles outbreak 2015 in California, in [26]). The results can be used to guide public health policies and adapt vaccination campaigns and communication around vaccination according to the representations and behaviors of populations. Another similar example concerns the Middle East Respiratory Syndrome (MERS) outbreak in Korea in 2015 [27]. Epidemiological indicators can therefore be derived from these analyses of social networks. However, like any indicator, these “digital” indicators require rigorous validation [28].

Conversely, social networks can be used as a communication channel for the dissemination of public health messages [29].

From Data to Decision: Data-and Model-Driven Knowledge and Decision in Epidemiology

The emergence of AI in any field always raises the question of what task will be automated, and therefore, to what extent AI will act as a substitute for humans. An optimistic view of the use of AI resonates with that of industrialization, then of automation and robotization of assembly lines in factories, and which would be that AI would free humans from tasks “unworthy” of his condition and would allow him to concentrate either on

tasks specific to human skills or on his hobbies. In epidemiology, then in its possible uses in public health, the place of the human being intervenes at all stages, from the collection of data to the interpretation of the analyses and the results, possibly the decision-making, passing by technical choices in terms of data and problem modeling.

We have seen that AI can intervene from the stages of data collection, reconciliation, and then structuring, in particular under conditions that would be difficult to access by humans in a reasonable time and resources. It can intervene at the data analysis stage, as complementary techniques to the more traditional ones used until then. It can still be placed a little further in the value-added chain of data processing: in the more or less automated choice of the “best” models (and “best” predictors), under the assumption that data-driven approaches would be more atheoretical than the choice of a model by a human operator – which remains a hypothesis at least naïve; in the automation of monitoring an entire part of the health care system and the health status of the population, triggering alarms that will require the attention of a human operator to decide whether the alarm is relevant or not; and finally, in helping, and even in decision-making in terms of public health management, directly based on the use of collected data.

The first use case is similar to 4P medicine (predictive, personalized, participatory, and preventive). We can, for example, mention the data-driven approaches to predict the occurrence of diabetic and cardiovascular diseases [30]. Some authors highlight the inability of human operators to effectively mix and synthesize large datasets, for example, data from the Global Burden of Disease study. AI is then used there to screen all the data and draw attention to potentially interesting results [31].

More ambitious, some projects and systems promise to make projections over several decades in terms of needs and use of the health system. Authors have produced such a 40-year projection model for Singapore, in order to take into account the impact of different factors such as ethnicity, social isolation, or disability [32]. Still other authors have endeavored to develop and then

calibrate an AI that they called automated time series machine learning, applied to Romanian data and making it possible to predict the health of the population over the coming years in relation to the ten most common diseases, more deadly [32].

Finally, to the extreme, some authors have taken the reasoning to the limit, sweeping aside any need for causal and explanatory models of diseases and health events, for any use of statistical inference and the setting up of controlled experiments: Data would be everywhere, would characterize everything, and its increasing accessibility coupled with the growing efficiency of AI would be enough that for any question and need for a decision, there would be an AI to answer it. This would be the “end of the theory” – here, the end of epidemiology, in its exploratory dimension and consisting in investigating the causes of the states of health of populations [33]. This vision is obviously highly contested [34].

Potential Trends and Future Challenges

The Challenges Related to Data

Since its first successes, epidemiology has still faced many challenges, in the extension of its first missions and following the natural evolution of its field of study, according to discoveries and the improvement of study methods. In particular, it is no longer possible to remain focused on an archetypal theoretical model restricted to “an exposure, a cause, a disease.” The challenges of modern epidemiology include the identification and simultaneous consideration of multiple risk factors, and also the long-term effects, whether low or high intensity, direct or mediated or resulting from interactions, or finally the notion of “personalized” medicine. The availability and possibility of combining data increasingly varied in nature and sources, the real and current possibility of secondary use of data (for example, that of hospital health data warehouses), seems particularly favorable the use of AI in epidemiology to keep it developing. However, controlling the quality of data is an imperative in epidemiology

– in reality, controlling the entire data chain: from its collection to the interpretation of analyses. The reasonable use of new data sources will have to go through the exploration and characterization of their quality: data from connected objects, behavioral data, data from social networks, etc. It is illusory to be able to directly derive robust epidemiological knowledge from the blind collection of unqualified data. In particular, the increasing secondary use of data raises the question of value of the data, the purpose for which the data has been originally produced [35]. The objective, method, and quality that guide data collection shape the information that is produced.

The potential contribution of big data and AI appears significant insofar as information on a wide range of characteristics of the environment or context of life (social, economic, and cultural) can be collected and be connected with health data, for example, to develop models on social determinants of health including individual lifestyle factors, social and community networks, and general socio-economic, cultural, and environmental conditions. The underlying assumption is that in the field of health, data from several bases, with their diversity, are likely to generate information and knowledge on health and the environment which builds it. Such approach of health is relying increasingly on the use of data not specifically collected for that purpose, including data *a priori* not related to health. Interestingly, this potentially broadened approach to health research that may be facilitated by big data and AI is largely underused in practice. The notion of big data and AI remains often focused on the use of large volumes of data, often biological (genome, omic), for individual purposes. Thus, it is aimed at predictive medicine, the determination of individual risks or diagnostic decisions through the multiplication of individual biological data, for an “*a la carte*” health, popularized by the term “personalized medicine” [35]. Far from allowing us to develop a “personified” medicine [36], integrating biological, clinical, psychosocial, and environmental elements to apprehend more broadly the determinants of health of an individual [35], the development of big data in health and personalized medicine tend to lead to a reductionism of the individual at its biological dimension.

The Challenges Related to Epidemiology as an Explanatory Science: Statistical Inference and Causality

C Andersen announced “the end of the theory” in 2008 in Wired, amid the explosion of data and data analysis capabilities [33]. This amounts to saying that the explanatory dimension of science is no longer a necessity, that correlation is sufficient and that prediction alone can and must guide our individual or collective actions. The establishment of knowledge making history and meaning for humans would be obsolete. In fact, all efforts on causal inference, the establishment of more or less complex causal links between given exposures and outcomes, are canceled. At the same time and following on from the work that occupied most of J Pearl’s life on the statistical approach to causality [37], several techniques relating to AI are progressing on the path to the discovery of interrelations, sometimes causal under certain well-defined assumptions as to the nature of the data used, from masses of data. This is the case with the numerous structure learning and learning algorithms of Bayesian networks [38]. Curiously, these methods have so far not interested epidemiologists much, even though they are applied more and more frequently in other fields, including those of industrial risk control. Between these two approaches, the one which denies the need for causality and the one which claims to automatically discover the causal networks in the masses of data, some authors explain that for certain situations, causality may on the one hand be unattainable, and secondly not necessarily useful. In these situations, in particular in the case of health policy and management of the care system, robust and precise prediction could be a tool synonymous with progress [39]. Nevertheless, there are cases where causality seems inevitable: In clinical epidemiology, the cause is sought in order to be able to act on it, and therefore prevent or treat people.

However, although the question of why cannot be essential for commercial uses or marketing, as opposed to the question of what, but it is essential in the specific field of health and intervention in

this area. Trying to identify factors to improve health without the prior attempt to approach the causes cannot be a relevant and efficient approach to health. At a time when the volume of data – both structured and unstructured – becomes difficult to use with conventional solutions, it becomes crucial to achieve using data from various sources and of various types to produce a “different” information certainly, and also information that is more complete and more reliable. The search for causal and veracity of data are more than ever of the major challenges in terms of big data, even in the specific field of health [40].

The Challenges Related to the Use Made of Epidemiology by Decision-Makers and the Involvement of Private Actors

In the end, it must be said that epidemiology, what it produces, to be useful, does not remain in the sole hands of epidemiologists. First, the actors involved in epidemiology and public health have changed somewhat over the past 20 years, not least because of the importance of data and the growing interest in new data sources. Thus, all private platforms, Google, Amazon, Facebook, and Apple (GAFAMS) have at one time or another, at one stage or another in the data processing chain, ambitions in the field of individual and population health. Their fundamental role as intermediaries leads them to position themselves not only as intermediaries but also as service provider due to their capacity to capture and process data. Finally, at the end of the data processing chain is the decision-maker, usually a policymakers. The experience of the COVID-19 pandemic underlines how the decision often remains above all political and unscientific approaches, for various reasons – the logistical reason not being the least (stocks of masks, number of hospital beds, availability of vaccines, etc.). In this context, the value of the epidemiologist as a researcher and human operator can become uncertain, and the use of AI both as a technical tool and as a guarantee for policy makers a real opportunity. This use of AI by policy makers,

without understanding how these results are produced and their limits, is a significant risk for health decision-making. The example of decisions taken in the face of the COVID-19 epidemic on the basis of partial data, imperfect models, is an illustration of this.

Conclusion

Since its origin, epidemiology has always been built on data and its interpretation, which makes it a discipline particularly concerned by the development of massive data and AI. Numerous uses are already in progress and are likely to develop. This development is not without raising major challenges for epidemiology in its ability to describe health of the whole populations, and identify risk factors accessible for action, while ensuring the quality and veracity of data. Over the course of its history, epidemiology has already had to deal with the integration of new data sources and new methods of analysis. We can therefore be confident in its ability to best integrate the exploitation of massive data and AI methods, remembering that these are methods and tools with evident advantages but also limitations, but that they remain tools, and not the solution, to better understand health.

Abstract

Malaria disease is due to the infection with *Plasmodium* parasites transmitted by a mosquito vector belonging to the genus *Anopheles*. To combat malaria, effective diagnosis and treatment using artemisinin-based combinations are needed, as well as strategies that are aimed at reducing or stopping transmission by mosquito vectors. Even if the conventional microscopic diagnosis is the gold standard for malaria diagnosis, it is time consuming, and the diagnostic performance depends on techniques and human expertise. In addition, tools for characterizing *Anopheles* vectors are limited and difficult to establish in the field. The advent of computational biology, information technology infrastructures, and mobile

computing power offers the opportunity to use artificial intelligence (AI) approaches to address challenges and technical needs specific to malaria-endemic countries. This chapter illustrates the trends, advances, and future challenges linked to the deployment of AI in malaria. Two innovative AI approaches are described. The first is the image-based automatic classification of malaria parasites and vectors, and the second is the proteomics analysis of vectors. The developed applications are aimed at facilitating malaria diagnosis by performing malaria parasite detection, species identification, and estimation of parasitaemia. In the future, they can lead to efficient and accurate diagnostic tools, revolutionizing the urgent diagnosis of malaria. Other applications focus on the characterization of mosquito vectors by performing species identification, behavior, and biology descriptions. If field-validated, these promising approaches will facilitate the epidemiological monitoring of malaria vectors and saving resources by preventing or reducing malaria transmission.

Introduction

Malaria is a disease caused by infection with *Plasmodium* parasites and transmitted by a mosquito vector belonging to the genus *Anopheles* [1]. These pathogens are transmitted to humans during the blood meal of infected female *Anopheles*. *Plasmodium* proliferation in red blood cells is responsible for chills and fever, the main symptoms of the disease [2]. Five species are involved in human malaria: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium knowlesi*. The most common and deadliest species is *P. falciparum*. Despite global malaria control efforts, the disease

persists, and approximately 229 million cases and 409,000 deaths were estimated to have occurred globally in 2019 by the World Health Organization [3]. The most primarily affected people are the sub-Saharan African population and children under 5 years of age. To combat malaria, direct and indirect control strategies have been developed. Direct strategies are aimed at curing malaria cases thanks to effective diagnosis and treatment using artemisinin-based combinations. Indirect strategies are aimed at reducing or stopping transmission by mosquito vectors through adapted vector control programs [4, 5].

Malaria Diagnosis: Parasite Detection and Species Identification

Malaria is a major cause of febrile illness in endemic countries. It requires rapid therapeutic management, especially due to the critical lethality of *P. falciparum* in non-immune populations [2]. However, such a clinical presentation is unspecific, and other causes of severe febrile illnesses are increasingly described [6]. Therefore, parasitological confirmation of malaria is necessary to guide healthcare workers in the management of patients with fever. Microscopic diagnosis by staining thick and thin blood smears is the most commonly used method for malaria diagnosis [2, 7]. Thick blood smears concentrate malaria parasites and are used for screening to detect the presence of *Plasmodium* parasites. A well-trained malaria microscopist should be able to recognize the *Plasmodium* species correctly in thick blood smears, even at relatively low parasite density. Indeed, the limit of detection of Giemsa-stained thick blood smears by expert malaria microscopists is estimated to be between 4 and 20 parasites per μl [7]. Thin blood smears are used for morphological differential diagnosis of *Plasmodium* species, analyzing erythrocyte details such as size, shape and crenation, characteristic dots in the erythrocyte stroma, parasite pigment structure and color, and parasite stages such as trophozoites (including ring stages), schizonts, and gametocytes. Nevertheless, when Giemsa staining contains very few parasites, differential

diagnosis is more difficult, and errors in species diagnosis are more common [7]. Thin blood smears are also used to estimate the parasite density of *P. falciparum*. For quantification using the thin film, many successive fields (a minimum of 100 fields at x100 magnification, which is equivalent to at least 2,000 erythrocytes) are counted for infected red blood cells (RBCs). Parasite density (also called parasitemia) is expressed according to the equation $\% \text{Parasitemia} = \frac{\text{Parasitized RBCs}}{\text{Total RBCs}} \times 100$ [8]. Fields used to estimate parasitemia should contain little to no overlap of red blood cells. When parasitized RBCs are counted, multiple infected RBCs should be counted only once. Gametocytes are not counted, as they are a dead-end stage in the human host. Parasite density is indicative of the severity of the disease, and mortality of *P. falciparum* malaria rises when the proportion of infected erythrocytes increases, although the relation between parasite density and prognosis is variable [2]. Examination of serial blood smears with parasite density quantification is also recommended for monitoring response to therapy.

Even if conventional microscopic diagnosis is the gold standard for malaria diagnosis, it is time consuming, and the diagnostic performances depend on techniques and human expertise. This expertise is rare, not only in malaria-endemic countries due to the lack of adequate initial training and scarcity of quality control but also in malaria eliminating countries and in non-endemic countries due to the lack of experienced microscopists. Indeed, routine microscopy diagnostics have been shown to be inaccurate in many health care centers across Africa [9–11], with a high rate of false positive results as high as 75.6% [11], leading to a frequent over-diagnosis of malaria. In addition, high variability in the estimation of parasite density is encountered due to the use of various methods [7]. Alternatives have been developed for rapid diagnosis in the field in the absence of microscopy infrastructures and experts, such as malaria rapid diagnostic tests (RDTs), to detect *Plasmodium* antigens. The accuracy of *Pf*HRP2-based tests for *P. falciparum* diagnosis is equivalent to that of routine microscopy, and they can be used as a screening tool in

resource-limited settings [2]. However, the identification of non-*P. falciparum* species is not feasible using each malaria RDT, and/or the sensitivity for these species is lower [7, 8]. In addition, malaria RDTs do not inform the parasitemia or the parasite stages, two crucial pieces of information for optimal clinical malaria case management.

Vector Ecology: Species, Biology, and Behaviors

Malaria vector control measures such as insecticide-impregnated bednets, insecticide spraying, or bacterial toxins are widely used to kill adult mosquitoes or larvae [5]. These measures are essential for controlling mosquito transmission of malaria parasites. However, to deploy effective malaria vector control measures, knowledge of *Anopheles* vector ecology is crucial. *Anopheles* mosquitoes are dipterous insects that develop in two phases: an aquatic phase for immature life stages and an air phase for adults. Adult *Anopheles* have a body segmented into three anatomic parts (head, thorax, and abdomen) and hosts three pairs of legs and a pair of wings attached to the thorax for locomotion. Only some *Anopheles* species are true vectors of malaria. Thus, the first step consists of identifying the *Anopheles* species. Species identification is usually performed using dichotomous keys based on the morphologic characteristics of collected specimens. It requires highly technical skills acquired after comprehensive training. For instance, morphometry of wing venation characteristics is a tool used by experts to discriminate between genera and species of mosquitoes. An additional challenge is identifying cryptic *Anopheles* species belonging to the same complex of species, as they do not have the same capacity to transmit *Plasmodium*. However, they are morphologically identical and can only be distinguished based on molecular tools, an alternative to morphology methods to identify *Anopheles* vector species [12]. Such tools are efficient, but the time required for sample preparation and the subsequent costs limit their use for extensive screening.

Protein profiling using matrix-assisted laser desorption ionization-time of flight (MALDI-

TOF) mass spectrometry (MS) is a promising new tool. Generated mass spectra protein profiles are fingerprints and characteristics of an organism (species, strain, or physiological stage). The method is rapid and accurate and is suitable for routine applications. Thanks to a comparison with a reference mass spectra database, it has been widely used in clinical microbiology for the species identification of bacteria [13], fungi [14], and parasites [15]. More recently, it has been developed for arthropod vector identification [16]. Several teams have built in-house databases to identify species of adult *Anopheles* by their MALDI-TOF spectra [17]. If deployed for mosquito surveillance, this proteomic method will avoid molecular analysis, with a gain of rapidity and cost of analysis. However, further research is needed to improve the resolution for cryptic species using new bioinformatic tools and for better standardization. Similar to DNA sequence databases, accessibility through online applications is essential for the broad use of MALDI-TOF MS databases. Such online platforms have already been proposed for fungi [14] and *Leishmania* species [18] and are currently being set up for mosquito species identification [17].

Aside from species identification, there is a need to perform more complex tasks to study *Anopheles* biology patterns, such as *Plasmodium* infection, past blood meal, age, and mosquito behaviors. These determinants of malaria transmission are particularly useful for vector monitoring. Evidence of *Anopheles* infection by *Plasmodium* is a prerequisite to confirm the role of a given species as a vector, and the proportion of individuals hosting sporozoites in their salivary glands (thorax) is a determinant of the capacity of malaria transmission [1]. Confirmation of a previous blood meal in captured specimens provides information about the human biting behavior of the population of mosquitoes. The human biting rate helps quantify malaria transmission. Within a given population of mosquitoes, only a small proportion of specimens can transmit malaria. Transmission only occurs after an infected blood meal, and individuals become infectious to humans only until parasite incubation is achieved (approximately 9–14 days, sometimes longer depending on the species and the temperature conditions). Thus, the average age of

the *Anopheles* female mosquito population is also an important determinant of the likelihood of malaria transmission since only the oldest mosquitoes in a population are responsible for *Plasmodium* transmission. Finally, exploring *Anopheles* mosquito behavioral patterns, such as blood feeding, is useful for understanding behaviors relevant to parasite transmission. All of these *Anopheles* mosquito characteristics may be useful for implementing adapted vector control measures and improving efficacy monitoring.

Overall, tools for characterizing *Anopheles* vectors are limited and difficult to implement in the field [19]. Apart from PCR tools that can detect *Plasmodium* in mosquitoes, methods are mainly based on laborious microscopy examination and require fresh material and technical skills [1]. In particular, there is a need for operationally attractive methods to characterize the *Anopheles* vectors, especially age, which is not accessible by DNA analysis. In addition, mosquitoes' feeding behaviors remain poorly understood, especially as they require scarifying researcher or mouse skin.

Deployment of Artificial Intelligence in Malaria

Technology now makes it possible to take photographs, including from a microscope, or to generate a mass spectrum from a biological sample and send images and spectra to an internet platform. These possibilities open the field to diagnostic procedures that can be activated from almost anywhere in the world. To finalize an online diagnostic system, it is necessary to make available automatic analysis methods of images and spectra obtained in the field. This opens up an avenue for artificial intelligence (AI) approaches addressing challenges and technical needs that are specific to the field of malaria-endemic countries, bringing new tools for malaria control [20, 21]. Progress in computational biology along with improved access to information technology infrastructures and mobile computing power in many low- and middle-income countries offers the opportunity to deploy AI-driven health interventions [22]. AI involves supervised machine learning methods, which are a set of algorithms applied to already labeled data to learn a statistical

model for pattern recognition, classification, or prediction. Such models must be able to generalize the learned task to new, unseen data. Most of them rely on artificial neural networks (ANNs), a class of machine learning algorithms. Among them, deep ANNs such as convolutional neural networks (CNNs) are specific architectures of deep learning models able to produce a reduced representation from sequences of elements (e.g., images as a sequence of pixels, text as a sequence of words) that are particularly well suited for image-based automated classification. There are various methods to train a neural network, one of them being to adapt pretrained models and use transfer learning approaches. Transfer learning consists of using the knowledge acquired on a general classification problem to apply it again to a particular classification problem.

In the following paragraphs, the trends, advances and future challenges linked to the deployment of AI in malaria are illustrated. Two innovative AI approaches are described in this chapter. The first is the image-based automatic classification of malaria parasites and vectors, and the second is the proteomics analysis of vectors. The developed applications are aimed at facilitating malaria diagnosis by performing malaria parasite detection, species identification, and estimation of parasitaemia. Other applications focus on characterizing mosquito vectors by performing species identification, behavior, and biology descriptions. Methods involving AI to model malaria transmission and vector ecology are considered indirect applications and will not be discussed in this chapter.

Applications of Artificial Intelligence in Malaria Diagnosis and Malaria Vector Characterization

Image-Based Automatic Classification for Malaria Diagnosis

For automated microscopy malaria diagnosis, three elements are crucial:

- Sample preparation, including smear realization and staining

- Acquisition of digital images using a microscope
- “Computer vision” algorithm to analyze and classify the captured digital images

Digital images are a finite set of digital values, called “picture elements” or “pixels.” The digital image contains a fixed number of rows and columns of pixels. Pixels are the smallest individual element in an image, holding values that represent the brightness of a given color at any specific point. Usually, a digital image is mathematically processed using the red green and blue (RGB) representation that converts a pixelated image into a matrix of intensity values of red, green, and blue (Fig. 1).

An automated image-based classification system for malaria diagnosis is a multistep process composed of two main processes: data processing and classification (Fig. 2). Data processing includes image acquisition and preprocessing techniques such as noise reduction and normalization. The classification of digital images consists of counting the infected and non-infected red blood cells (RBCs) and classifying *Plasmodium* according to its species and life stages. Traditional approaches to detecting malaria-causing parasites on thin smears involve specific data processing steps, such as feature engineering. Feature engineering consists of extracting patterns and signatures from images that can help identify specific objects such as RBCs (also called regions of interest). Prominent features are then selected to allow classification of infected and non-infected RBCs, such as morphology (shape and texture information), color, and granulometry. Different color space representations can be used, such as the hue saturation value (HSV) [23, 24] or the L*a*b* color, where L* represents the lightness, a* characterizes the red/green value, and b* characterizes the blue/yellow value, which is the more prominent color channel to characterize malarial parasites [25]. Traditional approaches use conventional machine learning models, such as multi-class support vector machines (SVMs) [26], naïve Bayes, or moving K-means [23, 24, 27]. Overall, the classification performance of such machine learning models ranged from 80% to 99% accuracy for *Plasmodium* species identification. However,

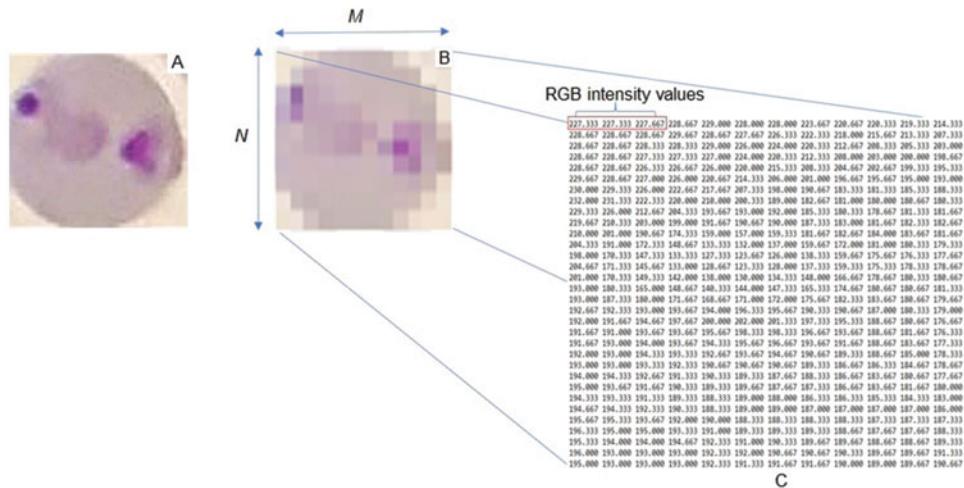

Fig. 1 RGB image representation: (a) *Plasmodium falciparum* infected red blood cell. (b) Pixelated image with the shape ($M \times N$) where M is the number of columns and N the number of rows. (c) The matrix of corresponding

intensity values defined by three values, red, green, and blue (RGB) in a range of 256 possible values: a mixture of these three values produces color in the image

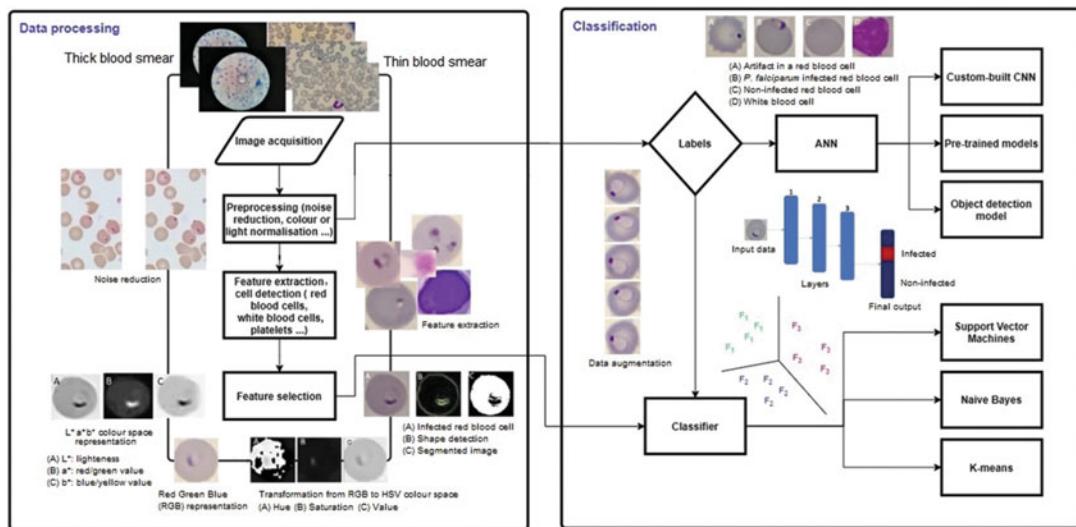

Fig. 2 Key steps of an automated image classification system for malaria diagnosis

evaluations were set on a relatively small number of images, corresponding to a limited number of blood smears (approximately one hundred). Most of these studies have proposed oversimplified solutions based on unicentric datasets, hence not applicable for routine diagnosis due to their low generalization capacity and their lack of robustness. The variety of staining methods and quality of smear preparation for microscopic blood smear

images makes it difficult to devise universal features using traditional approaches. Finally, a manual design of the features of interest requires expertise and is laborious and time consuming, especially for discriminating *Plasmodium* species and life stages.

With the advent of deep learning, ANNs, especially convolutional neural networks (CNNs), have achieved expert-level performance in the

detection of many pathologic characteristics. The high-performances mainly rely on medical image analysis, such as scans for retinal disease diagnosis [28] or histopathology slides for cancer disease diagnosis [29], to cite a few examples. Unlike feature computation methods, deep learning approaches usually avoid the explicit feature extraction step. Classification is based on several layers learning different informative latent image representations, with different levels of granularity (i.e., a layer can learn to recognize the general round shape of the blood cell, while another layer learns to detect localized parasites inside the shape).

***Plasmodium falciparum* Detection**

To date, all studies on the detection of *Plasmodium* in blood smears have focused on the species *P. falciparum*. CNNs were applied for the first time to the identification of infected and non-infected *P. falciparum* erythrocytes by Liang et al. in 2016 [30]. Good performances were obtained (accuracy of 97.37%) after training a custom-built CNN (i.e., a CNN designed by stacking and testing successive layers) on more than 27,500 images. In comparison, the pretrained CNN variant called AlexNet [31], which typically has a more complex architecture and is known for its good performance, was less accurate for the same classification task (accuracy of 91.99%). An explanation may be that the pretraining was not specific to the task of malaria diagnosis, and the previously applied data were of a very different nature and probably less complex. Nevertheless, other studies have exploited the efficiency of pretrained models to provide more flexibility to identify parasites or to extract malarial classification features. Pretrained networks (AlexNet [31], VGG [32], and GoogLeNet [33]) were used in a study to analyze thick blood smears for *P. falciparum* ring form detection [34]. The CNNs were trained on a large number of microscopic fields, including smears from 109 patients (78 positives and 31 negatives), and scored 90% accuracy. Although this study is the only one to have analyzed thick smears on a relatively important number of patients and obtained promising results, accuracy needs to be improved for clinical applications.

Transfer learning techniques coupled with the emergence of improved pretrained models also proved useful for *P. falciparum* identification in a study by Rajaraman et al. [35]. In this study, another CNN variant model, ResNet-50 [36], offered the best performance (98.6% accuracy) compared to other pretrained models (DenseNet-121 [37] and Xception [38]). Training was performed on the malaria National Institute of Health dataset (<https://lhncbc.nlm.nih.gov/publication/pub9932>) and included nearly 27,000 equally balanced, annotated blood cells of *P. falciparum* obtained from thin blood smears. Nevertheless, when evaluating the system on various slides from individual patients, a decrease in performance was observed due to staining variations in the slides (95.9% accuracy). This remains a technical problem to be considered as blood slides may show heterogeneous staining fields easily affecting classification results. To be as close as possible to diagnostic conditions in real life, models were trained on heterogeneous images, taking into account the variability in staining results. Artificial data augmentation techniques make it possible to enrich the data available, to learn new representations, and to make a model more efficient. To improve the work performed by Rajaraman et al. [35] for *P. falciparum* identification, Rahman et al. [39] proposed an improved classification score (accuracy of 97.64%). However, data augmentation by applying several morphological transformations, such as flips, rotation, and shifting, only slightly improved accuracy (97.89%).

Generative models have the potential to create entirely new images or to modify existing images. They have become a successful and popular trend in AI. This type of model, called conditional generative adversarial networks, has been tested to generate new photorealistic images of blood cells [40]. The approach employed some recent models, such as the pix2pixHD framework [41], to work on synthetic masks of blood cell images created by the FCN-8s model [42], which were compared to real masks. A system capable of generating new representations of infected blood cells will be interesting for generating data that are often difficult to acquire due to privacy constraints

and will allow the collection of a large quantity of data for training models.

Published studies show that CNNs are a serious asset for diagnosing malaria with AI. The use of CNNs makes it possible to analyze and learn a more representative sample of the clinical routine. However, ensuring the reproducibility of the results remains a major challenge, which will require a large-scale evaluation using different imaging sources. Building collaborative databases of digitalized images for *Plasmodium* species identification is a prerequisite to addressing the variations caused by different imaging setups or differences in specimen preparation (slide realization and staining). In addition, evaluations should be performed per-sample and not per-object to be meaningful from the clinical perspective to assess identification accuracy.

Determination of *Plasmodium* Life Stages

Detecting the presence of parasites and identifying their life stages are two key steps in automated malaria diagnosis. Very few studies have addressed the determination of *Plasmodium* life stages by deep neural networks. Bashar et al. [43] evaluated a custom-built CNN for identifying *Plasmodium vivax* life stages (including gametocyte, ring, trophozoite, and schizont images) and obtained high performance scores (97.7% accuracy) with a dataset of more than 46,000 annotated images of red blood cells extracted from thin blood smears. Another study by Hung et al. [44] applied a variant object detection model, faster region-based convolutional neural network (Faster R-CNN) [45], capable of detecting and discriminating life stages of *Plasmodium vivax* from thin blood smears. An object detection model operates directly on the image, outputs bounding boxes, and classifies the detected blood cells. The model was trained on different Giemsa-stained datasets of microscopy thin blood slide images from Brazil and Thailand and was tested on a dataset from Brazil. Red blood cells were detected and separated from other blood components and sent to the AlexNet model to classify them more precisely into life stages for infected red blood cells. The system accuracy was 98%, whereas the mean accuracy obtained by two human annotators was only 72%. This evaluation

of the diagnostic expertise of humans compared to the model prediction is important to validate the performances and the potential of such a framework. However, great variability was observed between the two tested operators, suggesting a lack of expertise. This raises the problem of the gold standard and the necessity to include more operators as a reference.

A good-performing system for *Plasmodium* life-stage determination requires connecting biological expertise to data. The variability in diagnostic interpretation is an important biasing factor, and a unique reading system trained on a large volume of data, well balanced between species, will help reduce this variability. The use of CNNs makes it possible to have a more in-depth analysis of the parasites.

Mobile Applications and End-to-End Systems for Parasite Identification and Density Determination

The determination of parasite density highly depends on the performance of the developed system for parasite identification. If most studies focused on parasite identification only, a few studies addressed this important issue when evaluating automated systems for complete malaria diagnosis, from parasite identification to density determination. Coupled with AI-driven tools, the developed automated systems are of two types: mobile applications or end-to-end systems. Zhao et al. [46] published a proof-of-concept mobile application for Android smartphones combining object detection models SSD300 [47] and VGG-16. The application displayed individual images of infected blood cells and allowed authors to screen thin blood smears for *P. vivax* and *P. falciparum*. The application detected the blood cells (accuracy of 90.4%) and bound them into infected and non-infected (accuracy of 96.5%). Finally, the parasite density was computed. The authors also applied upscaling models such as fast super-resolution CNN (FSRCNN) [48] to improve the resolution and quality of images. For the training process, they used the NIH malaria dataset (<https://lhncbc.nlm.nih.gov/publication/pub9932>) [35] for *P. falciparum* detection and the Broad Institute dataset (<https://bbbc.broadinstitute.org/BBBC041>) for *P. vivax*.

detection. The *P. vivax* dataset included 1,364 blood smear images infected and uninfected, giving 80,000 individually annotated blood cells, and the rate of individual infected blood cells was 5%. Infected blood cells were automatically classified and validated by a biologist. The application also offers the possibility to load other models that can be better trained for parasite identification. Similarly, Yu et al. [49] also developed an open-source Android application for smartphone malaria diagnosis. They extended the application to the analysis of thick blood smears, a great challenge for malaria diagnosis. They evaluated the application on 200 patients (150 *P. falciparum*-infected patients and 50 non-infected patients), and performance scores ranged from 96.9% to 98.6% accuracy for thick [50] and thin [49] blood smear analysis, respectively. The application automatically quantified parasite density but also offered the possibility to help the user do it manually.

End-to-end systems for malaria diagnosis require automating both image acquisition and image analysis. This type of device generally consists of an optical system and a capture device for scanning slides, unlike smartphone applications, which are very dependent on the quality of their camera equipment but also the conditions in which the images are captured (stable position, variable light source). A system for standardizing and normalizing image acquisition will facilitate blood smear analysis and parasite identification. To address these issues, a custom-built scanner for blood thin field stack analysis was proposed by Gopakumar et al. [51]. *P. falciparum*-infected blood cells were identified by analyzing candidate regions and best focus images of objects of interest. The customized portable slide scanner showed 97.37% accuracy for parasite identification. The developed CNN was found to be more accurate, as it obtained less false positive identification of *P. falciparum* compared to a CNN without the best focus step analysis (912 FP vs. 1051 FP). However, the density estimation of the system remains far from the true estimation due to an overestimation of the presence of infected red blood cells. Commercial platforms that are available in diagnostic laboratories have emerged and are promising for malaria diagnosis. The

automated scanning microscope EasyScan Go (Motic digital[®]) analyzes thin blood slides as inputs and displays results of parasite detection and quantification for *P. vivax* and *P. falciparum* species, thanks to dedicated software, in nearly 20 min (<https://motidigitalpathology.com/easyscango/>). Another promising fully automated system, the all-in-one miLabTM platform (Noul[®]), can analyze approximately 400 to 500 thin blood smear images in 15 min (<https://noul.kr/milab-platform/>). The entire slide process is automated, including staining, and allows the bias of variability related to the preparation of the slide to be reduced. These entirely automated systems can be the next major revolution in malaria automated diagnosis.

Even if progress has been made in the field of automated microscopy malaria diagnosis, applications have not yet been implemented on a large scale in routine clinical practice. Some barriers in designing an automated malaria diagnostic system persist and have been only partially addressed. Diagnostic end-points differed from one study to another, and most of the studies have focused on the analysis of thin blood smears. End-to-end systems are promising and help to reduce the variability of data acquisition, one of the limiting factors related to the automated diagnosis of malaria. Smartphones are now available to almost everyone and allow establishing diagnostics with fast screening applications at relatively low costs. This is particularly interesting in areas with limited access to the Internet or limited access to expensive automated systems, which often requires additional training for use. Nevertheless, smartphone applications may be constrained by memory space, computational resource flexibility, or security issues.

Image-Based Automatic Classification of Mosquito Vectors

Mosquito Species Identification

Advances in AI and machine learning methods have opened the door to the automatic classification of adult mosquito vector species using recognition techniques of morphological features. Coupled with ANN, the morphological characteristics of the wings were used to classify species of

Aedes, *Culex*, and *Anopheles* mosquitoes [52]. The wing images were obtained using a digital camera coupled with a microscope at 40x magnification. All digital images were scored by a geometric morphometric analysis following 18 points called landmarks using the right wing (Fig. 3). A total of 388 specimens from 17 field-collected Culicidae species were analyzed using ANN. A correct classification was obtained in 85 to 100% of cases, depending on mosquito species. This method could receive great interest if it discriminated sibling mosquito species. However, manually annotating the images is fastidious and time consuming and is not adapted for extensive screening. In addition, wing images can be difficult to capture.

To overcome the difficulty of focusing only on the wings, other teams analyzed photographs of

whole mosquitoes using CNNs [53]. However, only 93.5% accuracy was obtained, despite a very large set of images (7,561 mosquito images) and a very low number of species to distinguish (3 species). These insufficient results may derive from a lack of robustness of input images due to the use of various cameras, angles, and resolutions. Indeed, the variability in the pose of the specimen, the scale, and lighting have been shown to be important drawbacks of image-based recognition techniques [54]. To address the drawbacks of image-based recognition techniques and to increase the robustness of input images, Park et al. [54] developed a specific method for the training of CNNs. They constructed a dataset of 3,600 images of eight mosquito species of the three major genera, *Anopheles*, *Aedes*, and *Culex*, with various

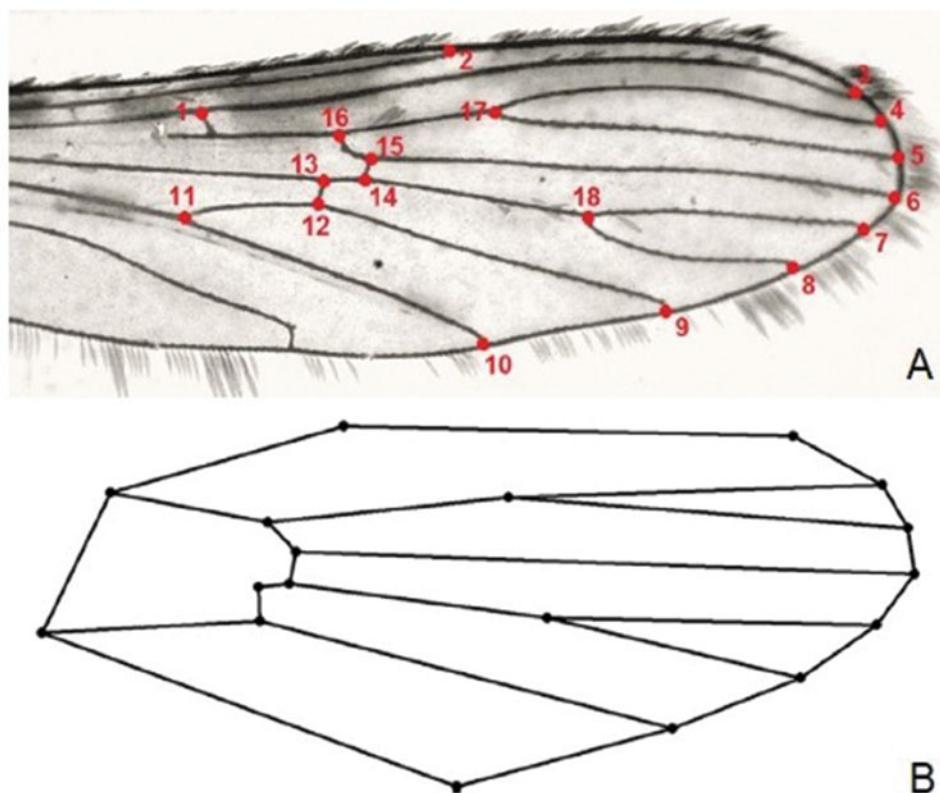

Fig. 3 Geometric morphometrics. (a) Wing of *Anopheles triannulatus* indicating the 18 landmarks used in analyses. (b) Hypothetical geometric diagram corresponding to the

wing portion examined in the study [52]. (©With courtesy of C. Lorenz)

posture, light intensity, and deformation positions (broken or missing anatomical parts) using a digital microscope. The authors achieved more than 97% accuracy by image processing using data augmentation techniques (normalizing pixel range, rotation, brightness, hue, contrast, saturation, etc.) and by fine-tuning general features using transfer learning methods (off-the-shelf features extracted from pretrained networks were reused for new target tasks).

The originality of this study was the visualization method to assess which properties of mosquitoes were used for classification, by localizing the discrimination regions of the mosquitoes that were targeted at each convolution step. Interestingly, the visual features targeted by the CNN matched the morphological key used by human experts, such as the wing venations for *Anopheles*, showing that CNN classification is supported by extracting pertinent anatomical mosquito features (Fig. 4). Nevertheless, this study highlighted the need for an important processing of mosquito images, both in terms of the number of images to acquire and in terms of preprocessing techniques, to generate a large quantity of quality data to build a performant CNN model. In addition, *Anopheles spp.* were only classified to the genus level, and

the classification of more similar species needs to be evaluated. In the future, image-based automatically classifying mosquito vectors can permit automated monitoring of mosquito species in remote field areas. Using in-field mosquito trap devices, the mosquito species can be classified automatically in real time. Such imaging systems within mosquito traps are already being developed for remote mosquito surveillance [55].

Mosquito Behavioral Patterns

An innovative AI-driven tool has recently been developed for high-throughput mosquito behavioral pattern description, the “biteOscope” [56]. It was designed to improve the comprehension of mosquito feeding behaviors around a feeding substrate (blood, sugar) and of mosquito behavioral alterations after impregnation of a surface with a chemical insect repellent. The device provides an artificial blood meal to mosquitoes by attracting them to a host mimic that they bite. For high-resolution imaging of the mosquito feeding process, the host mimic was transparent. To track each mosquito trajectory within BiteOscope, raw images were background subtracted, thresholded, and subjected to a series of morphological operations to yield binary images representing

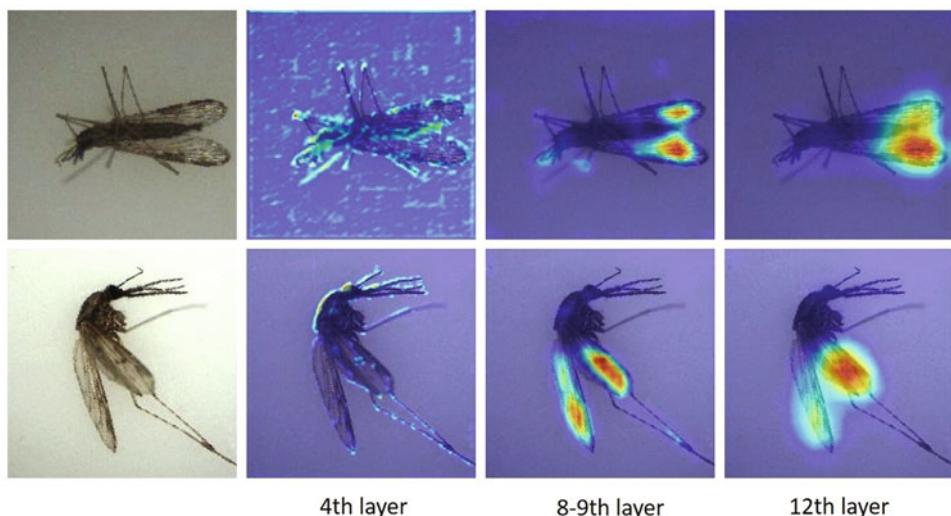

Fig. 4 Input images of two samples of *Anopheles spp.* and visualization of discriminative regions in different layers of a deep CNN: shallow (4th), middle (8th–9th) and deep

(12th) convolution layers, using a feature activation heat map [54]. (©With courtesy of J.Y. Park et al.)

mosquito bodies. Machine learning approaches were performed to extract detailed behavioral statistics from cropped images, applied as CNN input.

The locomotion, pose, biting, and feeding dynamics of *Aedes aegypti*, *Aedes albopictus*, *Anopheles stephensi*, and *Anopheles coluzzii* can be described statistically. In addition, the authors discovered how the common insect repellent DEET repels *An. coluzzii*: upon contact with their legs (Fig. 5a). This information is particularly important to design accurate mosquito vector control measures. They also observed that *An. coluzzii* approached and landed on the DEET-coated surface, but avoided prolonged contact with it. Indeed, the landing rate in the DEET area was approximately 1.9 times lower than that on the non-treated surface (Fig. 5b) and the time spent on the non-coated surface was an average of seven times longer than that on the DEET-coated surface (Fig. 5c), illustrating the precision of the statistical description.

This innovative mosquito tracking system can serve to evaluate mosquito control strategies aimed at reducing pathogen transmission by quantifying the behavioral effects of such interventions. Detailed behavioral tracking and chemical surface patterning may, respectively, enable a better knowledge of mosquito blood feeding mechanisms and ecological characteristics such as insecticide resistance. In addition, it can prove

useful for automated mosquito control and surveillance, especially in remote areas. An automated mosquito sensing system using deep learning networks has already been evaluated for the control of mosquito habitats [57]. The presence of adult mosquitoes attracted by a lure was detected by an automated system; then, mosquito detection activated the injection of a larvicide into static water to stop mosquito proliferation. This strategy targeting the larval stages can prove very useful for mosquito proliferation control in indoor urban areas such as sewage water tanks and rainfall collection facilities. These applications will constitute a real advance in the field of malaria research and mosquito control.

Characterization of *Anopheles* Biological Features Using Proteomic Tools

Only a few teams have assessed the use of MALDI-TOF MS coupled with AI tools for characterizing *Anopheles* vectors. Machine learning approaches have been tested with success to distinguish sibling *Anopheles* vector species [58]. A recent study addressed another challenge and evaluated whether MALDI-TOF mass spectra can provide suitable input for ANNs to classify the spectral patterns of *Anopheles* biological features [59]. Therefore, ANNs were coupled to

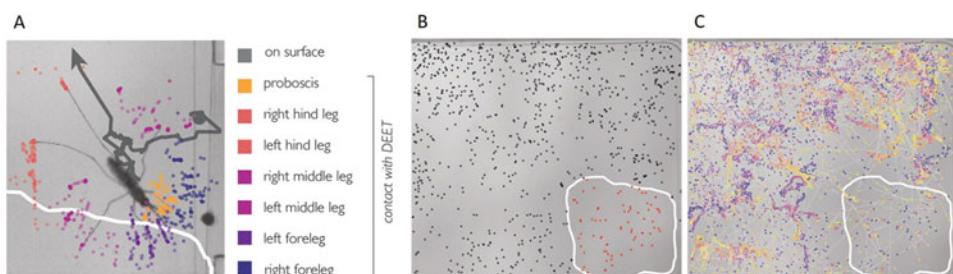

Fig. 5 DEET experiments of *An. coluzzii* repellency. (a) Body part tracking of a mosquito near the edge of the DEET-coated surface. Movement of the center of mass of the mosquito is indicated by a grey line (the start of the track is indicated by a dot, arrowhead departure). During the section of the trajectory where the mosquito is within reach of the DEET-coated area (indicated by the white line), colored dots indicate the position of the legs and

proboscis (mouth parts). (b) Landings on a substrate partly coated with 50% DEET (white line indicates DEET-coated surface). Black dots indicate landings outside the DEET area, and red dots indicate landings inside the DEET area. (c) Trajectories of mosquito movement on the surface. Dots of individual tracks are colored from purple (start of the track) to yellow (end of the track) [56]. (©With courtesy of F.J.H. Hol)

MALDI-TOF MS, and the impact on the proteome of laboratory-reared *Anopheles stephensi* mosquitoes was evaluated to predict mosquito age, blood feeding, and *Plasmodium* infection, which are *Anopheles* drivers of malaria transmission.

To build this AI application, three categories of adult *An. stephensi* mosquitoes were analyzed: (1) mosquitoes that did not receive a blood meal (unfed), (2) mosquitoes that received an uninfected blood meal on mice (fed and uninfected), and (3) mosquitoes that received a *Plasmodium berghei*-infected blood meal on mice (infected). A simplified scheme of the study design is represented in Fig. 6 for *P. berghei* infection prediction. Mosquitoes were collected at various ages and killed by freezing before processing for mass spectra acquisition. Spectra were generated from the three cohorts of mosquitoes and four body parts (head, thorax with wings, legs, abdomen). The spectra were preprocessed by smoothing and removing the baseline. Only the 100 highest peaks were fed to the ANNs to avoid background noise. Three separate ANNs (CNNs composed of

four convolutional blocks) were trained with different classification targets: age grading, past blood meal, and *P. berghei* infection.

Proteomic analysis revealed that the mass spectra were very similar, without any apparent, consistently reproducible single peak(s) correlated with each category. However, variations in peak intensity related to mosquito age, past blood meal, and *Plasmodium* infection were observed. These differences in peak intensity could create discriminant biomarkers that might be recognized by ANNs. Classification performance varied between anatomical parts, and the best prediction rates were obtained for the thorax and the legs, with 73, 89, and 78% correct predictions for age (0–10 days, 11–20 days, and 21–28 days), blood meal, and infection, respectively. This shows that the ANNs specifically recognized spectral patterns linked to *Anopheles* biology. Interestingly, the protein spectra classification was related to physiological changes, as blood meal anteriority was detected a long time after blood digestion (from 7 days to 25 days post-blood meal) from the thorax or the legs and not the

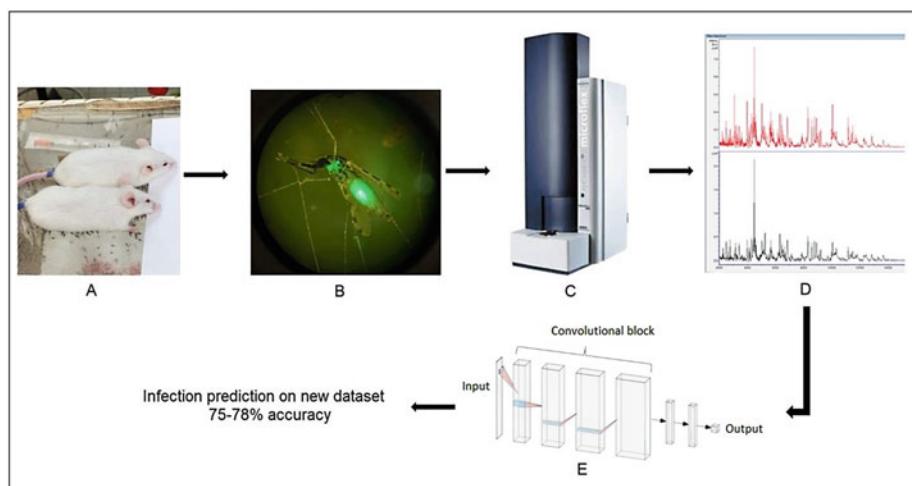

Fig. 6 Key steps to predicting *Plasmodium* infection in *Anopheles* using AI coupled to MALDI-TOF [59]. (a) Blood-feeding of *An. stephensi* mosquito on mice, either infected or not infected by *Plasmodium berghei*. (b) Control of infection by *Plasmodium berghei*. Visualization of *An. stephensi* infected with GFP-expressing *P. berghei* by fluorescence microscopy ($\times 10$ magnification), at day 24 postinfection. Fluorescence of oocysts and sporozoites

is visible in the abdomen and in the salivary glands, respectively. (c) Acquisition of MALDI-TOF MS spectra (Microflex LT Bruker[®]). (d) Categories of mass spectra protein profiles to be discriminated. Red color indicates a spectrum of a mosquito fed and infected. Black color indicates a spectrum of a mosquito fed and uninfected. (e) Machine learning using a convolutional neural network

abdomen. Similarly, the neural network could distinguish between infected and uninfected *Anopheles* from the legs, which are not supposed to host the parasite for a long time, suggesting detecting protein changes following *Plasmodium* infection such as the immune response rather than detecting the parasite.

This proof of concept illustrates that MALDI-TOF MS coupled to ANNs can provide new tools for vector control by estimating the proportions of *Plasmodium*-infected, blood-fed, and old mosquitoes. These proportions are expected to decrease under effective vector control measures. The age-grading approach is particularly interesting, as age cannot be provided by DNA analysis, and the reduction in mosquito age populations is one of the most effective measures for reducing malaria transmission [19]. Future studies must assess the field validity of this new approach in wild-caught adult *Anopheles*.

Conclusion

Researchers from computer science, life science, and medical science have addressed the challenges of malaria diagnosis and control using AI during the last decade. In the field of malaria diagnosis, many promising AI applications are under development. In the future, they can bring efficient and accurate diagnostic tools, having a real impact on clinical management, by revolutionizing the urgent diagnosis of malaria. Nevertheless, a standardized universal system for automated malaria diagnosis will have to consider the variability resulting from staining methods and the quality of smear preparation for microscopic blood smear images. A fair comparison of the performances between different algorithms was not always possible due to the use of different evaluation metrics and due to the lack of reference benchmark data. In addition, most systems have been developed and tested using a relatively small number of patients due to difficulties in acquiring and annotating a large number of images. However, computer-assisted diagnosis and mobile applications provide a significant opportunity for data collection and for promoting the creation of centralized collaborative red blood cell databases.

The generated data will permit researchers to improve model training and enrich the representations and cell variability of malaria, especially when these data are scarce. In the field of mosquito surveillance and control, few researchers have taken up the challenge of developing exciting AI applications. They can not only identify mosquito species but also characterize mosquito biology. If field-validated, these promising approaches will facilitate the epidemiological monitoring of malaria vectors and the saving of resources by preventing or reducing malaria transmission.

Abstract

Recent methodology advances in infection biology suggest a great potential of artificial intelligence. As the field paces into the digital age, data-driven techniques for analysis of pathogens are being widely embraced. From computer vision in microscopy to sequence analysis in genomics of pathogens, these advances allow to improve speed, specificity, and sensitivity of infectious disease diagnostics. Advances in host-pathogen interaction powered by artificial intelligence promise novel therapies. In this chapter, the background of infection biology field and types of data it deals with are introduced. Across the spatial and temporal scales, specific examples of how

the classic techniques are getting an artificial intelligence rehaul are provided. Furthermore, novel opportunities that artificial intelligence, machine learning, and deep learning are offering for the field are discussed. These include label-free infection detection, causal biological mechanism analysis, and AI-assisted design and identification of novel antivirals and antibiotics. Finally, a perspective on limitations and opportunities of artificial intelligence techniques in infection biology is discussed.

Introduction

Infectious diseases have made an immense socio-economic impact throughout the history of humanity. Traditions and cultures were shaped by diseases through effects in human populations and livestock. Advances in infection biology left noticeable hallmarks in science and medicine including works of Jenner, Lister, Koch, Pasteur, and Fleming [1, 2]. It would hardly be an overstatement to say that these achievements define the very fabric of our modern society. Yet, the ability to fight the microscopic parasites wasn't always a given and, in the face of the newly emerging infections, may not always continue to be [3].

Detecting and preventing the ever-changing microbes and viruses requires constant survey and research. However, today these efforts are greatly facilitated by the achievements of the past. Standing on the shoulders of giants, we are able to borrow from the basic concepts of biology, biochemistry, biophysics, genetics, and bioinformatics to devise new ways of fighting infectious disease. Discovered through centuries of empiric observations, remarkably, these concepts often hold today. Infection often meant deviation from the norm; hence the effect of pathogens on their hosts could be observed – i.e., learning from the data. This way of thinking about infection biology bears parallels to the machine learning (ML) and representation learning techniques. In this chapter, we will explore how artificial intelligence (AI) explores these parallels to give science and medicine an edge in this perpetual armament race.

Processes studied by infection biology exist on various scales and involve various agents. To capture this, complexity on a fairly abstract level lets us describe these agents across the scales, as well as the processes they are involved in (Fig. 1). In the first dimension of the scales, these agents exist on a spatial scale from molecules to organisms (Fig. 1a). In the second, these agents change in time on a broad range of temporal scales from milliseconds to days and, hence, have a temporal dimension. Throughout these dimensions, these multiscale agents engage in a plethora of interdependent processes (Fig. 1b), which, in

turn, may have outcome on each of the scales of the spatiotemporal range. In other words, infection biology studies entities from small to large and from fast to slow, and minute differences may dramatically change a life-or-death outcome for an organism.

Noteworthy, there are two distinct foci of infection biology. First is the focus on the pathogen as a biological entity itself. The second is the host-pathogen interaction [4] focus – i.e., on the interactions between the pathogen and the host, involving multiple stages of the pathogen's lifecycle (see Fig. 1b). Pathogen focus may, for example, relate to the analysis of its shape or genome. Host-pathogen interaction focus relates to interactions between genes and molecules of the host cell and the pathogen molecules. Such interactions may include mediating various host mechanisms exploitation by the pathogen. A great example of such exploitations is pathogen entry into the host cell [5].

Here, we will review the role microscopy and computer vision can play for AI in infection biology, akin to the role microscopy played first explorers of the microbiological world [6]. Next, we will discuss strengths and limitations of using various ML and deep learning (DL) techniques [7], which gained popularity in recent years. Specifically, we will focus on their application to pathogen detection or analysis of host-pathogen interactions. Finally, we will explore AI application to molecules in the context of infection biology. This chapter is not going to address epidemiology aspects of infections, which are reviewed in [8]. Furthermore, we will omit many important, yet complex, aspects of immunology.

Aim in the Infection Biology

Pathogens span a broad range of sizes ranging from nanometers to micrometers. Curiously, this range of scales is also divided by the so-called diffraction limit (see Fig. 1). This limit splits pathogens into resolvable by optical imaging and resolvable largely by electron microscopy [9]. When it comes to viruses, for example, the impact of electron microscopy on the field of

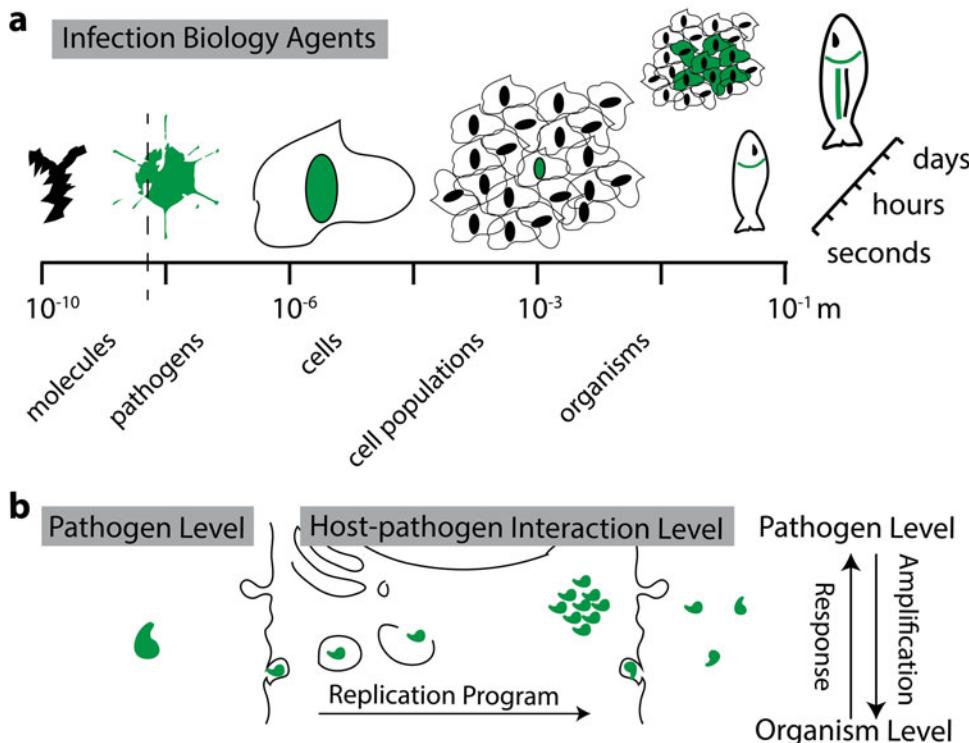

Fig. 1 Abstract description of agent space and processes studied by infection biology. (a) Agents involved and their respective positions on the spatiotemporal scale. Here green color indicates infected state or infectious agent. Dashed line denotes approximate location of the diffraction limit on the spatial scale. (b) Abstract depiction

of the processes the agents are involved in. Here curved lines are used to schematically depict host cell, endocytic cell entry, replication, and egress of the pathogen progeny. A generic pathogen is depicted in green. Any immune interactions, here, are depicted as “Response”

virology is difficult to overestimate. Ability to resolve virus particles allowed researchers to “put a face” on the virus entity. Yet, even larger pathogens like pathogenic bacteria and parasites clearly require special equipment to be visualized.

Conversely, the effect pathogens exert on their host is best appreciated on a larger scale. To be able to encompass the broad application of AI for the topic of infection biology, in this chapter, we will begin our journey with vision on nano- and microscales, proceed to the mesoscale, and wrap up with the macroscale. In mesoscale, we will mention some aspects of temporal dimensions of infection biology, although, wholeheartedly, this aspect may well deserve its own chapter. Finally, making a full circle, we will return to molecules and the role AI can play for the molecular techniques in infection biology.

Computer Vision in Infection Biology on Nano- and Microscale

In the past decade, the field of computer vision has been revolutionized by the convolutional neural networks (CNNs) and similar artificial neural network methods enabled by the gradient-based learning [10]. However, these are most powerful in situations where datasets are very large, while data annotation is trivial and unambiguous. It is easy to imagine how this can be problematic for rare pathogen analysis at a nano- and microscale. Consider, for example, annotation of handwritten digits – where ground truth is obvious, versus recognizing obscure virus particles in the gray scale electron micrograph. Such annotation task for a human specialist often requires years of training. Furthermore, consensus among

specialists often leaves much to be desired. In such cases, a simple rule-based analysis approach is often preferable [11].

Additionally, the nature of biomedical and other scientific images is often quite different compared to conventional image computer vision is dealing with. Scientific images are typically acquired in very standardized conditions using highly accurate equipment developed by a handful of vendors. Magnifications or the fields of view are often fixed. The very design of the scientific images is aimed at leaving very little to a mere chance: depth of field is shallow, shape and size distortion is minimized, background is standardized, and the perspective is eliminated. In case of so-called functional imaging (opposed to label-free imaging), entities of interest may be stained through chemical dyes and contrast compounds providing an experimental solution to problems like object segmentation. Hence, rule-based algorithms have dominated the field for a long time.

One remarkable breakthrough in the field, with respect to ANN, came from the U-net architecture addressing the segmentation problem in the label-free imaging modalities [12]. This architecture is exploiting highly standardized scales in the scientific image to draw various representations of such fields of view. In turn, pathogens in general and viruses in particular often have a very distinct morphology. This peculiarity may be exploited both for novel imaging methods (using pathogens as fiducials) and for better understanding structure and function relationships with the pathogens [13]. Unsurprisingly U-net architecture was shown to be of a great use for virus particle recognition in electron microscopy images [14].

Beyond segmentation, computer vision and AI opened another avenue in the label-free imaging, namely, performing quantitation of biological entities based on their distinctive morphology rather than specific labeling. Examples include gram stain classification from bacterial morphology in blood culture [15] and use of holographic imaging modalities accompanied by CNNs for screening of anthrax spores [16], as well as Raman spectroscopy-based bacteria pathogenicity interpretation [17]. Noteworthy, methodologies utilized

in these works all use CNNs, yet they differ significantly in the specific implementation. Jo et al. employ a relatively shallow CNN architecture they term HoloConvNet consisting of merely three consecutive CNN layers. At the same time Smith and colleagues use a deep residual network architecture based on Inception v3 equipped with 23,885,392 trainable parameters. Generally speaking, the expressive capacity of ANN grows with the number of trainable parameters. However, the annotated data requirements grow with the increase of expressive capacity. High-capacity networks tend to overfit on smaller datasets. Perhaps it was the data availability that dictated the choice of ANN architecture for these papers. Another aspect of residual architecture, however, is their ability to tune the expressive capacity through so-called skip-connections between the layers. That said, deeper architectures typically require more memory on GPU devices for training, hence likely a more expensive device at hand – an important fact to consider while designing a project.

Another opportunity for AI in the infection biology on a nano- and microscopic scales comes from analysis of the host-pathogen interactions. In these applications, algorithms like CNNs can assist with understanding how host cell molecules interact with the intruding pathogens. If the detection of interacting and non-interacting pathogens is formulated as a classification problem, the implicit unsupervised component of CNNs may be employed to learn and visualize previously unknown characteristic properties of the image [18, 19]. Furthermore, certain aspects of data requirement of ANN architectures may be relaxed by employing so-called transfer learning approaches, which work surprisingly well in a cross-domain application [20]. Taking this notion further, CNNs may be readily employed to decipher unknown host-pathogen mechanisms, like in the example of infected cell lysis by some human adenoviruses [21]. For example, Andriasyan et al. employ residual CNN accompanied by saliency techniques (so-called class activation maps (CAMs)) to identify elusive phenotype of cell infected by human adenovirus yet unable to spread the virus. Using these techniques accompanied by laser-ablative infected cell probing,

authors unveil that the build-up of intranuclear pressure plays a key role in human adenovirus cell lysis.

Computer Vision in Infection Biology on Mesoscale and Aspects of Temporal Dimensions

Effects of pathogens are rarely limited to the nano- and microscale. On the path of infection spread, pathogens transcend the limits of individual cells. In monolayers of cultured cells, viruses form distinct clonal lesions called viral plaques. Computer vision algorithms can greatly assist in quantitation of these infection phenotypes [22]. On a slightly larger scale, individual bacterial cells can be grown in colonies on dishes covered with solidified growth medium. This technique is widely used throughout microbiology and molecular biology (e.g., for molecular cloning of DNA), as well as in clinical diagnostics. Quantitation of such colonies, however, is often done manually in a slow and cumbersome process. Recently, CNN-based methods for automated colony counting [23] and classification [24] in digital microbiology imaging have been proposed. Noteworthy, however, Ferrari and colleagues took great care in standardizing the image acquisition condition for their agar plates. This suggests that their model may not be immediately applicable for everyone and may require retraining. Nevertheless, these works clearly demonstrate viability of CNN application in infection biology at a mesoscale and suggest an enormous potential for improving speed and precision of infectious disease diagnostics.

Effects of pathogens in the populations of cells do not occur in an instance. Depending on the duration of the pathogens' lifecycle, such effects may be taking place on a temporal scale ranging between hours and days to even weeks. Curiously, quantitating the rate of change in such processes can bear a great deal of information about infection spread. For example, tracking migrations of vaccinia virus infected cells has been recently used to unveil that the pathogen hijacks host cell EGFR signaling mechanism to enhance virus

spread through cell motility [25]. A curious approach taken in this study emphasizes how important mechanistic cues may be retrieved from swarm-like infected cell behavior at a mesoscale.

Finally, employing computer vision methodology to measure infection at the mesoscale paves the way to new approach to scientific instruments. For example, recent advances in mobile photography have seen a tremendous increase in detail and quality (i.e., pixel resolution in cameras and postprocessing). With minor modifications, a smartphone can literally be converted into a low-cost microscope. In turn AI algorithms can facilitate analysis, like bacteria-type detection [26]. Furthermore, the farther end of the mesoscale allows phenotypes to be large enough to be visible with a naked eye – a scale where mobile photography can provide highly available and reproducible way of digitalizing research results.

Computer Vision in Infection Biology on Macroscale and Digital Biomarkers

When infections expand beyond the mesoscale of cellular neighborhood, they spread to tissues – or the macroscale, as termed here. The adoption of imaging in clinics has truly transformed medicine in recent years: digitalization of X-ray, computed tomography (CT), and magnetic resonance imaging (MRI) are more often becoming common tools to extend the diagnostic picture. Detecting tissue abnormality can be a powerful tool in medicine. One remarkable example is the usage of retinal scans to detect macular diseases. Furthermore, retinal scan data may provide cues to a whole range of systemic pathologies. Unsurprisingly, CNNs and DL in general are spearheading analytics in this aspect [27]. Beyond analytics formulated as pathology classification problem, great advances have been achieved in using AI for signal processing. Training model on pre- or low-dosed contrast-enhanced brain MRI combined with the full-dose images as ground truth have been shown to allow for reducing the amount of contrast compound required for functional brain MRI imaging [28]. This, in turn, may

allow for safer diagnostics through decreasing adverse events' frequency connected to contrast compound.

Similarly, CT and MRI imaging are advancing diagnostics of infectious diseases. Although detecting individual pathogens in whole organ scans would be impossible due to the massive difference of scales, one can readily observe the damage they cause. These techniques bridge the medical gap between the infection and disease. While infection is the mere fact of presence and replication of the pathogen in cells and tissues, disease is the condition caused by the infection itself or response to the infection. Bridging this gap is important to broaden our understanding of pathogens and infectious diseases in general, as not all infections lead to the development of the disease. One recent and illustrative example is the SARS-CoV2 virus infection being the causative agent of coronavirus infectious disease 19 (COVID-19). While COVID-19 is characterized by the manifestation of a severe acute pneumonia, as of this writing, the general consensus stands that by far not every infection of SARS-CoV2 leads to the development of the COVID-19 condition. Hence, molecular diagnostics of SARS-CoV2 infections like polymerase chain reaction (PCR) remains insufficient for the obtaining a clinical picture for COVID-19 patients. However, this gap can be filled by the clinical picture obtained from imaging and accompanied by DL [29].

Beyond imaging, other AI techniques may be of great use in clinics for infectious disease diagnostics. For example, reinforcement learning (RL) technique holds an immense potential for optimizing treatment strategies by taking into account a myriad of input features measured by the various medical sensors available today. Signals with high temporal resolution from wearable devices and advanced medical equipment used in the intensive care unit wards are a valuable source of so-called digital biomarkers. While gigabytes of data from such sensors are recorded, they rarely play a big role in today's diagnostics, which is wired for more conventional bulk readouts. Furthermore, such big diagnostic data by itself may lead to information overload for clinicians and hamper fast clinical decisions. However, if such rich

clinical data source is accompanied by an advance analytics system, it may prove remarkably useful. One example of such synergy is the use of RL to select optimal treatment strategies for sepsis in intensive care [30]. In this study, authors used a set of 48 variables, including laboratory values, demographics, vital signs, comorbidity status, fluids, and vasopressors received to power their AI system. These data were recorded as multi-dimensional discrete time series with 4-h time steps and with a total of up to 72 h of measurements for each patient. All this allowed to estimated time of onset of sepsis at the level of human physician. Furthermore, the system developed by Komorowski et al. occasionally outperformed optimal vasopressor dosage suggestion compared to the dosage proposed by human doctors, suggesting potential improvement of the state of the art.

Yet, simply matching the performance of human physician in diagnosis and treatment of infectious diseases is not the only promising advancement of AI. The digital biomarker paradigm allows to bring novel information sources to be used for diagnostic purposes. For example, Laguarta and colleagues have recently proposed a CNN-powered strategy to detect COVID-19 from a forced-cough audio recording obtained through a cell phone [31]. Using data of over 5000 COVID-19 patients and ResNet-based architecture, authors developed a model capable of detecting COVID-19 from audio with a sensitivity of 98.5% with a specificity of 94.2%. This and other examples of digital biomarker application in infectious disease diagnostics bear a great inspiration of utilizing previously untapped sources for diagnostics.

Artificial Intelligence in Molecular Infection Biology

While computer vision may be one of the most obvious applications of AI methodology in infection biology, it would be a gross omission to ignore the great advances AI is driving in pathogens genetics and molecular infection biology. For example, DL may be readily applied as pattern recognition approach to identify genetic

variations responsible for higher pathogenicity in either host or pathogen genomes [32]. Beyond genetic variations, DL can assist with DNA methylation analysis, base calling and SNP analysis [33], transcription analysis, RNA analysis, as well as DNA accessibility analysis (reviewed in [32]). However, opportunities for AI in infection biology are not limited to improving conventional genomics of individual host and a pathogen. Whole microbiome may be taken into account in the clinical setting through the approach known as clinical metagenomics [34].

More often than not, molecular infection biology deals with analysis of patterns in sequences. Hence, hand in hand with CNNs, ANN approaches like recurrent neural networks (RNN), for example, architecture known as long short-term memory (LSTM) RNN [35], are widely used in the field [32]. In fact, in some cases, these architectures can also be synergistically combined. For example, the work of Veltre et al. uses consecutive combination of CNN and LSTM layer in a single architecture aimed at antimicrobial peptide recognition [36]. Authors show superiority of their approach to either layers applied individually.

Our overview would be incomplete without mentioning the incredible innovation DL has demonstrated for the chemical synthesis [37]. This, in turn, allows to appropriate the AI methodology for drug discovery. Specifically, Stokes and colleagues have recently proposed a DL approach to antibiotic discovery [38]. In their work, authors use a graph neural network and data from Drug Repurposing Hub, as well as ZINC15 databases to predict a novel antibiotic. Remarkably, Stokes et al. identify a small molecule Halicin (5-[(5-nitro-1,3-thiazol-2-yl)sulfanyl]-1,3,4-thiadiazol-2-amine) as a potent antibiotic candidate. Furthermore, they demonstrate that the molecule readily shows activity in mice – a remarkable step for an *in silico* methodology. Similar methodologies also show promise in the scarce antiviral space. One remarkable advantage the use of AI may provide is the rapid reaction speed to the emerging infection. For example, using a DL model of drug-target interaction, Beck et al. identified potential antivirals for the pandemic SARS-CoV2 from a broad range of

commercially available antivirals. In this study, the team has developed molecule transformer-drug target interaction architecture capable of utilizing molecular information represented as simplified molecular input-line entry system (SMILES) code. Authors have identified human immunodeficiency virus drug as a putative candidate against SARS-CoV2 [39].

Yet, one of the biggest criticisms of large DL models remains their poor interpretability. For domains like drug discovery, such limitations may be critical for the viability of the approach. To this end, Yang and colleagues have recently proposed a white-box ANN approach [40]. To achieve this, Yang et al. counter-screened a number of metabolites against bactericidal antibiotics in *Escherichia coli*. Next, authors simulated the corresponding states of the metabolites using a genome-scale metabolic network model. This allowed the team not only to identify novel molecules but also obtain causal mechanisms underlying drug efficacy.

Conclusions

In this AIM chapter, we have discussed the multi-scale nature of infection biology as well as multi-faceted approaches required to detect, study, and ultimately treat infectious diseases. We have dived into the origins of the field of infection biology. Also, we have introduced the space of agents involved in the infection biology as well as pathogen-centric and host-pathogen-interaction-centric views in the field. We have reviewed recent advances in domain specific AI pushing the boundaries of previously available infection biology methodologies. While these advances are truly breath-taking, the “No Free Lunch” theorem dictates that all these advances come at a cost and must be perceived with a grain of salt.

Indeed, a lot of AI approaches in the field are not immediately applicable to any conceivable problem at hand. These large models require immense annotated datasets to train, as well as large computational resources. A typical size of a dataset used in DL may count tens or hundreds or thousands of individual data points (e.g., images), as well as days of training on expensive

GPU-enabled computers. Furthermore, for these datasets to be suitable for supervised ML, they need to be annotated by domain experts of each individual narrow field, making the annotated datasets scarce. Further complicating the adoption of the AI methodologies in the infection biology, data are often imbalanced – i.e., only few positive examples are often overwhelmed by the vastness of negative examples. The abovementioned challenges with DL models' interpretability additionally hamper the motivation of applying AI to these problems. Needless to say, all these present great challenges for the field to overcome. However, some of these challenges are not unique to AI in infection biology.

Indeed, recent advances in semi- and self-supervised ML/DL as well as work on universal representations promise to address the scarcity of annotations. Advances in techniques of data augmentation and synthetic data give hope to tackle dataset imbalance. Use of transfer learning [19] and broader availability of GPU resources could hopefully address the computational costs. Finally, the white-box causal AI model design [40] as well as approaches to CNN saliency [18, 19] could shed light on the inner workings of the advanced models – a necessary condition for their wide adoption in the domain. All these opportunities provide a promise of the wide adoption of AI in infection biology driving the field into the new age.

Abstract

The classical approach to modeling, and thus predicting, the trajectories of outbreaks is to use the SIR model. This is a compartmental-based technique that has a number of limitations including limited population granularity. This chapter describes a richer agent-based approach. Computer requirements and the issue of parameter uncertainty are also discussed.

from neighborhoods to global. In this chapter, we will focus on the modeling of the dynamics of infectious diseases, particularly the use of AI for this purpose.

History

One reason for mathematically modeling an epidemic within a population is to attempt to predict how the epidemic will change over time. Following on from the initial observations made by Hamer [18] over 110 years ago, and the work of Ross and Hodges [33], Kermack and McKendrick [23] proposed that individuals can be classified according to their epidemiological status, namely, (i) those that are *susceptible* to the infection of interest, (ii) those that are *infected*, and therefore infectious, and (iii) those that have *recovered* and hence are no longer infectious. This SIR model is

Epidemiology

A broad definition of epidemiology is that it is the study of the distribution of health-related states and events (not just diseases), and the associated determinants, in specified populations ranging

R. Dybowski (✉)
St John's College, Cambridge, UK
e-mail: rd460@cam.ac.uk

based on the following set of ordinary differential equations:

$$\frac{dS}{dt} = -\alpha SI, \quad (1)$$

$$\frac{dI}{dt} = \alpha SI - \beta I, \quad (2)$$

$$\frac{dR}{dt} = \beta I, \quad (3)$$

$$S + I + R = N$$

where α is the disease transmission rate, β is the recovery (or death) rate, N is the total number of the whole population. $S = S(t)$, $I = I(t)$ and $R = R(t)$ are, respectively, the number of susceptible individuals, the number of infected individuals, and the number of recovered individuals at time t . See Fig. 1. The average number of infections arising initially from a single infected individual is the basic reproduction number $R_0 = \alpha/\beta$.

Although the SIR model provides a simple and generic framework for understanding and predicting epidemiological dynamics, a number of modifications are possible which increase model realism but also increase the number of parameters that have to be estimated (e.g., [15]).

SIR-type models assume population and spatial homogeneity, but this is often too simplistic an assumption. For example, motivated by the occurrence of measles amongst school children [35], Dietz and Schenzle [10] provided explicit expressions for the transmission potential of an

immunizing infection where the contact rates and the vaccination rates depend on the chronological age of an individual, and the infectivity and recovery rates depend on the duration of an infection. This consideration of the age structure of a population is also relevant in the context of the COVID-19 pandemic. One of the earliest considerations of the risk structure of a population was done with respect to sexuality heterogeneity during the HIV epidemic of the late 1980s and early 1990s [27].

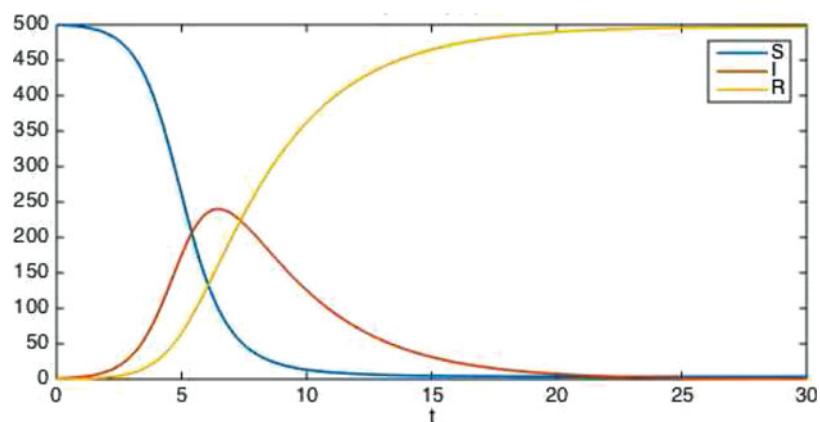

In addition to the assumption of uniformity of the spatial structure of an epidemic, SIR-type models also assume that populations are large; however, this assumption can be addressed by the use of stochastic models [2], an approach that has been used to model the spreading of influenza [25]. The foot-and-mouth disease epidemic of 2001 highlighted the importance of spatially explicit modeling as transmission between farms was a highly localized process [22].

Using Artificial Intelligence

The Recurrent Neural Network Approach

Recurrent neural networks (RNNs) [12, 21] with long short-term memory (LSTMs) [19] have performed impressively as time-series predictors, for example, in the realms of financial market prediction [44] and weather forecasting [5]. Therefore, it is natural to consider their use to predict the trajectories of epidemics.

Fig. 1 Typical plot of $S(t)$ (blue), $I(t)$ (red), and $R(t)$ (yellow) over time t

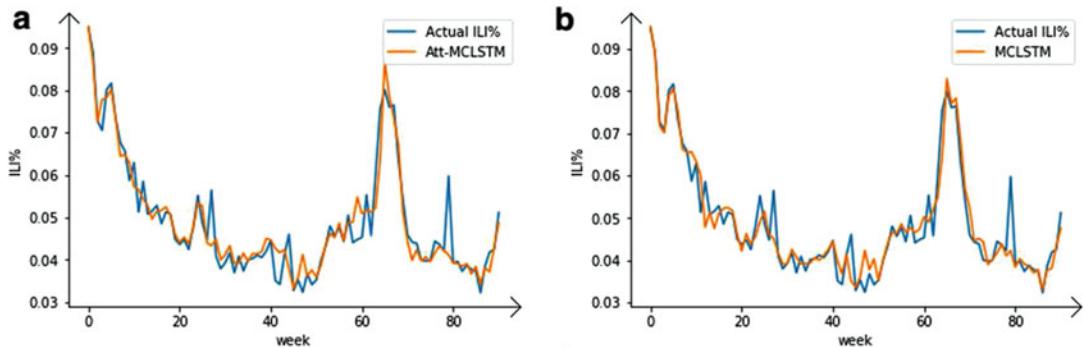

Fig. 2 Plot of observed influenza-like illness rate (ILI%) (blue) and ILI% predicted 1-week ahead (orange) using an RNN-LSTM (a) with attention mechanism, and (b) without attention mechanism [47]

Zhu et al. [47] applied a multi-input RNN with LSTM to predict the progress of the influenza-like illness rate 1 week ahead in Guangzhou, China (Fig. 2). They obtained a mean absolute percentage error (MAPE) of 0.118. When an attention mechanism [41] was added to the RNN-LSTM, the MAPE was reduced to 0.086.

Akhtar et al. [1] employed an RNN (but without LSTM) to predict the occurrence of the Zika virus across the Americas with an average 1-week-ahead accuracy of AUC 0.94. Inputs to the network included previous numbers of Zika cases and population densities.

With regard to forecasting the COVID-19 pandemic, Shahid et al. [36] showed that the use of a bidirectional LSTM gave better accuracy than a standard LSTM.

RNNs with LSTM generally have a good track record [40], but there is another AI-based technique that can produce rich epidemiological models, and it is to this approach that we turn next.

The Multi-agent Approach

Instead of using a set of differential equations (either deterministic or stochastic) to model the dynamics of an epidemic, an entirely alternative approach is to use an agent-based approach in which each member of a population is represented by an individual agent.

In general, a *multi-agent system* consists of multiple decision-making agents that interact in a shared environment to achieve common or

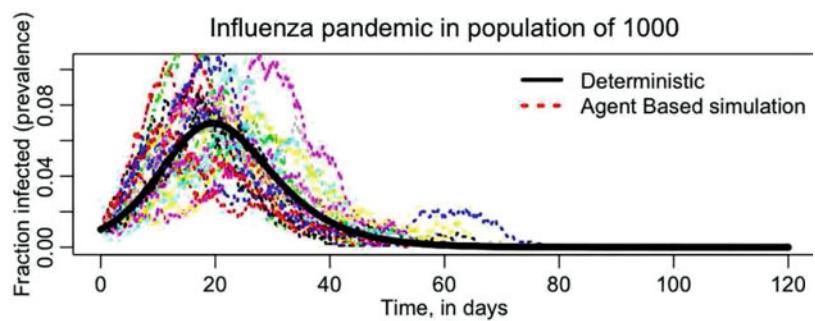

conflicting goals [37]. Multi-agent systems are regarded as a subfield of distributed artificial intelligence [45].

A general agent-based modeling scheme consists of the following steps. First, a set of A agents $\{a_1, \dots, a_A\}$ are initialized. Under this stage, agents are configured in a determined position or in a specific state. Then, each agent $a_i \in \{1, \dots, A\}$ is selected randomly or in a particular order. For a_i , a set of rules is applied in order to change its position, state, or relationship with other agents. These rules consider a relation of conditions imposed by other agents or local influences. This process is repeated until a predetermined stop criterion has been reached.

Agent-based models are generally simple – they do not use sophisticated architectures or difficult behavioral rules – but, in spite of these simple behaviors, they are capable of generating complex global patterns (behaviors) as a consequence of the interactions of a set of simple agents. Figure 3 shows a plot of $I(t)$ based on the deterministic SIR model (Eq. 2) for an influenza outbreak overlaid with 50 agent-based simulations of $I(t)$. Note the variety of plots obtained from the agent-based simulations. This stochasticity gives a more realistic measure of the uncertainty of $I(t)$.

The standard SIR-type epidemiological models are based on a number of assumptions that will not always be valid, for example, large and homogeneous populations. In contrast, agent-based epidemiological models are more flexible than the conventional equation-based compartmental

Fig. 3 Plot of $I(t)/N$ from Eq. 2 (black) for a hypothetical strain of influenza with $R_0 = 1.5$. The plot is overlaid with 50 agent-based simulations of $I(t)/N$ (various colors). $N = 1000$

models (e.g., [20]). They fully allow for heterogeneous populations, varied contact patterns, and relevant networks.

Furthermore, agent-based systems can be applied to small communities as well as to entire nations, and achieving such granularity allows interventions to be targeted locally. This would avoid unnecessary blanket lockdowns and their crippling economic and social costs.

Another advantage of agent-based systems is that the flow of infection over time within a community can be visualized. An example of this is the work of Hackl and Dubernet [17] that simulates the spread of an outbreak of influenza in the metropolitan area of Zurich over a 17-h period (Fig. 4).

Because agent-based approaches model individuals with distinct characteristics, they provide more realistic results. In particular, one can consider each agent's internal biology in the simulations. This would allow one to go beyond saying if someone is infected or not by being able to say that someone is infected and that they have a higher likelihood of transmission. This, in turn, allows a richer and potentially more accurate model of infection. An example of this is the work by Venkatraman et al. [42] on the use of an agent-based approach for forecasting the 2014–2015 Ebola epidemic in Liberia.

The above agent-based models were built for human-human transmissions, but what of vector-borne diseases such as malaria? This need was first approached by Roche et al. [32], and agent-based simulations have recently been proposed for schistosomiasis [8].

SARS-CoV-2

As regards the SARS-CoV-2 virus, Nanna et al. [29] developed a multi-agent system to model COVID-19 outbreaks. The human population, modeled as agents, behaved and interacted in a randomly generated urban setting, where the places with higher risk of contagion are considered. This included households, hospitals, public places, the transportation system, businesses, and mass gatherings. In their simulations, humans and businesses dynamically change their behavior depending on the measures and the restrictions enacted by the local government aimed at slowing down the spread of the disease. In order to simulate a more human behavior, they also admitted the possibility of reckless actions. Both Bouchnita and Jebrane [7] and Cuevas [9] provide technical details of the use of multi-agent systems for COVID-19 transmission simulations.

Magalhaes et al. [26] developed a simple multi-agent model that describes the transmission dynamics of coronavirus for a given location. This is done with respect to three parameters: population density; rate of social isolation rate; and the effective transmission probability represented by the Coronavirus Protection Index (CPI). The CPI is a measurement of a given territory's vulnerability to the coronavirus that includes characteristics of the health system, socioeconomic development as well as infrastructure. The model was calibrated by immunity surveys, and their simulations demonstrated the possible existence of multiple epidemic curves in the same city due to different vulnerabilities to the virus across regions.

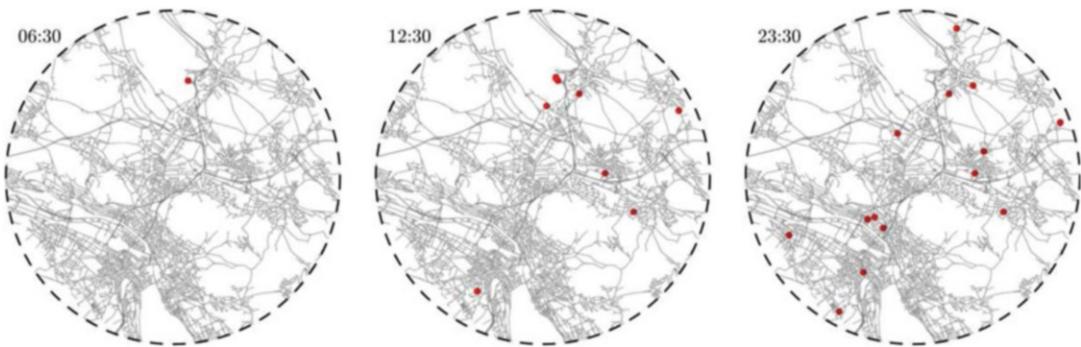

Fig. 4 Simulation of a temporal-spatial spread of influenza virus in a part of Zurich over 1 day starting with a single infected agent (red dot) at 6:30 am to many agents becoming infected by 11:30 pm [17]

The use of multi-agent systems to simulate and compare the efficacy of different outbreak intervention policies in silico has been adopted by a number of groups. For example, the model developed by Vyklyuk et al. [43] allowed them to compare the impact of various quarantine measures and restrictions on transport connections imposed by Ukraine, Slovakia, Turkey, and Serbia. Silva et al. [38] also compared intervention policies looking at economic impacts as well as consequences on health.

Fiore et al. [13] used multi-agent simulations to estimate the testing capacity required to find and isolate a number of infections sufficient to break the chain of transmission of SARS-CoV-2. Depending on the mitigation policies in place, a daily capacity between 0.7 and 3.6 tests per thousand was required to contain the disease. However, if contact tracing and testing efficacy dropped below 60%, the number of infections kept growing exponentially, irrespective of any testing capacity.

Contact tracing has become an important part of the attempt to manage the COVID-19 pandemic, and Omae et al. [30] used a multi-agent system to simulate the effectiveness of a Japanese contact-tracing app in various scenarios.

The effectiveness of vaccination campaigns was investigated by Nadini et al. [28], who supported the intuition that vaccination in central and dense areas urban should be prioritized.

During the early phase of the pandemic, *The Lancet* wrote that there should be research to “determine the best ways to apply knowledge about infection prevention and control in healthcare settings in resource-constrained countries” [4]. Furthermore, an article by *the Economist* highlighted how the pandemic is likely to devastate poor countries with healthcare systems that are not in a position to cope [11]. This need to support poor countries during the pandemic is still of immense importance, and this has led Gilman et al. [14] and others to focus on the use of multi-agent systems to determine the optimal outbreak interventions to be used in refugee camps.

There have been other AI applications in response to the coronavirus pandemic [3], such as predicting the impact of air travel [6], early diagnosis of COVID-19 via CT scans [39], CoV-2 protein structure prediction [31], and robots for COVID-19 field hospitals [34], but here our focus has been on infection dynamics.

Computing Requirements

Computational efficiency is an important concern when modeling the potential interactions of millions of individuals. Although multi-agent systems are far more flexible than the conventional deterministic models, they are also far more computationally expensive and can require fast, parallel processors.

Various software packages have been developed to facilitate the construction of multi-agent

systems, including IDESS [46] and FRED [16]. FRED (a Framework for Reconstructing Epidemic Diseases) is a freely available open-source epidemic modeling system that uses census-based synthetic populations to capture the demographic and geographic heterogeneities of the population, including realistic household, school, and workplace social networks. FRED requires between 750 and 1000 MB of memory per million simulated individuals. The exact amount of memory required depends on the demographic and geographic characteristics of the synthetic population, as well as the severity of the simulated epidemic. Simulations of an influenza spread like the H₁N₁ pandemic in a population of 1 million people takes less than 2 min on a typical dual-core laptop computer but the runtime will vary depending on the number of individuals infected during the epidemic. For example, on an SGI Altix UV shared-memory architecture with up to 16 TB of shared memory, a simulated pandemic over the entire United States population requires approximately 200 GB of memory and takes approximately 4 h using 16 threads.

Born out of the games industry, which demands high fidelity simulations, a recent development is the Aether Engine produced by Hadean [24], which can be readily sealed up to provide large-scale simulations of COVID-19 outbreaks within the UK and beyond.

Parameter Uncertainty

The plots shown in Fig. 1 were based on fixed (i.e., known) values for parameters α and β in Eqs. 2 to 3; however, in reality, these are estimates with an associated uncertainty.

Suppose that, in place of a single value for α , we have a probability distribution function $\mathbb{P}(\alpha)$ that expresses the uncertainty in α . Similarly, for β , we have a probability distribution function $\mathbb{P}(\beta)$. More honest plots for $S(t)$, $I(t)$, and $R(t)$ could then be obtained by randomly selecting α and β from $\mathbb{P}(\alpha)$ and $\mathbb{P}(\beta)$, respectively, obtaining the resulting plot, and then repeating this a large number of times, each time randomly selecting α and β .

In the case of multi-agent systems, the same approach could be adopted for all relevant parameters. Note that this would give an additional stochasticity on top of the intrinsic stochasticity resulting from using multi-agent systems. But these uncertainties lead to the important question of how best to respond to epidemics under (sometimes extreme) uncertainty.

Conclusion

Recurrent neural networks have significantly improved forecasting over traditional approaches to time-series modeling, such as the autoregressive integrated moving average (ARIMA) [36].

As discussed, the multi-agent approach provides a richer modeling of infectious disease outbreaks than the compartmental models. These are visual over a geospatial display and are not restricted to populations that are large and homogeneous. Furthermore, the availability of powerful computers with efficient algorithms means that multi-agent systems are scalable and thus a realistic alternative to the conventional forecasting techniques.

Abstract

In the last decade, artificial intelligence (AI) has revolutionized many scientific areas. Due to huge amount of data being generated in biomedical fields, AI has been a crucial computational tool to improve predicting modeling and simulation. AI can find hidden pattern in biological data (genomic, proteomic, transcriptomic, small molecules, etc.) and connect the unknown parts of a big puzzle. Immune system is for sure one of the most complicated molecular networks in human body. A good question would be how these immune cells and

proteins recognize the normal inner cells from other foreign or abnormal cells (infected or cancerous cells) and viruses. For many years, scientists have been working to answer this question in detail. Understanding the immune system is equal to ability to trigger it against strong viruses and bacteria. AI has been helping scientists in the field immunoinformatic and vaccine discovery to improve the efficacy of predicted epitopes. However, dealing with immunological data has been very challenging, and the representation of each sample has not been easy. In this chapter, we discuss how AI started to improve vaccinology and how it will be leading the future of computational vaccine development and immunoinformatic.

Introduction

Immunology is for sure one of the most crucial subdivision in biomedical sciences. After an infection in body, a very complex and organized system of cells and their secreted proteins start many complicated processes in order to overcome the foreign attach and keep a record of it for future references. However, this system would also recognize and destroy any inner threat such as cells out of their natural cycles including cancerous ones [1]. In evolution, a very smart way of distinguishing cells coded in our DNA has been developed. In a simple language, a very important genomic complex entitled major histocompatibility complex (MHC) is responsible for a system of critical proteins named human leukocyte antigen (HLA) [2–4]. These genes are very polymorphic and can vary between different people. Any infected cell would just present fragments of the bacteria or viruses' proteins, epitopes, on surface by HLA system and then the immune system would do the rest and get rid of that cell [2].

The idea of human body having an inner immune system goes back to thousands of years ago. One of the first mentions in this regard is recorded in Gilgamesh poem, a written document in Babylonian period (2000 BC) [5]. Thucydides was an Athenian historian who understood some aspects of acquiring immunity from prior infection in plague era of Athens (430 BC) [6]. In a revolutionary breakthrough of immunology history, two Iranian (Persian) alchemist and philosophers, Rhazes in tenth century and Avicenna in eleventh century, developed the idea of adoptive immune system from understanding the fact that fever is an immune process to combat diseases [7]. Avicenna, who is called the father of modern medicine by many, further developed the idea of acquired immunity and made a revolution in this regard [8, 9]. In addition, one of the first practical

implementation of vaccines and intriguing of adaptive immune system was done by Edward Jenner, an English physician who used crusts from smallpox pustules as the world's first vaccine against smallpox [10]. Similar methods are reported to be executed in 1000 AD in China. In 1880, Louis Pasteur and Emile Roux attenuated cultures in chicken which lead to the induction of immune system and a very first artificially made vaccine. Nowadays, vaccines are widely practiced in the whole world for the artificial induction of immune system (*Vaccines and Immunization, WHO*).

Humans mainly have two central types of immune response, innate and adoptive immune system. Innate immune system is basically older in evolution as the first line of defense in most of creatures including insects, mammalians, and fungi. One of the primary functions of this system is informing and recruiting another immune components using some chemicals called cytokines [11]. The second immune response which is smarter and more specialized in the recognition of already encountered pathogens is adoptive immune system. This immune system is seen in vertebrates, and it consists of both humoral and cell-based immunity [12, 13]. Humoral immune response consists of mostly macromolecules such as antimicrobial peptides, antibodies, and defensins. On the other hand, cell-based immunity includes the cell-mediated responses to pathogens, as an example we can point to the cytokine secretion or macrophage involvement. The biggest distinguishable difference between the innate and adoptive is the specialized reaction [14]. Adoptive immunity is fundamentally a specialized memory response to pathogens. This memory would last months to couple of years as protection and in some cases a lifelong immunity. The idea of vaccination and artificial immunity is literally generated by understanding the fact that immunity's memory and response can last longer than the infection duration. Epitopes' generation and representation to immune system is the core approach for mimicking the natural long-term immunity memory [15].

Old school vaccine discovery and development is very tedious, time consuming, and

expensive. In these approaches, scientists have to culture the pathogens (for bacterial vaccine discovery) or grow cells containing pathogenic particle (for virus vaccine discovery), inactivate them, and inject them to healthy and nonhealthy volunteers [16]. This may take years for vaccine production, testing, and trial. Therefore, there has been an urgent need for alternative approaches and technologies for vaccine discovery [17]. After the introduction of different biological assays to measure diverse factors of immune responses and other variables, huge datasets started to pile up in many laboratories of universities and companies. Soon a new concept was born, computational analysis of big immunological datasets or immunoinformatic. With the rise of robots and high throughput assays, there has been a pleading need for new software and algorithms to analyze the large, generated datasets [18].

Basic areas of immunoinformatics include T cell and B cell epitope prediction, in silico vaccine discovery, discovering immune-related genes, allergy prediction, virulence gene identification, and most importantly, HLA typing and sequencing, database creation, and design [19–21]. Old school modeling and algorithm implementation has not been able to leverage the full potential of huge databases created by many diverse immunological assays. Also, the accuracy of those modeling has not been satisfying. Most of the time, the hidden patterns and information inside the mentioned databases are way more complicated for scientists to discover and distinguish. As an example, we can mention the HLA typing process. In spite of 8/8 HLA matching, many patients have complications after transplantation (we will talk more about HLA typing in following sections). Therefore, there should a type of modeling and algorithm capable of learning hidden pattern in an abstract way. Machine learning comes to rescue!

AI and Vaccine Discovery

With the emergence of artificial intelligence in last decades, automation has become a new reality in many industries. From autonomous driving and credit card fraud detection to face recognition and

cancer detection, artificial intelligence has revolutionized many fields [22–26]. Biomedical sciences inherently are a type of field that deals with very large amounts of generated data. From hospitals to biological labs, a huge number of genomic, molecular, proteomic, etc. class of data is collected every day. Old school type of data analysis and modeling has not been capable of getting the most out of biomedical big data. Therefore, there has been a need for newer computational technologies for analysis and prediction. Artificial intelligence comes to rescue. AI helps the scientists gain insights via combining multiple datasets from real-world cases which are inherently messy. In vaccine discovery, AI aids in the same manner and can help with recognizing which pieces of the virus are more likely to be recognized by the immune system [27], which epitopes are likely to be presented on the surface of the cells [28], and which peptides can be toxic.

The search for a vaccine has four steps, finding the vaccine's target, determining the needed immune response, generating the needed response, and discovering what responses are generated in the vaccine's subjects. The first two steps are more understood than the latter steps. AI and modeling can help make sense of the complexity of the immune system, accelerate the process of vaccine discovery, and increase the probability of vaccine's success [19, 29]. System Vaccinology tries to predict the beneficial and harmful responses generated from the vaccine in the forms of immunogenicity and reactogenicity [30]. AI can be used in this regard to learn from different input data sources such as clinical, genome, transcriptome, proteome, metabolome, mass cytometry, and cytokine profiling data sources to model and predict outputs such as antibody response, T cell response, adverse events, and vaccine protection [31].

Another area which has been impacted by the use of AI is vaccine distribution and planning. Traditional machine learning models such as Random Forest (RF) and Support Vector Machine (SVM) have been used to identify children who may drop out from the immunization course and not follow up on the subsequent immunization visit [32]. These predictions can be used to better

plan for these high-risk individuals and ensure universal immunization coverage.

Use of AI in vaccine discovery has also faced challenges. One of the main challenges for AI is that it cannot replace one of the most time-consuming steps in the vaccine discovery process, which is animal and human trials (Emily Waltz, 2020). Moreover, imbalanced datasets with numerous features which are prevalent in the field of immunology still pose a challenge to machine learning algorithms [31].

AI and Vaccine Discovery for SARS-CoV-2

Due to the nature of the pandemic and the necessity of a prompt response, AI-based approaches were heavily used by researchers around the world to accelerate the vaccine discovery process for SARS-CoV-2 [33]. In the early days of the outbreak, the Stanford Institute for Human-Centered Artificial Intelligence (HAI) used neural network-based tools such as NetMHCpan 4.0 [28], MARIA [32], and linear regression-based tool DiscoTope 2 to release a list of possible epitopes for SARS-CoV-2 [35].

Deep-Vac-Pred trains a convolutional neural network to aid in the design of a multi-epitope vaccine for SARS-CoV-2. This model predicts potential vaccine subunits from the virus's spike protein sequence and filters the predictions via investigating the linear B cell epitopes, cytotoxic T lymphocytes (CTL) epitopes, and the helper T lymphocytes (HTL) epitopes [36]. An innovation of this work is the dataset design, in which the positive data points must contain at least one B cell epitope, one T cell epitope, and be protective antigens. This dataset design narrows the predictions immensely and accelerates the process overall. Further in silico tools are utilized to filter the prediction, i.e., BepiPred [37], NetMHCpan 4.1 [28], and NetMHCIIPan [27], and to evaluate the quality of the designed vaccine, i.e., Vaxijen 2.0 [38] and ToxinPred [39].

AI has also been a useful resource in predicting the 3D structure of several proteins linked to SARS-CoV-2. The structure of the protein plays

an important role in defining how the protein functions, and in the case of SARS-CoV-2, how the protein can be targeted. Therefore, many researchers used different tools, including AI and deep learning, to predict these 3D structures. DeepMind provided these predictions using AlphaFold [40], a convolutional neural network-based model which learns to predict the pairwise distances between the amino acids of the protein sequence, then optimizes the potential of mean force to find the shape of the protein. Another model which assisted the prediction of SARS-CoV-2 protein structures was trRosetta [41]. This model consisted of a deep residual convolutional neural network which learns to predict the orientation of all residue pairs alongside their relative distance. Some of the main predictions made by AlphaFold and trRosetta were soon after verified to be accurate [42].

AI for MHC Binding Peptide Prediction and Organ Transplant

It has been shown that for having a recognition of peptides by T cells, they need to bind to MHC molecules first. As mentioned before, major histocompatibility complex (MHC) are a class of cell surface proteins (also called human leukemia antigen or HLA) that are coded by a very polymorphic region of DNA. One of the most important function of HLA molecules is the regulation of immune system [2, 43]. These molecules also have the responsibility of distinguishing between self and outside proteins, therefore they can be very crucial in organ transplantation. Any mutation in these genes would be destructive and result in autoimmune-related problems. As a rule of thumb, any cell representing a nonfamiliar HLA type is considered a threat by immune system and will be removed by it. Transplant rejection is basically a reason of representing the non-self HLA by the new organ [44].

HLA typing is an important step before organ donor selection. We inherit these biomarkers from our both parents. That is why the chance of finding a perfect HLA match in our family is higher than unrelated people [45, 46]. Also, it is more

probable that we can find a match in the same race of the patients than farther ones. Nowadays, health care organizations and hospitals suggest matching at least 6 out of 8 loci of HLAs to decrease the chance of having problems after transplantation [47]. However, still about 40% of patients experience complications and death after 8 of 8 matching. To find a solution for this problem, artificial intelligence and immunoinformatic come to rescue [48]. AI can find unknown loci and other important biomarkers by discovering the hidden patterns in immunological data.

The Challenge of Variation

Class I HLAs commonly bind to short peptides which are around nine-mers; however, Class II HLAs usually have the capability to bind to larger peptides around 15-mers and longer. It has been theorized that even though these peptides are longer, the binding core is still around nine-mers similar to Class I HLAs [49]. The variation in binding peptide length for both classes becomes a challenge for machine learning methods which use fix-sized input length, such as fully connected neural networks used in NetMHCpan or NetMHCIIPan [28], nHLAPred [50], and IEDB [51]. This challenge necessitates first detecting the binding core within the longer peptides, which requires preprocessing steps.

Aside from variation in peptide length, the diversity within the HLAs impacts binding, presentation, and the immune response. To accommodate this variation, two general methods have been developed. First approach is to train different models for different alleles, which are usually selected based on the amount of available data or the importance of the given allele. The second approach implemented in response to the variation within the HLAs is to train a single pan-allelic model which can make predictions unrestricted by the input allele. Commonly a pseudo-sequence is used to represent the allele and normalize the input. Removing the allele restriction and training a pan-allelic model ensures that the model encounters different alleles during training and can learn generalizable and sharable features for

the alleles which may increase the prediction performance of the model.

However, pan-allelic models may still be challenged if the input HLA is rare with scarce training data. This shortcoming is addressed in works such as MixMHCp [52] and RBM-MHC [53] which use semi-supervised approaches to generate candidate presentable peptides for rare HLAs. Rare alleles also present a challenge for genotyping given their low frequency. DEEP*HLA [54] alleviates this problem by using convolutional neural networks for allelic imputation.

Drug Discovery and Vaccine Discovery Differences for Learning

As mentioned before, artificial intelligence has proved its strength in automizing many fields. However, because of inherent differences in different fields, AI has been implemented in different ways. Therefore, the challenges in these fields can be diverse as well. In computer vision, data is abundant, and often easily labeled in a costly manner. One other such example would be structured hospital-driven data which would be list of patients with different features and characteristics like the type of disease, severity of the disease, the age of patient, etc. However, some data are inherently not structured, like molecular data. Each molecule can have different creative shapes in space due to diverse characteristics of atoms to form various types of bonds and angles. Having that said, structured representations would not be helpful for such type of data. Therefore, different types of modeling and data representation would be crucial to train a learning-based model [55].

Graph convolutional neural network (GCNN) are a suitable candidate for the unstructured case of drug discovery. Each molecule can be presented as a graph, with nodes representing atoms and edges representing the bonds between the atoms. Therefore, a model capable of learning graph-based data would be beneficial for drug discovery field. GCNN has proved that it can reach amazing results for drug discovery, and there are multiple helpful resources to implement these types of libraries like DeepChem

[25, 56]. But what about vaccine discovery? Are antibodies and epitopes representation the same as simple small molecules? Is genomic sequence of HLA loci the same as well? These are some important questions we should investigate here.

Even though antibodies or epitopes are basically molecules, but they are not small. Proteins are often bigger in size, and they are made of small molecular compartments called amino acid. Therefore, proteins can simply be viewed a sequence of at least 20 different types of small molecules. Since antibodies and epitopes are proteins too, we should consider other types of representation and modeling for them. This is also the case for DNA or RNA as well which are sequenced based; however, the length of these sequences is even longer which presents a higher challenge. A normal DNA consists of four compartments called adenine guanine cytosine and thymine (AGCT) [57].

One example of such long sequences is HLA loci, which is about 3 Mbp in length. However, protein sequences are often much shorter in length. For example, anti-microbial peptides (AMP) which are among the first defensive lines against microbes and even cancerous cells are 10–50 base pare in length [58]. If we want to compare the input data of a normal small molecules data to a variant call format (VCF) data of different SNPs as samples, we should mention that a VCF data can have millions of different features in itself, but a small molecular data would have tens or hundreds of features and label in total. Therefore, dealing with molecular data is easier in this regard. However, small molecular data from a phenotypic screening assay also have the challenge of being highly imbalanced. A problem that would not be the case for genomic or proteomics data. Balancing the low number of active small molecules has been one big challenge for data scientists and cheminformatician so far and some methods like transfer learning has been applied to overcome the challenge [59].

Overall, in the case of molecules, GCNNs have proven to be useful while in the case of sequential input, sequence-based models such as recurrent neural networks are often successful in learning representations. One main point that unites these two fields together is the benefits of deep learning.

The traditional approaches in these fields, similar to many other fields, are extracting subject matter expertise related features from the data as an input to a simple machine learning model. While these traditional approaches are tried and true, they often lack in generalization and efficiently learning from a bigger size of input data.

However, deep learning solves these challenges by combining the feature extraction and modeling stages together, and automatically extracting features which are helpful for modeling during training. This automatic representation learning can be viewed as the main advantage of deep learning and might result in predictions or insights that were previously overlooked or undiscovered from the perspective of subject matter experts. The same as medicinal chemist being unable to detect all molecular features, biochemists are not able to detect all hidden complicated features in a 3D representation of proteins. As an example, we should investigate antibodies more which are very complex proteins with some reserved and diverse compartments. In most of the cases, it is better to let the deep learning model to discover hidden patterns in all first, secondary, and tertiary formations. However, deep learning models are not that easy to interpret what is happening when the model is training and featurizing the data [60].

Discussion

Artificial intelligence is the new reality of automation. Considering the big data being generated in biomedical fields every day, AI has been one of the best computational tools to leverage the valuable information inside. Pandemics has shown us that old school vaccine discovery are not fast enough to save millions of people, and there should be cheaper, faster, and more efficient tools to discover and approve vaccines. In addition, the huge percentage of patience experiencing complication after HLA matching is another proof that newer method is in need for discovering unknown biomarkers important in immune response. One crucial part of any vaccine development is clinical trial. The trial would take many years and it is for sure very tedious and expensive.

One of the biggest challenges for AI in future would be solving the problem of human trial. The goal would be having a fast model capable of predicting the chance of any vaccine's failure in clinical trial. This way, vaccines can get developed and approved in a very fast pace, helping societies allocate their resources in a more efficient manner. These challenges appear solvable via discovering newer and better technologies for data representation, modeling, and learning.

The field of clinical immunology is expansive and includes both clinical and laboratory science of relevance to human immune health and disease. Across the continuum of host defense, immune homeostasis/regulation, immune genetics, and laboratory immunology we are now seeing the emergence of artificial

intelligence and data science approaches. These computational tools are being leveraged to analyze the inherently large datasets of relevance to clinical immunologists. Here, we outline some recent advances in clinical immunology which have been made possible or are being explored via artificial intelligence. We discuss analysis and use of electronic health record data, human cytometric data, and multiomic data after providing a brief introduction to artificial intelligence in healthcare.

Keywords

Artificial intelligence · Machine learning · Computational biology · Clinical immunology · Data science

Introduction

Since the widespread adoption of electronic health records (EHR) health data are accumulating rapidly [1]. This explosion of EHR data makes health record information truly “big data”; thus, inferences from these datasets present an important opportunity, but require implementation of data science in healthcare and biomedicine to glean insights [2]. In this manner, artificial intelligence (AI)-based computational tools can lead to more robust analysis of clinical and scientific datasets resulting in improvements in patient safety and healthcare quality [2, 3]. For these reasons, AI and machine learning (ML) are finding greater penetration into the healthcare domain space by tackling use cases across multiple spectra [4–6].

While the terms AI and ML are often considered synonyms, AI is more general and refers to computed decision-making and ML is a sub-category of AI [7]. We also make note of the term “augmented intelligence” which is an important distinction in this space, referring to a symbiosis between human efforts and paired digital systems [8]. In ML, a model is programmed to allow machine readable input ingestion and analysis for computer task learning to make predictions with increasing precision over time [2]. In this manner, the machine adjusts weighting of

features to optimize the prediction and minimize error through training and validation.

A useful, recent concept description between humans and computers illuminated a spectrum between fully human and fully computer-driven processes with varying degrees of contributions between the two [9]. This human-computer interaction spectrum incorporates the strata of dataset size as well as complexity of analysis, thereby providing a schema for understanding how humans and machines can interact along the AI continuum. In this schema, one use case may require substantial human domain expertise to build an effective AI, while a deep learning convolutional neural network (CNN) may classify images with minimal human input. These are two extremes of human-computer interaction in AI. Neither is generally superior as it is important to understand that one approach may be more optimally suited to a particular use case. Given the diversity of opportunities and approaches across data science/AI/ML we will use the term “AI” in this chapter as a general reference for such methods across the computational spectrum unless otherwise noted.

Given the aforementioned background, how can and how has AI impacted the field of clinical immunology? Clinical immunology is a field of medicine which concerns itself with the human immune system across host defense, regulation, treatment, and laboratory diagnostics [10]. With this perspective, the impact of AI is noted in clinical immunology by developing methods for improving disease diagnosis via use of computational methods for identifying patients with risk for primary immunodeficiency diseases (PID) [11]. In this way, a risk assessment algorithm can be utilized to scan health plan claims data for the purpose of identifying patients with medical conditions, risks, or trend forecasting to enable early intervention and cost savings. One such example of population-wide risk assessment includes a rule-based analysis of calculated globulin fraction to identify patients who may have hypogammaglobulinemia [12]. Such approaches suggest early penetration of automated computational methods within clinical immunology providing a glimpse into approaches which range from novel disease gene identification to subject selection for

enrollment into clinical trials [13, 14]. In this chapter, we will provide a brief overview of AI followed by an exploration of present clinical immunology approaches. We will cover use cases spanning the advancement of basic biological approaches, improving diagnostic rates and quality of care for patients with immunological disorders.

Healthcare Data as Big Data

Healthcare data are expanding rapidly given the widespread use of EHRs. In every aspect and manner, data generated from healthcare encounters represent “Big Data” (BD). In general, BD implies data which are tremendously voluminous, generated with velocity and highly varied in nature, form, or content [15]. The size and complexity of BD offers challenge and opportunity. These unique features of BD require specific tools to accomplish data inference. These tools, the life cycle of data science, include AI.

Machine learning algorithms are built and trained to ingest diverse data inputs, perform a classification or regression task, and provide output in accordance with that task. The inputs can come from any number of routine clinical, laboratory-, or claims-related data as part of an “example” which is analyzed after labeling them based upon the predefined task [16]. During the model training phase an AI algorithm weights some features more heavily for predicting a specified outcome in accordance with the methodology chosen [2, 7]. Given sufficient performance in validation, an algorithm’s feature weighting may be retained by fixing the algorithm so that new inputs can be classified with the retained weighting [17]. The validated algorithm can then ingest and classify inputs following appropriate structuring.

Structuring Healthcare Data

One way to facilitate the use of AI in healthcare is the construction and use of validated datasets [2]. This requires careful attention to data governance and presents a number of challenges. The

assembly of a useful healthcare dataset first involves the extraction of data elements from the EHR which can have substantial variability, and be unreliable and challenging to extract in systematic fashion [18, 19]. Given the nontrivial task of accessing and making EHR data ready for AI use, clinical teams need to partner with data scientists who can help facilitate information extraction and use by clinicians and laboratory scientists [20]. The expertise of data science teams can be synergistic with clinical and scientific teams to optimize data extraction, creation of validated datasets, and enable rational use and analysis of comprehensive healthcare datasets [21].

What Is AI and How Does It Work?

Machine learning, defined as the process of a computer learning without explicit programming, is the basis of artificial intelligence [2, 22]. In all workflows, AI-algorithms are trained, validated, and then tested prior to their use. There are many machine learning methodologies, each with the goal of automizing computerized learning to complete specific tasks. The common tasks used in AI include classification, regression, and/or clustering. Of these tasks, the most intuitive to understand is “classification” in which the algorithm aims to assign each input into predefined categories (e.g., pneumonia vs. normal study on chest X-ray) [23]. Regression attempts to predict a specific numerical outcome (e.g., length of inpatient stay) and clustering attempts to determine specific categories of output depending on patterns in the data (e.g., finding new classifications for COPD). The inputs used range from structured (e.g., vitals, lab values) to unstructured (e.g., images, text) data [24].

The next step after defining a task is to apply a specific or a set of machine learning methodologies. There are many distinct types of machine learning methods such as deep learning neural networks, random forest, and logistic regression, each with their own advantages. For example, neural networks are a type of deep learning model that mimics the human brain by bidirectionally processing data through a multilayered structure with differentially weighted connections

[25]. This is especially useful in healthcare as additional layers can be added to process large and complex datasets. Once a methodology or combination of methodologies are decided upon, the next step is to “train” the algorithm with a labeled dataset in a process known as supervised learning [24]. If the desired task is to determine the presence of pneumonia on chest X-ray (CXR), the machine would be fed a set CXRs labeled as “normal” or “with pneumonia.” Additional labels (i.e., outlining opacities) may be added to enhance the algorithm’s performance. From there, the algorithm independently learns and discovers specific features to differentiate normal from pathologic X-rays. In contrast to supervised learning, unsupervised learning uses unlabeled data and asks the algorithm to create its own classification scheme. Supervised learning, however, remains the most common form of machine learning [26].

Once the algorithm is trained, the model is put to the test with unseen and unlabeled data. The performance metrics used depends on the type of task desired. For classifier algorithms, commonly used metrics used include recall, precision, positive predictive value, and negative predictive value. Depending on the parameters set on the algorithm, these metrics can be optimized for clinical use. One popular metric, the F1 score, is a composite recall and precision. High F1 scores generally implies good accuracy of an algorithm. Similarly, the area under the receiver-operator curve (RAUC) determines how well an algorithm performs compared to random guessing in a classification task [23]. In the example of the presence of pneumonia on CXR, an algorithm with an AUC value of 1 would differentiate presence versus absence of disease 100% of the time. The other tasks of regression and clustering also have commonly used performance metrics; the discussion of these is outside the scope of this chapter.

AI and the Learning Health System

Ideally a system focused on quality and safety in healthcare will learn and improve over time. This concept was born out of concerns about the overly complex environment in the U.S. rife with

systemic errors, leading to suboptimal outcomes (morbidity and costs). Looking forward with an attempt to address these challenges, the US Institute of Medicine (IOM) considered a different healthcare system which is focused on iterative improvements and optimal outcomes [27]. Circumventing such problems and aiming for quality care produced the notion of the learning healthcare system (LHS) [28]. An LHS was conceived to make it easier to “do the right thing” more often by improving quality and safety, while reducing preventable errors, inefficiency, and sub-optimal processes [29]. In this way, systems could be engineered to redefine healthcare structure and process with intentional use of digital platforms which enable effective clinical decision support systems (CDSS), coordinated care, interoperability, and knowledge acquisition [29].

Visions and early discussions of what is possible brought forth the emergence of concepts from which actual health systems processes were born. These systems were conceived which leverage optimized clinical datasets to drive toward intelligent healthcare systems which are more effective [30–32]. One example of a LHS incorporates time series, structured EHR data for real-time use, and in conjunction with natural language processing (NLP) to forecast clinical events in the intensive care unit (ICU) [33]. Systems of this nature might enable foreshadowing of suboptimal clinical outcomes at the bedside, thereby providing guidance to reduce morbidity or additional patient costs. Another one of many examples includes the use of technology for assessing population risk trends for hospitalization and lockstep adjustment of hospital staffing resources [34]. In this way, population-wide use of wearable sensors can drive real-time health system adjustments while providing precise clinical recommendations for improved health acutely and throughout the lifespan [35]. The intercalation of technology into healthcare processes will move us toward a true LHS by fostering maximum use of data. Such changes have not come easily as they require a culture change and system-wide infrastructure modifications [33].

In order for a holistic HLS to become reality, one that serves patients and clinicians, we need

secure and pervasive data access which take into account the complexity and sensitive nature of healthcare data. The use of common data models and open source tools for clinical data science will then allow for interoperable AI [36, 37]. Along these lines, partitioning a secure development environment containing useful EHR data elements and access to best practice informatic tools will allow for gleaning insights for patients during routine clinical care [38]. Allowing for efficient and secure reuse of clinical data can lead to stepwise improvements in care while extending knowledge via local population health information [39–41]. One important and distinctive feature of health data science and health informatics relates to the highly sensitive nature of the data along with the privatization of platforms (i.e., EHR systems) which capture the bulk of this data. These challenges may be overcome by extracting the most useful data elements and appropriately structuring EHR data within a secure environment where healthcare practitioners and clinical researchers can collaborate together and with data scientists to enable ultimate realization of the HLS.

Applications of AI in Clinical Immunology

Disease Diagnosis: Primary Immunodeficiency

Artificial intelligence has been utilized for improving screening, risk stratification, and disease phenotyping for a variety of conditions [26, 42]. The development of sepsis prediction algorithms to aid clinicians recognize and treat sepsis prior to decompensation is an example of computerized risk stratification in an automatized workflow [43]. In the context of PID, artificial intelligence has been proposed as a diagnostic assist tool for clinicians. The relatively low prevalence and clinical heterogeneity of PID can be a diagnostically challenging, especially for practitioners in nontertiary settings [44]. Work is already underway to leverage large databases to build upon a rule-based algorithm called the

Software for Primary Immunodeficiency Recognition Intervention and Tracking (SPIRIT) to assist in early identification of PID [11]. Using claims data (i.e., ICD codes) the SPIRIT algorithm screens and classifies individuals into low, medium, and high risk for PID categories to help facilitate clinician diagnosis. The addition of supervised learning to this to a population-wide screening tool such as a SPIRIT could aid in earlier recognition of PID, potentially mitigating significant morbidity, mortality, and cost associated with this condition.

In a similar fashion, probabilistic models have been explored as classifiers for various conditions in the field of allergy/immunology [45]. Bayesian networks are an ideal model that combines conditional probabilities and domain expertise to calculate probabilities of interest (e.g., likelihood of disease) [46]. Bayesian networks are built on intuitive nodal structures (e.g., directed acyclic graphs) that represent probabilistic relationships between relevant features and the outcome desired. Using structured EHR data from a large population cohort, a Bayesian network classifying PID versus age-matched controls yielded an AUC of 0.945 [47]. Furthermore, authors demonstrated an 89% accuracy of the model when classifying PID patient into the appropriate International Union of Immunological Societies (IUIS) diagnostic categories. As additional data is incorporated within the algorithm, the Bayesian network can be expanded to include more nodes and connections, thereby improving the model's performance. Incorporation of Bayesian networks and probabilistic models into EHRs will provide clinicians with tools to enable real-time diagnosis [48].

With the advent of electronic health records (EHR) and widespread gene sequencing, clinical phenotyping has become a focus point and a proposed use case for AI algorithms [49]. Over the past decade, distinguishing clinical phenotypes of PID using EHR and genomic data has led to a dramatic increase in the number of distinct PID-associated entities [50]. Machine learning methodologies such as support vector machines (SVM) have been used to discover new PID-associated genes [51]. Integration of

multiomic data, including clinical, genomic, metabolomic, and microbiome data will serve as the basis for molecular phenotyping in foreseeable future [52].

Structured ontologies leveraging structured and unstructured text data have been shown to successfully capture clinical phenotypes through analysis of medical terminology and claims data [53, 54]. For example, ICD-9 codes have been used to capture and characterize PID cases in a statewide population [54]. On the national scale, projects such as the Human Phenotype Ontology (HPO) combines multiple ontologies in the quest to phenotype rare diseases. By linking medical terminology, including terms associated with immunological disorders, HPO attempts to link phenotypes with genomic variants [55, 56]. The use of deep learning methodologies, such as NLP, to extract HPO terms from EHR narratives has been shown to identify causal genes in patients with Mendelian disease [57]. Indeed, similar approaches with NLP have yielded positive results in identifying distinct phenotypes in diseases such as Parkinson's, major depressive disorder, and multiple conditions in the field of allergy/immunology [14, 58, 59]. Ultimately, combining HPO terms, unstructured EHR data mined with NLP, and other structured genomic data to enable artificial intelligence-guided insights and discoveries of immune disorders is the goal of major multi-institutional efforts [60].

Clinical Decision Support

Clinical decision support (CDS) is a subdomain of clinical informatics which focuses on delivering the right information to the right clinician in the most appropriate channel and timing via the EHR [61]. The options for a given CDS intervention range widely, including alerts and custom order sets, among others, including AI-based prediction [62]. Ultimately, CDS is customized according to the given use case and must be formulated with a deep understanding of the particular work flow [63].

Applications of CDS within the domain of CI are beginning to be explored. For example, use of

a rule-based algorithm for assessment of health plan data to provide a risk score for underlying immunological dysfunction [11]. Pilot studies of this nature suggest that automated methods of disease classification could embed within health system workflows to advance clinical analytics processes, as well as improve diagnostic rates and quality of care along the lines of a LHS [26]. Another example includes the prediction of optimal applications for precious clinical resources such as immune globulin (IVIG) in patients with Kawasaki's disease (KD) [64]. In this study, a gradient boosted machine (GBM) was able to predict which KD patients may become resistant to IVIG enabling decision support about best therapeutic options for such patients.

The above studies point toward opportunities to leverage AI to improve care of patients across the spectrum of CI. As of this writing such use cases are only beginning to be explored. As we seek to refine CDS and uncover new applications for using AI to drive insights from the clinical record, CI will continue to benefit from CDS approaches.

Candidate Selection for Clinical Trials and Patient Identification Efforts

Within the field of CI, candidate selection for clinical trials and clinical phenotyping is being improved via AI [65]. For example, NLP can facilitate patient detection for clinical research applications [66]. Patients with lupus and spondylarthritis have been identified with systematic EHR-focused data mining approaches using machine learning [67, 68]. Additionally, use of NLP has been leveraged for understanding atopic dermatitis perception by patients and to better understand the epidemiology of allergic drug reactions [69, 70]. In these two use cases, one can expect to extend the focus of the NLP systems to provide deep phenotyping of the clinical record to identify distinct patient subtypes.

In particular, much has been learned about the electronic phenotype of asthma patients as extracted from clinical records. Patient ascertainment

across the asthma severity spectrum has been accomplished with NLP approaches [14, 71–73]. Asthma control and level of severity can also be mined from clinical note text [74, 75]. These approaches underscore the utility of AI in CI as it pertains to phenotyping patients and identifying subjects for research studies. Additionally, the onerous task of manual patient finding is made more clear from studies that utilize AI to ascertain differences in computable asthma phenotypes from one health system to another [76]. Given a need to assess portability of health records and find patients for a multitude of use cases, AI is being utilized within the domain of CI for these very tasks.

COVID19 Applications and Impact

The greatest public health challenge of our time, the pandemic spread of SARS-CoV-2 and COVID19, is being tackled via AI approaches. First, since the clinical response in COVID19 is heterogeneous, use of artificial neural networks (ANNs) and random forest learning algorithms can be trained to analyze blood count data to diagnose SARS-CoV-2 infection with a high degree of accuracy (AUC 94–95%) [77]. Use of ML to detect COVID19 cases as applied to peripheral blood samples also sheds light on the biology of disease. For example, use of unsupervised ML approaches such as T-REX (Tracking Responders Expanding) can identify rare subpopulations of immune cells in COVID19 patients and provide insights into both early diagnosis as well as the host response to infection.

Understanding how both antibody and cell-mediated immune responses are directed against COVID19 will be important for elucidating biology and driving toward therapies. To better understand humoral immunity against SARS-CoV-2, one group coupled enzyme-linked immunosorbent assay (ELISA) to an ML model for making immunoglobulin binding predictions [78]. Here, the ML model was used to discriminate prior COVID19 infection from binding data. Additionally, use of deep serologic profiling can both

identify exposures as well as find unique viral epitopes for targeting therapies [79]. These applications of AI-based tools can improve therapeutic options for patients and cast light on the biology of this disease.

In addition to diagnosis of individual patients, use of AI and data science may help identify spread and community-level vulnerability [80, 81]. Such approaches may lead to using AI for pattern recognition and augment public health efforts to stem hot spot development. Such tools could also lead to direction of funds in communities where infections are likely to lead to more severe outcomes or enable decision-making about public health worker staffing. Machine learning may also help predict how the SARS-CoV-2 virus spreads and who may be most likely to die from infection [82].

A major focus early and ongoing during the COVID19 pandemic is how best to treat patients. Synthetic drugs and convalescent plasma are important tools in the armamentarium. One example of computed decision-making about COVID19 therapy involves the use of multicriteria decision-making (MCDM) for selecting patients most in need of convalescent plasma (CP) when ill with COVID19 [83]. Also, drug repurposing in the face of a novel pandemic is being approached with AI [84, 85]. From this approach, immune cells can be rapidly profiled for response to viral stress. Additionally, high throughput and AI-based ML can guide drug compound selection and identification based upon their antiviral mechanism of action.

Lastly, vaccine development for COVID19 is being impacted by AI. Use of computational tools and AI for analysis of large datasets is being explored to facilitate the rapid creation of vaccines [86]. Such approaches can leverage the computational efficiency and power of ML to identify novel vaccine targets [87]. In this way, the expanding datasets relating to SARS-CoV-2 genome and proteome can be analyzed. Specifically, coupling reverse vaccinology and ML has allowed for interesting viral-host protein interaction predictions [87]. Ongoing work along these lines will improve our

understanding about the basic biology of current and future pandemics as well as provide prompt options for therapies.

Biomarker Identification in Clinical Immunology

The complex nature of biological systems and their interacting features presents an important opportunity for large dataset analysis with AI. Specifically, identification of biomarkers which yield insights about immune mechanisms and therapies is becoming a subject of great interest and application for ML/AI. Toward understanding mechanisms of allergic skin disease and identification of biosignatures, ML is being used to clarify gene expression patterns from skin biopsies to distinguish allergic contact dermatitis from irritant contact dermatitis [88]. Here, co-expression network analysis and a random forest classifier were used to illuminate biomarker differences between the two forms of immune-mediated skin inflammation. Along these lines, complex diseases such as those which fall within the CI subdomain “atopic diseases” result from polygenic contributors and are amenable to study via computational modeling [89]. The overlap of multiple pathways in atopic dermatitis, for example, has been suggested as a challenging and important use case for advanced analytics approaches [90]. In this way, functional associations and pathway interactions can be drawn with tools such as STRING (<http://string-db.org/>) to tease out mechanistic insights via a multiomics approach.

A multitude of other foci have been described which are amenable to using AI/ML for studying mechanisms. In the field of transplant immunology, ANNs have been created to optimize and personalize immunosuppression through analysis of single-nucleotide polymorphisms (SNPs) [91]. Machine learning has also been used to predict graft versus host disease (GVHD) and response to transplantation [92, 93]. Additionally, a decision tree approach for biomarker ascertainment was created to clarify distinct phenotypes of GVHD and predict outcomes among patients with hematologic malignancy [94].

In addition to host immune approaches, infectious disease-related AI tools are being developed to provide better methods of diagnosis and predictions about outcomes of infectious diseases. Analysis of metabolomics data via a random forest classifier allowed researchers to improve diagnosis of paracoccidiomycosis from other fungal infections [95]. Another study utilized AI/ML in longitudinal fashion to identify unique antigen signatures associated with immunity to malaria [96]. Another example of AI application for biomarker identification of relevance to human disease relates to the prediction of outcomes of *Clostridioides difficile* infection. Use of an elastic net and logistic net facilitated identification of plasma cytokine profiles that predicted clinical endpoints and furthered understanding about immune responses to the bacteria [97].

Microbiome Analysis

Analysis of the microbiome is a separate chapter in and of itself. However, a few mentions about AI biome approaches warrant attention with respect to CI. In particular, machine learning approaches have been applied to predicting outcomes in patients with inflammatory bowel disease (IBD) [98]. Complexity reduction techniques such as unsupervised ML to assess most relevant microbial signatures and classical supervised ML have been used to predict disease severity course and response to treatment, respectively [98, 99]. Specific microbiome signatures have also been analyzed and identified via random forest classifiers to help predict clinical response in Crohn’s disease (CD) with biological agents [100].

Aside from IBD, host pathogen interactions are another use case of relevance in CI. For example a causal mixed graphical model was used to help associate pulmonary microbiome profiles with pneumonia subtypes in ventilated patients [101]. In this way disease-biome correlations can be made via AI to better understand and treat conditions. Similarly, gut microbiome analysis and classification by ML, including other clinical features, was able to predict outcomes in pediatric acute lymphoblastic leukemia (ALL) [102]. Other big data AI approaches toward microbiome study

have provided insights into understanding lung function in cystic fibrosis (CF), methotrexate response in rheumatoid arthritis (RA), delineating asthma endotypes, and helping to clarify the infection-relevant features of immunosenescence in Alzheimer's disease [103–106].

Cytometric Analysis

The human immune system has jurisdiction in all body organs and tissues. It is made up of a variety of cell types which can be studied readily via a sample of blood. To assess cellular constituents of biological samples cytometry utilizes cell biology techniques, physiochemical properties of immune cells as analyzed by lasers (flow cytometry), or mass isotopes (mass cytometry/CyTOF) to perform multiparametric evaluations of cells in solution [107, 108]. In addition to its clinical utility, cytometry approaches have involved AI for more broad applicability. For example, mechanistic immunological domain knowledge and flow/mass cytometry has been fused within an ML platform called the “immunological Elastic-Net” (iEN) [109]. The iEN utilizes prior domain knowledge into Bayesian reasoning for causal modeling which reduces needed cohort training sizes without impairing performance. The end result of this combination of clinical and cytometric data, nestled within a Bayesian framework, is a robust predictive model. Another approach utilized a deep CNN with multiple hidden layers to analyze samples for the purpose of classifying cell populations associated with latent CMV disease [110]. These examples are important applications of AI into the field of CI, specifically immune cytometry, where deep learning can be expertly tailored to recognize cell biomarker populations of relevance to immunological conditions of interest.

AI Governance for CI

Ethical Implications in AI

Notably, data science and AI are extremely useful and will transform healthcare and clinical immunology; however, remembering the distinction

between artificial and augmented intelligence is crucial. Cerrato and Halamka underscore the essence of augmented intelligence when they state “our enthusiastic take on digital innovation should not give readers the impression that AI will ever replace a competent physician. That said, there is little doubt that a competent physician who uses all the tools that AI has to offer will soon *replace* the competent physician who ignores these tools” [62]. Thus it is important that ML model function and prediction is transparent. The “black box” paradigm where mechanisms of output are not clearly evident raises suspicion and leads to mistrust [111]. Past failures are important lessons to heed in making sure that the technology serves patients in a safe and effective manner [112].

Perpetuation of implicit bias must also remain on our minds as we seek to leverage and expand the utility of AI in clinical immunology and healthcare in general [113]. To combat such biases, training datasets must include a diverse population which encompasses geographic disease states, genders, socioeconomic status, and ethnicities that represent the population accurately. Healthcare inequalities remain a challenge to be addressed. These are not isolated to the use of AI, but it is important for us to ensure that new technologies do not worsen discrimination [113, 114]. Yet we already see that healthcare use and outcomes differ across socioeconomic strata, thereby altering the efficacy of CDS systems [115]. For example, extremely well-done and high-profile studies have inadvertently excluded underrepresented minorities in their training algorithms [116]. These examples suggest a field which is maturing and experiencing some growing pains. As such, we need to continue refining the use of AI across healthcare and within the field of clinical immunology.

Conclusions

The field of clinical immunology is growing rapidly with the advent of widespread use of unbiased genomic analysis and more widely available biological therapies [117, 118]. Similarly, use of artificial intelligence in healthcare is expanding to

accommodate large and complex dataset analysis across a variety of use cases [2, 9, 22, 119]. For these reasons, we see a very bright and important future for AI within the domain of CI. Collaboration between data scientists and clinical immunologists will be important. Similarly, training the next generation of clinical immunologists with data science competency is imperative to meld CI domain knowledge and technical skills for solving critical use cases within this specialty.

Abstract

Allergic disorders are highly complex and heterogeneous in the sense of pathogenesis, molecular mechanisms, diagnostic tools, and

treatment success. The advent of novel systems immunology approaches unraveled new dimensions in the field of precision allergology to improve patient well-being and outcome. However, a major challenge within the field is to deconvolute the vast and diverse datasets to extract innovative and valuable information out of clinically heterogeneous patient populations. Machine-learning algorithms offer new tools to gain insights into high-dimensional omics datasets as well as clinical patient records, providing data-driven methodologies to decipher hidden features and patterns behind big data. These methods have a high translational aspect since newly identified mechanisms or endotypes can lead to innovative treatment approaches. This chapter gives a short overview of the current literature as well as an overview of the used machine-learning

approaches in modern allergology. Furthermore, representative examples are given to illustrate the rationale behind the different machine-learning algorithms used in the research field of allergology.

Keywords

Machine learning · Disease risk prediction · Biomarker discovery · Disease endotypes · Allergy diagnostics · Disease prognosis · Precision allergology

Introduction

Allergic disorders, which entail a number of hypersensitivity conditions with exaggerated immune responses toward environmental exposures, are a major health problem particularly during childhood, showing an increasing prevalence worldwide [1]. The growing incidence in allergic diseases is associated with changes in lifestyle and infection control, often referred to as the “hygiene hypothesis” [2], later extended by the “Old friends” [3] and “Biodiversity” [4] hypotheses. In addition, the continuous introduction of new potentially sensitizing substances in various consumer products, adds to the already extensive repertoire of sensitizers in our living environment, leading to increased risks of sensitization [5].

Allergic disorders that result from exaggerated IgE-mediated immune responses toward harmless environmental substances are known as atopic disorders, manifesting in diseases such as atopic dermatitis (AD), food allergies (FA), allergic rhinitis (AR), and asthma [1]. This disease sequence is also referred to as the “allergic march.” Contrarily, other allergic disease entities such as allergic contact dermatitis (ACD) is IgE-independent, exhibiting strong T cell-mediated reactions from direct topical exposure to environmental substances such as metals or rubbers [6]. Although ACD and atopic diseases display different molecular mechanisms, patients with AD often suffer from ACD as well, making clinical diagnosis and treatment more complex [7].

AD is the most common form of eczema in childhood, manifesting as a chronic, relapsing itchy rash. Constant itching and stigmata associated with visible skin disease can have a major impact on the quality of life of individuals suffering from AD [8]. FA, which is an abnormal immune response to food, has a growing prevalence worldwide. The symptoms range from mild to severe, including itchiness, swelling of the tongue, vomiting, diarrhea, trouble breathing, and low blood pressure. Disease management heavily relies on avoidance and emergency preparedness [9]. Asthma is a common long-term inflammatory disease of the airways, characterized by airflow obstruction and easily triggered bronchospasms. Symptoms of asthma include episodes of wheezing, coughing, and shortness of breath [10], whereas AR, which is an inflammation of the nose, includes symptoms such as a runny or stuffy nose, sneezing, and red, itchy, watery eyes. In subjects with asthma or AR, or both, quality of life is greatly impaired by physical limitations, difficulties with daily activities and poorer mental well-being [11].

In recent years, extensive progress has been made in identifying pathomechanisms of allergic disease, refining the definition of disease phenotypes, identifying novel biomarkers for a better perspective of the patients’ pathology, and for the development of preventive strategies as well as new treatment modalities [12]. However, many important questions remain unsolved regarding disease mechanisms, disease susceptibility, personalized patient treatment, treatment efficacy, and treatment-induced adverse side effects and long-term effects.

The widespread availability of new high-throughput technologies, such as genomics, proteomics, transcriptomics, and lipidomics, has greatly increased the amount of data available for the discovery of diagnostic or prognostic markers and therapeutic targets in allergic diseases [13]. However, using conventional techniques, it is a challenge to combine the high number and mixtures of data sources to find meaningful patterns. Machine learning (ML) algorithms offer an opportunity to more easily analyze all the available data, significantly speeding up, e.g., the discovery of drug

candidates or biomarkers for diagnosis. Moreover, ML can automate the complicated statistical work needed to predict a patients' response to a particular treatment. Therefore, ML methods are expected to significantly empower management of allergic disease and related research in the near future.

General Principles of Machine Learning

ML is a branch of Artificial Intelligence (AI) focusing on developing algorithms that can learn from data, without being explicitly programmed. The process by which ML algorithms learn from the data can be classified in four major categories: supervised learning, unsupervised learning, semi-supervised learning, and reinforcement learning.

In supervised learning, the ML algorithm maps an input to an output based on a known set of sample data with known characteristics (e.g., clinical data, biomarkers, etc.) and labels (e.g., patients with a skin disease and healthy controls). A typical supervised learning task is classification, which can be particularly useful for diseases with known subtypes that require proper subtype classification for adequate therapeutic measures. For instance, diagnostic discrimination between the allergic and irritant form of contact dermatitis (CD) is of importance for the clinical disease management, and supervised ML methods have been employed to identify diagnostic biomarkers to distinguish these two types of CD [14].

Similarly to supervised learning, the goal of unsupervised learning is to place input data into categories. The main difference is that the input data are not labeled in unsupervised learning, and therefore, the ML algorithms try to categorize data (e.g., patient samples) based on their inherent features (e.g., gene expression signatures, clinical features, etc.). Unsupervised techniques are instrumental in finding hidden patterns or grouping the data based on the identified patterns. Typically, unsupervised learning tasks include a) dimensionality reduction, which reduces the initial number of features (e.g., number of genes quantified by using microarrays or next-

generation sequencing (NGS) technologies); and b) clustering, which aims to organize different variables or samples into groups based on observable similarities. For example, patients exhibiting similar clinical or molecular features could provide precise identification of patient subsets for tailored therapeutics [15]. Asthma, for instance, is a heterogeneous disease comprising a number of subtypes, which may share similar molecular patterns (sometimes referred to as endotypes) or similar clinical characteristics (phenotypes). The use of unsupervised clustering is a very common practice in identifying subtypes of asthma based on observable molecular and clinical characteristics [16].

Semi-supervised machine learning is a hybrid strategy of ML that combines aspects of supervised and unsupervised learning. In this strategy, large and unlabeled data sets are combined with a small number of labeled inputs in order to alleviate the problem of data labeling. For example, patients in certain types of patient data (e.g., electronic health records – EHR) may be largely unlabeled as it can be expensive and time consuming for clinicians to label the data at research quality. In addition, this task can be tedious and can lead to labeling errors. For that reason, semi-supervised learning techniques are often preferred in order to prevent or, at least, reduce the risk of human errors in sample labeling. Moreover, deep learning-based approaches (e.g., denoising auto-encoders) have been successfully applied for the training of semi-supervised classifiers that enable the use of large un-annotated EHR-data in order to improve classification accuracy [17].

Last, reinforcement learning is a distinct category of ML alongside supervised and unsupervised learning, and their hybrid, semi-supervised learning. In contrast to supervised learning, reinforcement learning does not depend on labeled input or output, or the revision of near-optimal decisions. Instead, the mission is to find a balance between searching the unknown and processing current knowledge. Reinforcement algorithms use dynamic programming techniques, and target large decision processes, where exact mathematical models become infeasible. In the medical field, decision analysis and techniques of reinforcement

learning could theoretically mitigate challenges such as harm caused to patients due to cognitive and judgment errors made under time constraints, the uncertainty regarding the patient's diagnosis, or as a result of doubts regarding the predicted response to treatment. In the medical context, the available methods are poorly understood and rarely used clinically [18]. Therefore, promoting a better understanding of these approaches could substantially support clinical decision making, facilitating, for instance, the prediction of asthma exacerbations [19].

The Allergic March: Can We Predict the Direction?

As mentioned above, allergic diseases arise from an inappropriate immune response against environmental antigens. Although allergic diseases can seemingly affect specific organs, the different clinically observed entities are also systemic with partial overlapping etiologies. Allergic children have an estimated ~10-fold higher risk to develop further allergic conditions in later life [20]. These stepwise developing allergic co-occurrences are currently referred to as the "allergic march." The "classic" allergic march starts with AD in infancy, followed by the development of FA and subsequently AR and asthma [21]. Furthermore, patients with such progressive allergic history are at increased risk of developing eosinophilic esophagitis [22]. However, the individual clinical course can vary between patients, underlining the importance of novel tools to predict and characterize allergic diseases. In the advent of systems-level omics techniques, dissecting the clinical phenotype into allergic endotypes may be a promising approach to improve our understanding of allergic diseases in the context of precision medicine [23].

Various single- and cross-omics approaches have been used to decipher the complex and interwoven biological data layers of AD [24]. This inflammatory skin disease is primarily characterized by epidermal barrier dysfunction and altered immune responses, clinically presenting as itchy and eczematous skin lesions. Deeper insights into

the pathophysiology of AD might unravel novel treatment targets for AD patients as well as decipher unknown mechanisms of the allergic march. For example, AD cross-omics overlap signatures at the tissue level identified enrichment for skin and esophagus, highlighting a potential link between AD and the progression toward FA [24]. Recent studies further suggest that skin and gut are linked via the modulation of the immune environment by the human microbiome, and that certain microbiome patterns can determine sensitization to food and environmental allergens, and may predispose the host to develop an allergy [25–27]. Therefore, cross-omics approaches combined with ML tools have the power to provide novel disease models as well as predicting disease risk.

Example 1 Disease Risk Prediction with ML-Driven Models

Important tasks of precision medicine include the classification of patients according to disease risk as well as the estimation of disease probability, which is often accomplished by the use of different univariate statistical methods such as Student's t-test or Fisher's exact test. However, ML-based approaches could offer some advantages over classical statistical methods as it allows statistical testing in a multivariate fashion. For instance, when considering genome-wide association studies (GWAS), the goal is to identify a subset of genes and causal variants that determine the susceptibility to disease. The basic association test to discover single genetic variants (and genes) that are informative for assessing disease risk is based on comparing allele frequencies of single nucleotide polymorphisms (SNPs) between cases and controls. Strongly associated genetic variants are then combined into a Polygenic Risk Score (PRS), which is defined as a linear combination of individual SNP effects determined by using linear or logistic regression [28]. Although the PRS depends on statistical techniques that are commonly used in ML, it is built on the assumption that the underlying data are normally distributed, the data observations are non-correlated, and that they include additive and independent predictor effects [29]. However, PRSs rely on statistical

association tests that tend to select a very small set of SNPs with large effect sizes [30]. This means that the models tend to oversimplify the biological processes underlying complex diseases by ignoring SNPs that make a smaller contribution to the phenotype [30, 31]. Moreover, in the search for associated sets of SNPs, many causal variants may be missed [32]. More advanced ML approaches, such as Support Vector Machine (SVM) or Random Forest (RF), can generate more accurate predictions, by computing the complex relationships between risk SNPs (either a large subset of SNPs or all SNPs) and associating them with complex disease phenotypes, such as asthma. For example, recent studies have shown that the use of SVM- and RF-based classifiers can improve SNP-based predictive models of asthma [33, 34]. The predictive performances of ML-driven models are evaluated by using repeated, cross-fold validations and evaluation metrics such as the AUC, the positive and negative predictive values, or the coefficient of determination R². The main advantages of the ML-driven approaches are that they account for inter-SNP correlations, rather than assuming independence across the individual SNPs (Fig. 1).

The Needle in the Hay: ML-Approaches for Allergy Biomarker Discovery

The accurate diagnosis of allergies requires validation of allergen sensitization as well as detailed description of antigen exposure to the putative allergen. Skin tests, especially the Skin Prick Test, represent the current gold standard for the diagnosis and management of IgE-mediated allergic diseases. However, in some cases (young children below 2 years of age, patients with an unstable medical condition or at high risk of anaphylaxis, etc.) blood testing, such as in vitro serum IgE (sIgE) detection, might be preferred. Nevertheless, those blood tests need to be standardized and accurate, and especially FA panels need to be approved for cost-effectiveness and specificity [35].

FA encompasses a range of different food hypersensitivities as well as clinical phenotypes, including mild to severe allergic reactions.

Currently, it is estimated that nearly 8% of children and 3–5% of adults are affected by FAs and the incidence is increasing worldwide [36, 37]. Interestingly, the majority of children with a positive Skin Prick Test or sIgE results do not suffer from FA. Therefore, oral food challenges are the current gold standard to diagnose clinical reactivity against food allergens. However, this procedure is expensive, stressful for the child, time-consuming, and potentially riskful for the patient by developing anaphylaxis [38]. Consequently, a suitable blood test with high accuracy and minimal risk (e.g., blood drawing) could solve current diagnostic problems in FA. In recent years, epigenetic markers have been discovered to diagnose FA, showing a high accuracy when ML-driven approaches are used to identify biomarkers [39–41].

Example 2 Discovery of Biomarkers in Allergic Diseases Using Feature Selection

The implementation of precision medicine in managing chronic diseases strongly relies on the definition of biomarkers. The use of biomarkers in medicine is based on the presumption that there are measurable markers that can be used as a proxy of a biological process by, for instance, being an indicator of the presence of disease [42]. Even though they are often referred to as diagnostic tools, biomarkers can serve a wide range of clinical applications including population screening, prognosis, monitoring, and prediction of therapeutic response or toxicity [43]. In modern translational research, the development of novel biomarkers heavily relies on use of omics technologies as an important data source for the discovery of new diagnostic and prognostic biomarkers. These technologies allow precise measurements for millions of within-cell molecular features, such as genes, mRNA, proteins, and metabolites in a specific biological sample, which results in a plentitude of molecules that may be selected to composite biomarker panels for prediction tasks in precision medicine. For this reason, biomarker discovery from omics data is a laborious task. Moreover, it is important that this process leads to the selection of a subset of molecular markers that identify target classes of clinical

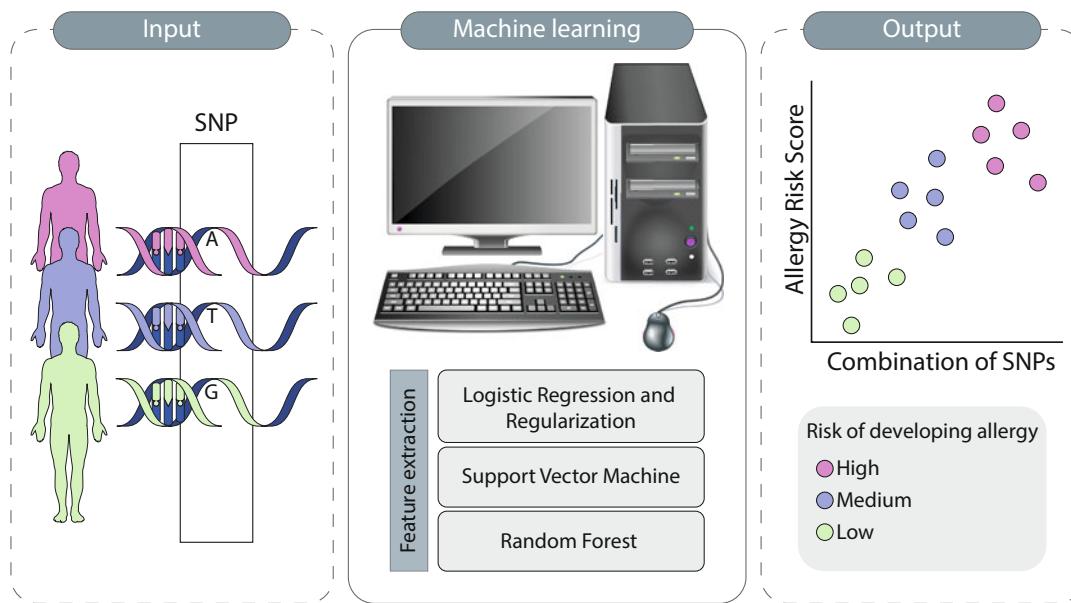

Fig. 1 Example of ML methods that can be applied for disease risk prediction in allergology. Data obtained from genome wide association studies (GWAS) such as allele frequencies from cases and controls (leftmost column) are combined and the contributing features, such as disease-associated SNPs, can be extracted through ML-based

approaches (middle column). As a result, the risk of allergy based on the combination of disease-associated SNPs can then be predicted as illustrated in the plot in the rightmost column. (This figure was created using vectors from Servier Medical Art, under a Creative Commons Attribution 3.0 Unported License; <http://smart.servier.com>)

cases [44]. Indeed, the discovery of biomarkers from omics is typically modeled as a feature selection problem, where the aim is to identify the most discriminating features for a given classification. For example, when identifying biomarkers to distinguish between the allergic and irritant CD or classifying skin diseases, ranging from melanoma to psoriasis, a feature selection methodology may be applied. In ML, this is the process of selecting a subset of relevant features (variables, predictors) to be used in the model construction. Common approaches for feature selection are filter, wrapper, and the embedded methods. Filter methods measure the relevance of features (or the potential biomarkers) by assessing their correlation with the target variable and wrapper methods quantify the “usefulness” of a set of features by evaluating a machine learning model on it. Finally, the embedded methods are based on ML algorithms having a feature selection process that is embedded within the model fitting process.

A classic wrapper method is based on the use of Genetic Algorithms (GAs). An example of

GA-based wrapper feature selection methods is GARBO [45], which is an omics-driven approach that is able to optimize accuracy and set size simultaneously for selection of reliable biomarkers. GARBO has been recently used to identify robust gene expression-based biomarkers for the discrimination between allergic and irritant CD [14] (Fig. 2).

Finding a Pattern: Disease Subtyping for Clinical Management

An important feature of precision medicine is disease subtyping, which can lead to a better understanding on how to optimally treat individual patients. Disease subtyping aims to identify subpopulations of patients showing similar phenotypic, clinical or molecular characteristics. When the subtypes can be linked to distinct pathophysiological mechanisms of the disease, they are also called endotypes. The endotype may also include data from environmental exposures, and

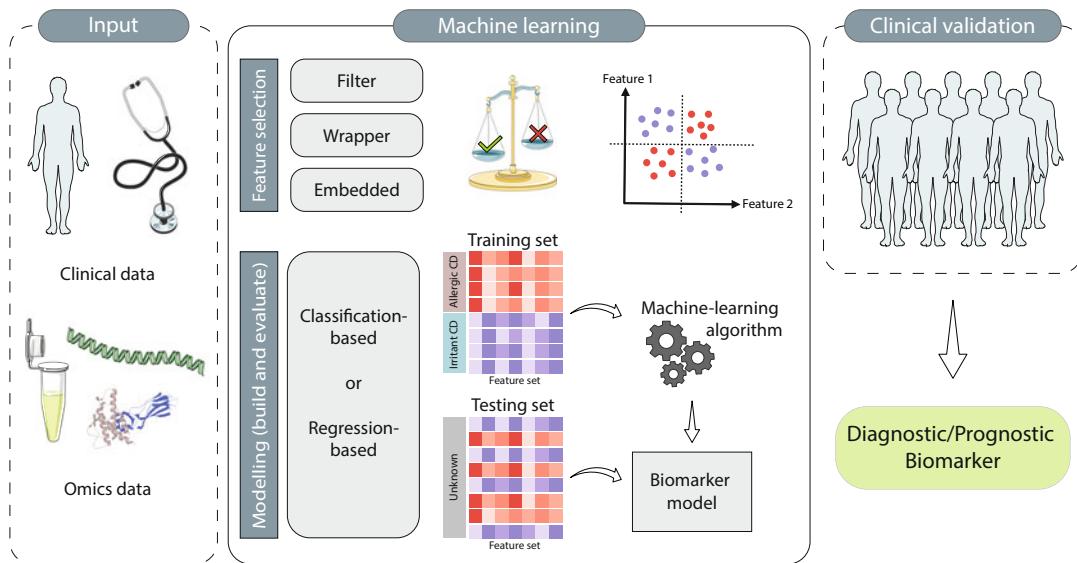

Fig. 2 Example of how feature selection and classification analysis can be applied for biomarker discovery from omics data. The classical steps of ML consist of feature extraction, model learning, and model evaluation. First, clinical and omics data are collected (leftmost column) and features that can classify clinical conditions are extracted by feature selection methods (middle column). Next, models of extracted features are built using a training set

features of the human microbiome. Together with the clinical phenotype, the endotype is now considered a fundamental tool for stratification of these highly complex diseases.

AD is still largely considered and managed as a single disease, lacking tailored prevention and therapeutic strategies. However, the clinical phenotype of AD is highly heterogeneous, and will benefit from dissection into more homogeneous subgroups for refined management [46, 47]. A prerequisite for precision medicine in AD is the discovery and validation of reliable biomarkers, and ML methodologies will help to merge the increasing amounts of data to define reliable endotypes. One important, unanswered question is whether there are endotypes in AD related to skin microbiome diversity or specific bacterial strains. A recent study used supervised learning based on Random Forest classification to pinpoint AD relevant skin communities of microorganisms, discovering two subtypes of AD, characterized by either high or low abundance of *Staphylococcus aureus*, with distinct consequences for disease severity and expression of

and the prediction accuracy is tested using a testing set of unknown samples. Finally, the biomarker model is validated clinically to ensure its generalizability and clinical validity (rightmost column). (This figure was created using vectors from Servier Medical Art, under a Creative Commons Attribution 3.0 Unported License; <http://smart.servier.com>)

inflammatory and skin barrier function related host genes [48].

In contrast to AD, the model of a single entity in asthma is no longer in use; Asthma is currently considered as an umbrella diagnosis for several diseases, driven by distinct mechanisms (endotypes) and with variable clinical manifestations (phenotypes). Asthma is broadly divided into type 2 (T2)-high or T2-low endotypes, depending on the extent of the involvement of Th2 type immune signaling. In the management of asthma, proper definition of endotypes and their sub-endotypes is essential due to inherent therapeutic and prognostic implications [49].

Example 3 Disease Phenotyping and Endotyping by Unsupervised Cluster Analysis

As mentioned in section “[The Allergic March: Can We Predict the Direction?](#),” distinct subtypes of asthma can be discovered by applying unsupervised clustering algorithms [50–52]. Traditionally, diseases have been stratified into disease subtypes based on their clinical manifestations, or the

so-called phenotypes. For example, distinct clinical subtypes of asthma have been identified using unsupervised hierarchical cluster analysis or latent class analysis of cohorts based on phenotypic data, including questionnaire data, demographic data (sex, race, age), disease severity (age of onset, asthma duration), and physiologic measures (lung function, atopy) [51, 52].

Although the clustering of patients based on phenotypic data may be relevant, the resulting subgroups often show inconsistencies, which can be due to differences in the demographic or clinical characteristics of the populations studied [53]. Moreover, a single phenotype may consist of multiple molecular endotypes [13].

Molecular endotypes can be characterized by using -omics approaches, including transcriptomics, epigenomics, microbiomics, metabolomics, and proteomics. Single- and multi-omics profiles of patients with asthma can help identify endotypes, or subtypes of disease based on distinct pathophysiological mechanisms [54, 55]. For instance, the k-means clustering algorithm was applied to the gene expression profiles of PBMC from asthmatic children in order to define novel endotypes from asthmatic children [56]. Metabolomic and epigenetic data have also been used, in combination with clustering algorithms, for the identification of novel asthma endotypes [57, 58] (Fig. 3).

Bridging the Gap: Insights into Disease Biology by Integrative Analysis

Most studies using omics data to identify biological targets and pathways involved in asthma and allergic disease pathogenesis have primarily focused on single-omics subtypes. Although important insights have been gained from these studies, they provide only a partial view of the disease process. An integrative approach, where features from multiple omics data layers are modeled as a set, offers an opportunity to study complex biological processes holistically [54]. The recent arrival of new high-throughput techniques, a growing availability of data from large patient cohorts, and the development of several promising methods for data integration, pave

the way for improved mechanistic insight, disease subtyping, and biomarker prediction. For instance, a study examining 361 children of 3 years of age investigated the effects of the exposome on the risk of developing childhood asthma through coinertia and sparse correlation analysis of intestinal metabolome, intestinal microbiota, plasma metabolome, and diet [59]. In this study, several intestinal metabolites, specific bacterial taxa (such as the family Christensenellaceae) as well as plasma metabolites and a meat-rich diet were found to be associated with the development of childhood asthma. In another study, metabolomic data from plasma samples, peripheral blood CD4+ methylation and transcriptomic profiles, and genome-wide genotypes from 20 asthmatic patients were integrated to create a conditional Gaussian Bayesian network [60]. As a result, the integrative approach revealed that two pathways, specifically arachidonic acid metabolism and linoleic acid metabolism, may be of importance for asthma control. Furthermore, the analysis implicated altered sphingolipid metabolism as a potential underlying feature of uncontrolled asthma. Both of these examples illustrate the potential of successful generation of meaningful insights into pathophysiological mechanisms of asthma by integration of multiple omics dimensions to create a more complete picture of complex biological systems.

Challenges and Promising Research Directions in ML Applications

With allergies representing exceedingly heterogeneous disorders, it is of utmost importance to decipher key biological pathways to improve the current knowledge of diagnosis and treatment of such diseases. However, ML approaches are challenging, not the least from a technical point of view. One important issue is the risk of overfitting due to small sample sets, which include a high number of features – a common trait of biomedical data (e.g., EHR, omics, imaging data, etc.). The problem of overfitting arises when ML generates a predictive model that performs perfectly

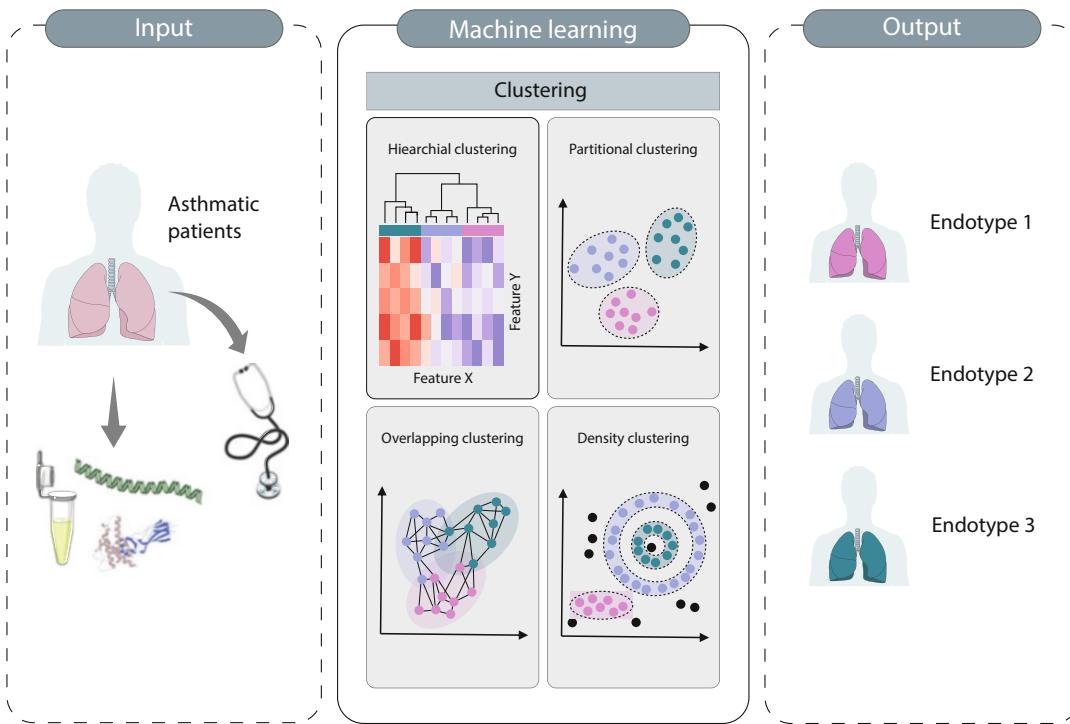

Fig. 3 Example of how ML methods can be used for disease stratification through determination of endotypes. Using clinical data or omics, or both (leftmost column), unsupervised ML-based clustering methods can be applied (middle column) to find patterns for disease stratification. As a result, patients may be categorized into disease

subgroups, such as endotypes, based on molecular features associated with a certain cluster (rightmost column). (This figure was created using vectors from Servier Medical Art, under a Creative Commons Attribution 3.0 Unported License; <http://smart.servier.com>)

on the training data but poorly with new data. In general, small training sets do not suffice to build a model that can generalize well on a much larger sample set. Moreover, datasets often lack information regarding confounders and can incorporate features that are perturbed by technical variation (e.g., batch effects), adding unwanted bias. Thus, a careful study design, including well-characterized patient groups, and methods that ensure high data quality, is necessary for generating reliable results.

Nevertheless, it is possible to solve the problem of small sample sets. One way is to systematically include external data sets in the analysis. For omics studies, external data sets are available in public repositories, such as the ArrayExpress, Gene Expression Omnibus (GEO), GenomeRNAi and dbGAP. Automatizing the search and reuse of publicly available data for ML-driven approaches

is a laborious task, but it is considerably facilitated by the current availability of several omics search engines, which can link omics studies with a similar experimental setup (e.g., same disease, same tissue, similar omics technology, similar clinical phenotype, etc.) [61, 62].

In the near future, more advanced ML techniques will be needed in the field of allergology, and particularly ML models enabling the use of real-time data will play a major role. For example, a recently published pilot study evaluated the feasibility of a deep learning algorithm that provides people with real-time risk assessment of their asthma exacerbation based on the dynamic patterns of indoor air pollutants and their general health condition [63]. Another study investigated the use of deep learning models for the prediction of allergic reactions by using safety event reports across hospitals [64]. For the time being, ML

applications based on real-time data are not available for omics data. Although omics technologies have improved tremendously over the past 30 years, they are still expensive and not readily accessible to most individual laboratories and scientists. Therefore, it is a challenge to build a continuous workflow from omics data to patient monitoring systems. However, within the last few years, new omics-based technologies, including Oxford Nanopore Technologies (ONT, Oxford, UK) [65], have been emerging. These new technologies enable genomics experiments to be performed in minimal facilities and operated in essentially any environment. Moreover, very recently, iGenomics, which is the first iOS application for pre-processing genomics data in a mobile environment, has been released [66]. This emerging new technology will bring us closer to the future of medical tests that utilize real-time genomics data and ML-based methodology for creating fast and reliable diagnostic tools.

In conclusion, the current accumulation of clinical and research-related data will allow for more applications of AI in healthcare and high-performance data-driven medicine. However, many of these applications are still under development, and rarely used in the clinic. Medical professionals will need to understand and adapt to these advances, for better transition of these technologies to the clinic. Finally, any ethical concerns, such as those regarding privacy or representative biases, will need to be addressed.

Abstract

Haematology is a field that offers the gateway to life itself. This chapter provides a very brief treatment and discussion of haematology and artificial intelligence, looking at areas where machine learning has captivated the imaginations of haematologists to aid the diagnosis and management of blood-related disorders.

We commence the chapter with a historical overview of AI in haematology and then investigate the subspecialties of haematology where AI has been used to discover new answers to various questions that haematologists have been asking for many decades. We explore decision support systems for diagnostic haemopathology, genetic profiling in haematology, and areas such as immune

checkpoint blockade analysis in haem-oncology including AI in leukaemia, lymphoma, and lymphoproliferative disorders, as well as AI for haemo-parasitology and AI for haemo-virology.

We then suggest future areas where AI may impact the treatment of current diseases such as sickle cell anaemia.

Introduction

Blood has signified life throughout the ages, but modern haematology has had to continuously evolve to meet the changing and high-throughput demand for this specialty. For example, our improved and comprehensive understanding of the blood group system has allowed considerable advances in the approach to managing blood transfusion-related disorders. Under the guidance of a haematologist, the modern clinician is now usually involved in transfusion medicine, thus ensuring that the right blood is available for patients when required. Haematologists also provide crucial support for haem-oncology management, stem cell transplantation, and the detection of blood cancers such as leukaemia, etc.

The role of haematologists in the perioperative period is also critical. They ensure that the right crossmatched blood is available so that patients can be adequately transfused intraoperatively, even in an emergency situation, for example, anaemic patients with anticipated high blood loss undergoing complex surgical procedures, patients with pre-existing complex syndromic haematological conditions, or actively haemorrhaging patients. Antigens in the patient's blood that could lead to dangerous adverse transfusion reactions also need to be identified early to circumvent transfusion-related complications.

Similarly, artificial intelligence and its subfacets of deep and machine learning have continued to achieve significant diffusion into most clinical subspecialties including neurology, dermatology, cardiology, rheumatology, genetics, and cardiothoracic surgery etc. All of which have been discussed in detail in various chapters within this book. Haematology is another specialty that is benefitting from the advances in

artificial intelligence and seems to have significantly embraced it for laboratory diagnostics. Haematopathological analysis of benign and malignant disorders of red cell, white cell, platelet, and bone marrow pathologies requires unique methods for accurate diagnostics and is an area that machine learning promises to augment.

This chapter reviews the literature discussing areas where artificial intelligence has been applied to haemato-rheological diagnoses. We review and discuss the subspecialty areas of haematology in which AI has made successful inroads. We then extend the discussion to future areas where we believe haematology could benefit from the multiple facets of artificial intelligence.

Discussion

The exponential growth and explosion of medical data and insight discovery have enabled significant advances to be made in multiple fields including haematology. The era of big data has also led to advances in medical informatics, opening doors for insight discovery from sparse medical data. We begin this chapter discussion with a historical overview of AI as it pertains to haematology and then extend the discussion to areas where we believe AI has impacted haematological diagnosis and treatment, including leukaemia diagnosis, etc.

History

Rosenblatt is quoted as one of the pioneers who presented the modern learning machine paradigm in the 1960s, which detected optical patterns, and that led to the development of the first adaptive artificial neural network called the multiple adaptive linear elements (MADALINE) used for the real-world problem of eliminating phone-line echoes [1, 2]. Other noteworthy projects include Stanford's DENDRAL, from which MYCIN evolved and leveraged heuristic programming for detailed task-specific scientific hypothesis discovery [3]. For details about the history of machine learning and AI, the reader is referred to the early chapters that provide a detailed account of the historical origins of the field. We

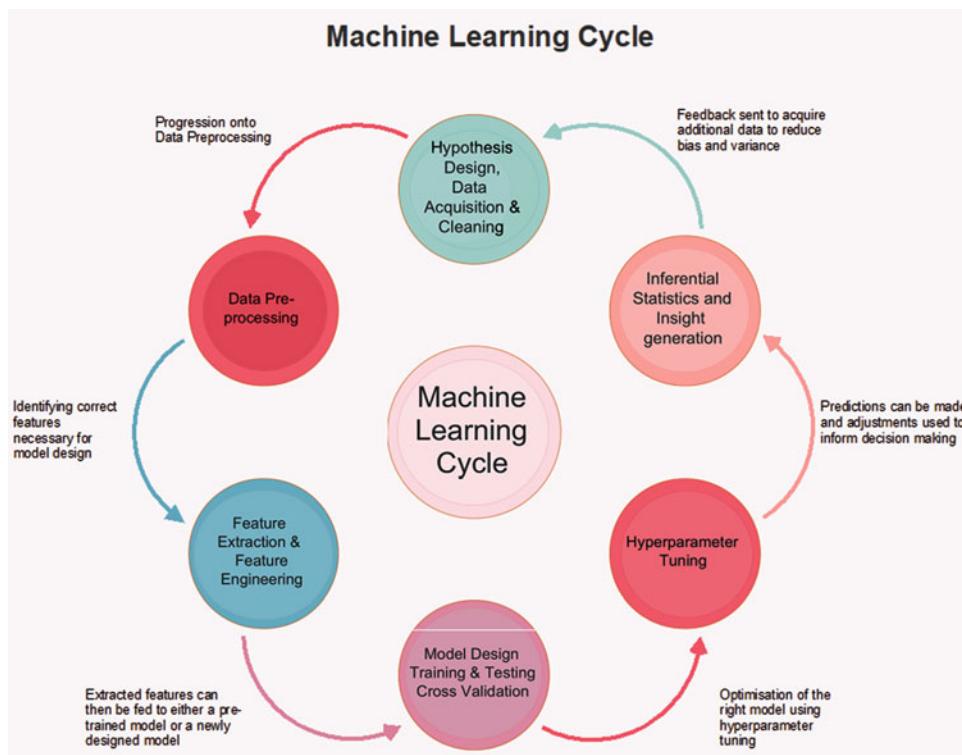

Fig. 1 Illustrates the machine learning cycle. Presented here is one of the many approaches to machine learning, moving counterclockwise from data acquisition to data pre-processing; to feature engineering; to model design, training, and testing; to optimization; and to inference

generation. This is a cyclical process, where additional data from the last step (inference) is utilized to improve the model and thus continue the cyclical nature to the process

do however summarize an example of the modern methodology of how a machine learning pipeline unfolds in Fig. 1. Since 1998, when just about 400 publications were available for artificial neural networks, the field has now seen a tremendous explosion of research interest and adoption into clinical practice with consequent advancements, ranging from deep neural networks to generative adversarial networks. Recent machine learning paradigms such as meta-learning and quantum machine learning have also been developed and have been discussed in various chapters in this book. Nevertheless, this section will look at the history of artificial intelligence in relation to haematology and evolve discussions from there.

Initial applications of machine learning for haematology were linked to clinical haematological laboratory investigations, diagnostics, and decision support as three knowledge-based systems installed in five European hospitals dating back to

1995 [2, 4–9]. These tri-interactive systems were named Professor Petrushka, Professor Fidelio (a heuristic-based diagnostic pattern system, tested on leukaemias, lymphoproliferative disorders, and lymphomas), and Professor Belmonte [2, 7–11]. They were created for peripheral blood interpretation, flow cytometry immunophenotyping, and bone marrow reporting and generated 94% diagnostic accuracy compared with 99% human counterpart on haem-oncology diagnostics [10]. However, this paved the way for intelligent knowledge-based systems in haematology. Apart from accuracy, these systems were also efficient and reduced the turnaround time.

Various studies are summarized in Table 1 below and have looked at machine learning applications for acute myeloid leukaemia, acute promyelocytic leukaemia, aplastic anaemia, and bone marrow disorders. We begin our treatise on diagnostic haemopathology using artificial intelligence.

Table 1 Studies discussing artificial intelligence and machine learning models in acute myeloid leukaemia (AML). *HCST* haematopoietic stem cell transplantation, *TCGA* The Cancer Genome Atlas, *DDx* differential diagnosis, *NGS* next-generation sequencing, *GBT* gradient boosted tree, *ELN* European Leukaemia Net, *HMA*

Author, year	Study size	Application	ML model	Results
Warnat-Herresthal et al. 2019 [30]	12,029 AML, leukaemia, control patients; 102 studies	Transcriptomics-based AML diagnosis and subtype classification	LASSO regression	98% accuracy for AML DDx; ≥ 97% accuracy for AML subclassification (except FAB M7 leukaemia)

Artificial Intelligence in Diagnostic Haemopathology

The need to effectively identify abnormalities in peripheral blood for effective clinical decision-making is paramount in clinical practice and serves as one of the backbones of good clinical care. Clinicians need diagnostic haematology to

hypomethylating agent, *AUROC* area under the receiver operating characteristic curve, *CNN* convolutional neural network, *LASSO* least absolute shrinkage and selection operator, *MDS* myelodysplastic syndrome, *CR* complete remission, *OS* overall survival. (Adapted from Radakovich [29])

support, refute, or primarily augment their clinical hypothesis and usually require this information at the bedside following history-taking and examination. Leukocyte count, peripheral blood films, and biochemistry on blood samples can identify infections, haemoglobinopathies, acute and chronic conditions including oncology, and familial and genetic disorders. These tests are crucial

adjuncts to the effective diagnosis of multi-systemic conditions and form the bedrock of modern clinical care.

Use of Neural Networks for Peripheral Blood Film Analysis

A neural network with a 100% diagnostic accuracy was trained on 512 peripheral blood samples (146 normal) [2]. This was then used to perform peripheral blood film analysis on the ADVIA 120, a Mie theory-based blood analyzer that was built as a laser cytometer. The device applies isovolumetric spherling containing sodium dodecyl sulfate and auto-analyzes about 40,000 red blood cells. Automated analysis via neural nets was achieved using unsupervised learning paradigms leveraging concepts of inductive reasoning to create a self-organized inductive map to help classify haematopathological diseases. Preliminary data validating their system on 1,025 samples demonstrated 703 abnormalities ranging from alpha- and beta-thalassemia, with globin variants E, CS, iron deficiency anaemia (IDA) and IDA with thalassemia, and other identifiable haemoglobinopathies. There were 322 normal samples.

Classification of White Blood Cells Using Transfer Learning

Leukocytes are defenders of our immune system and interact with pathogens that enter the body. Using machine learning to classify, identify, and screen these immune defenders for deficits has been presented in the literature. One such study showed that two deep convolutional neural networks showed the best classification performances for white blood cell classification [12]. In this study, the method of two-module transfer learning weighted optimized deformable convolutional neural networks (TWO-DCNN) was proposed for WBC classification, and the performance was validated against classical algorithms commonly employed in machine learning science including support vector machines, standard neural networks, decision trees, and random forest. They also used prebuilt models such as VGG16 and VGG19, inception V3, and the ResNet-50 algorithms. Their best reported performance was a

precision of 95.7% and recall of 95.7%, F1-scores (F1s) of 95.7%, and area under curves (AUCs) of 0.98, for low-resolution images. Although this is impressive, one disadvantage is the fact that the data was a noisy dataset.

Screening Blood Disorders like Thalassemia

Others have leveraged logistic regression, k-nearest neighbors, support vector machine, extreme learning machine and regularized extreme learning machine, AdaBoost, and neural networks for screening purposes in inherited hemoglobinopathies, which are known to arise in 7% of the world's population [2, 13–15]. Erler and others demonstrated thalassemic variant detection in 1995 using a backpropagating artificial neural network using optimized linear and quadratic discriminant functions with reported discriminant efficiencies of 94% [16]. Similarly, others have used haema-chromocytometric analysis on red blood cell, haemoglobin, haematocrit, and mean cell volume parameters that demonstrated a 94% accuracy using a feedforward artificial neural network [2, 17–20].

In another study on 342 patients, classification performance was evaluated with accuracy, sensitivity, f-measure, and specificity parameters using haemoglobin, RBC, HCT, MCV, MCH, MCHC, and RDW with reported accuracy of 96.30% for females, 94.37% for males, and 95.59% for both [13].

The classification of various leukocytes is an area that benefits from automated cytochemistry due to the high throughput of requests for diagnostic investigations. Identifying the right class of leukocytes is dependent upon optical methods of characterization of volume, myeloperoxidase activity, nuclear density, and chromatin content as well as cellular distribution. From this, leukocyte types can be differentiated based on the above as well as their chromatin content and myeloid and lymphoid pattern distribution [2, 21].

A feedforward artificial neural network trained with 84 features was built and used to identify and differentiate normal vs abnormal archetypes in blood and achieved 89% accuracy for Hb E/b-thalassemia [22].

Screening for Polycythaemia Rubra Vera

Decision rule extraction through data mining was used to identify an optimized set of parameters for polycythaemia diagnosis from eight features identified by the gold standard polycythaemia vera study group criteria including gender and haematocrit value. An artificial neural network was able to diagnose polycythemia in 98% of cases [23].

Screening for Pyruvate Kinase Deficiency

Other complex inherited diseases that have benefitted from employing machine learning include the use of binary classification models in metabolomics for pyruvate kinase deficiency on dried blood spots, with an AUC of 0.99 and an accuracy of 94% [24].

Digital Morphological Analysis

Machine learning algorithms have been employed for the morphological analysis of blood smears using convolutional neural networks [8, 25]. Kalman filters for physiological cardiovascular dynamics such as blood pressure and heart rate were also used for diffused optical tomography in oxyhaemoglobin analysis [11].

Artificial Intelligence in Haem-oncology, Cancer Stem Cells, and Cancer Immunotherapy

With the rising global burden of new haematological cancers reaching approximately 18.1 million in 2018, haematological and other cancers affect people of all ages; hence, newer methods of screening, diagnostics, and approaches to treatment have been proposed to aid early identification [26].

Various methods have been adopted to aid this, ranging from haematological bone marrow biopsies, immunological tests, flow cytometric methods, etc. The gold standard haematological test opening the gateway into blood disorder diagnosis for blood cancers is the full blood count (complete blood count). Derangements in full blood counts can provide key diagnostic clues for haematological malignancies.

It is hoped that the application of machine learning and artificial intelligence will reduce the diagnostic conundrum associated with haematological disease, by narrowing down the combinatorial diagnostic challenges and thereby aiding the prediction of haem-oncological disease.

AI for Haem-oncology Screening

In a population-based screening study by Syed-Abdul and colleagues, they applied machine learning algorithms such as artificial neural networks(ANN), stochastic gradient descent, support vector machine, random forest, decision tree, linear models, and logistic regression to the diagnosis of International Classification of Disease-10-coded haematological diseases [26]. These included malignant neoplasms of lymphoid and haematopoietic and related tissue, nutritional anaemia, haemolytic anaemia, aplastic and other anaemia, coagulation defects, purpura and other haemorrhagic conditions, and diseases of blood and blood-forming organs. The ANN with the neural network outperformed the other machine learning models in diagnostic accuracy, precision, recall, and $AUC \pm$ standard deviation as follows: 82.8%, 82.8%, 84.9%, and $93.5\% \pm 2.6$, respectively.

AI for Immune Checkpoint Blockade Discovery

Immune checkpoint blockade refers to the concept of being able to direct the host's immune system against an aggressively dividing tumor cell [27]. The body's own immune system performs the necessary checks to ensure that the immune response to a particular insult does not elicit aggressive immune overactivity. Blocking these checks leads to an uncontrollable immune response in certain individuals and has been found to be effective at fighting off cancers and improving outcomes. These checkpoints are triggered when immune cells, such as T-cell surface proteins, bind to partner cell surface proteins to verify that they are normal. In the case of tumors, the T-cell surface proteins can bind to a tumor cell surface protein, which will have evolved to switch off the checkpoint status to treat the interaction as normal.

Chemotherapeutic checkpoint inhibition drugs therefore allow the immune system to attack the dividing tumor cell. The immune system's T-cells are thus misled into not attacking the tumor cell. So when this checkpoint system inhibiting the "off signal" to the immune system is not triggered, the immune system can attack the tumor cells. Still, sometimes the checkpoint protein inhibitors do not work, and this dampens the response for the patient placed on this particular chemotherapy agent. Two established biomarkers such as programmed death ligand 1 (PD-L1) and tumor mutational burden (TMB) can enable the selection of patients who will benefit most from ICI [27]. Artificial intelligence has been adopted to help predict the response to the chemotherapeutic agent in certain patients with haematological cancers.

Kim et al. built Neopepsee as one such machine-learning-based neoantigen prediction platforms which incorporates nine immunogenicity features to determine immunogenic neoantigens in melanoma and chronic lymphocytic leukaemia [28].

Leukaemia and Lymphoproliferative Disorders

Leukaemia is a blood tissue-forming cancer and a wide-ranging group of disorders with characteristic differences that require appropriate diagnostic protocols to identify. Some forms of leukaemia affect children, whereas others affect adults.

Machine learning has been applied to the diagnosis, subtype classification, treatment, progression monitoring, and other aspects of the disease, which are explored in the subsequent sections.

AI for Acute Myeloid Leukaemia

The models used in leukaemia range from recommender systems to convolutional neural networks. We summarize them in Table 1 below and explore some others in detail [29].

Warnat-Herresthal et al. applied Lasso regression to predict transcriptomic changes in 12,029 acute myeloid leukaemia patients adopting it for subtype classification at 98% accuracy [30].

Convolutional neural networks were used for bone marrow cellular classification and

differentiation between anaplastic anaemia with over 96.2% accuracy [36, 37]. Mortality prediction was achieved at an area under receiver operator curve of 72% using a combination of in silico approaches ranging from naïve Bayes, alternating decision tree, and logistic regression in 26,266 AML and haematopoietic stem cell transplant patients. A summary of the research is presented in [29].

AI for Acute Promyelocytic Leukaemia

Artificial neural networks have again been adopted for the predictive modelling of acute promyelocytic leukaemia. The model was applied to full blood counts to predict APML from non-APML groups with a 95–97% accuracy with a 2.3% false prediction rate [39].

AI for Lymphoma

A semantic network-based artificially intelligent knowledge-based platform capable of describing pathologically aberrant antigen expression in non-Hodgkin's lymphoma diagnosis showed a 97% accuracy [40]. Immunophenotyping is crucial for non-Hodgkin's B-cell lymphoma diagnosis with multiple clinical-pathological entities. Machine learning was applied to a database of 1,465 B-cell non-Hodgkin's lymphoma samples to build 4 artificial intelligence platforms for diagnosis that were able to identify 9 of the most common clinical-pathological entities with an accuracy of 92.68%, sensitivity of 88.5%, and mean specificity of 98.77% [41].

Mantle cell and small lymphocytic lymphomas are matured B-cell lymphomas that are known to have similar immunophenotypic profiles and are usually diagnosed with flow cytometry, which can be ambiguous and thus suboptimal. An artificial intelligence approach to automatically differentiate the two by mean CD20/CD23 fluorescent intensity ratios has been discussed in the literature by Zare and colleagues with a 100% accuracy for mantle cell lymphoma classification and 97% accuracy for small lymphocytic lymphoma [42].

AI in Acute Lymphoblastic Leukaemia

Acute lymphoblastic leukaemia (ALL) is a common childhood cancer with a variety of powerful

risk factor prognosticators of which the most independent is its response to induction chemotherapy according to Bradford et al. and others [43, 44]. Machine learning has also been applied in its capacity as a monitoring tool for patients receiving treatment for ALL. A deep neural network and various other learning algorithms like support vector machines, random forests, and naïve Bayes were trained to differentiate an ALL cell from normal B-lymphocytes. Deep neural networks were then used to extract discriminating bright- and dark-field imaging features ignoring fluorescence approaches on antibody-labelled diagnostic and on-treatment bone marrow samples that had been labelled. Analysis showed accuracy of 88%. Other approaches included feature extraction and dimensionality reduction leveraging principal component analysis and t-distributed stochastic neighbor embedding (t-SNE) for visualization [44].

AI in Multiple Myeloma and Cancer Stem Cells

Epidemiologically, multiple myeloma has a median age of diagnosis of 70 years. The diagnosis is heralded by identifying the clonal expansion of plasma cells and includes monoclonal gammopathy of uncertain significance [45].

Single-cell cancerous subclones that are usually suppressed by current treatments can rapidly switch from dormant to dominant subclones in the pathophysiological course of multiple myeloma, and this subclone switching can lead to cancer drug resistance. Recently, advancements in technology have evolved to track the subclone formation [45].

AI in Neoplastic Bone Marrow Disease

An artificially intelligent knowledge-based workstation built for peripheral blood analysis, flow cytometry immunophenotyping, and bone marrow morphology, linked together by a relational database, was trained to classify neoplastic bone marrow pathology in 526 cases. There was agreement with the expert in 97.9% of cases ($n = 515$ cases) with 11 diagnostic errors with minimal misclassifications [46]. There was agreement

with the gold standard for diagnosis in 87.8% of cases.

An unsupervised clustering algorithm was used to differentiate between normal and malignant human bone marrow on classical flow cytometry data using the flow self-organizing map, an R-solution applied together with a Kaluza® software platform [47, 48].

AI for Lymphoproliferative Disorders

In the detection of basket cells in lymphoproliferative disorders, artificial intelligence has been used for the identification of degenerate lymphocytes in this condition. These degenerate cells, called smudge cells, were identified using Cellavision. An artificial intelligence platform called the AI-Heme-1 was built by Barouqa and colleagues for the automated detection of basket cells. They created an in vitro model to form NETs in blood and generated a library of their morphological changes at various maturation stages and then correlated their presence to infections in the absence of leukocytosis [49].

Indolent B-cell lymphoproliferative disorders (BLPDs) include chronic lymphocytic leukaemia (CLL), hairy cell leukaemia (HCL), follicular lymphoma (FL), splenic marginal zone lymphoma (SMZL), nodal marginal zone lymphoma (NMZL), mucosa-associated lymphoid tissue (MALT) lymphoma, lymphoplasmacytic lymphoma/Waldenström's macroglobulinemia (LPL/WM), and other unclassified chronic BLPDs. By contrast, the aggressive B-cell lymphoproliferative disorders include diffuse large B-cell lymphoma (DLBCL), Burkitt lymphoma (BL), mantle cell lymphoma (MCL), and B-lymphoblastic lymphoma (B-LBL) [50]. Yi et al. initially applied principal component analysis on 15 T-cell immune signatures generated by flow cytometry, but this was not sufficient to efficiently separate aggressive vs indolent groups due to the heterogeneity of the cellular groups [50]. However, a random forest machine learning model was also used to model the rank of T-cell immune signatures, which showed dysregulation and best performance on binary classification of all indolent B-cell lymphoproliferative disorder patients [50].

AI for Cancer Immunotherapy

In immunotherapy, T-cell distribution and subset T-cell counts demonstrate the effectiveness of the immune system at combating cancer as well as gauging response to therapy. An artificially intelligent immune cell analyzer for T-cell subsets called ImmuCellAI has been developed to help achieve this [51]. It works using a gene-set signature-based method and can identify T-cells, dendritic cells, cytotoxic T-cells, and gamma-delta T-cells.

AI for Haematological Gene Profiling and Molecular Sequencing

Acute leukaemia was used as a template to categorize cancers and stratify them into various classes [2, 52]. Using DNA microarrays, thousands of genes can be identified and screened for pathological variants. Signal-to-noise feature extraction was then used to identify and analyze large gene datasets. Unsupervised and supervised learning methods included self-organizing maps, hierarchical and probabilistic clustering, support vector machines, and k-nearest neighbors [2, 53].

Decision support in systems for oncogenomic analysis has also been developed including the Oncompass calculator – a self-learning AI that is designed to learn from a big dataset and analyze the complex case management of various patients with haem-oncological genomic diseases [6].

For chemically induced DNA damage, the FlowSight® imaging cytometry platform applies machine learning to imaging flow cytometry to access DNA damage via a cytokinesis block micronucleus (CBMN) assay [54]. In their work, Verma and colleagues rapidly imaged and collected a population of about ~20,000 bright-field cells together with DRAQ5™ fluorescent stained nuclei/MN in under 10 min, and in-focus cells were isolated using IDEAS® software. Mono-, bi-, tri-, and tetra-nucleated cells were scored and classified with a mention of supervised machine learning algorithms; however, the specific machine learning algorithms were not clearly identified and are likely proprietary. However, they did mention toxicological modelling using exponential and Hill nested model families.

Other areas that have had machine learning augmentation include single-cell gene expression disease profiling, high-throughput gene profiling, and single-cell RNA transcriptomics for haematopoietic stem cells, where tools such as the hscScores have been scientifically developed with translational considerations [55, 56].

AI for Cancer Disease Progression Monitoring

In their work studying genome-wide expression of chemo-resistant genes noted to cause minimal residual disease for acute myeloid leukaemia cells in 157 patients, Coustan-Smith and colleagues used machine learning-related dimensionality reduction techniques to identify 22 (CD9, CD18, CD25, CD32, CD44, CD47, CD52, CD54, CD59, CD64, CD68, CD86, CD93, CD96, CD97, CD99, CD123, CD200, CD300a/c, CD366, CD371, and CX3CR1) aberrantly expressed markers of minimal residual disease [57]. The machine learning models used included the t-distributed stochastic neighbor embedding (t-SNE) for visualization.

Gaussian mixture models have also been used for minimal residual disease monitoring of acute lymphoblastic leukaemia trained on multi-parameter flow cytometry data from 337 bone marrow samples collected at day 15 of induction therapy [58].

Other machine learning approaches such as support vector machines have been applied on newer technologies of stain-free classification of cancer cells and for blood cell interferometric phase microscopy, which measures the refractive index of the cells [59]. Nassim and colleagues used support vector machines on holographic interferometry to differentiate blood cells from colonic cancer cells. Peripheral blood flow cytometry for the evaluation of circulating cancer cells and monitoring with machine learning models such as logistic regression (100% sensitivity and 54% specificity (AUC = 0.919)) and decision trees (decision tree model achieved 98% sensitivity and 65% specificity (AUC = 0.906)) have also been discussed [60].

AI for Haemo-virology, Haemo-parasitology, and Immune System Studies

AI in COVID-19 Haemo-virology

Our immune system is a sophisticated and well-evolved system that provides the body with support and protection against various pathogens while also distinguishing between foreign substances and the body itself. It is divided into innate immunity, which is the body's first line of defense present from birth, and adaptive immunity. With no memory, the innate immune system encompasses physical and chemical as well as cellular barriers like phagocytic cells and the complement system, whereas the adaptive immune system has memory and is capable of antigen detection, recognition and processing, and the destruction of a previously encountered antigen. However, viruses have evolved to sometimes circumvent this process of detection, as we learnt from the COVID-19 pandemic where there was apparent dysfunction of the adaptive immune system.

COVID-19 spread worldwide causing a global pandemic. It is characterized by acute respiratory distress, multiple organ failure, haematological manifestations, neuro-olfactory disturbances, coagulopathic manifestation, and death. During the COVID-19 pandemic, newer methods of artificial intelligence were used to diagnose and predict the outcome of COVID-19 from blood results. Chung and colleagues used deep neural network, ensemble-based methods, and random forest models called EDRnet [61]. This accurately predicted mortality from blood biomarkers, patient's age, and gender information with a high sensitivity (100%), specificity (91%), and accuracy (92%). A diagnostic web platform was built to facilitate mortality prediction.

AI in HIV and AIDS Haemo-virology

The human immunodeficiency virus (HIV-1) is a global, sexually transmitted disease that has significant repercussions for the patient and society. Machine learning has been suggested to aid in diagnostics and AIDS progression analysis. FloReMI is a method of flow density regression that has been designed to aid prediction of time to

progression of HIV to AIDS using random survival forests [62].

The detection of neutralizing antibodies for effective protection against the virus is also a subject of intense research and an area of current research focus [63]. One study on broadly neutralizing antibodies for the HIV-1 virus aimed to resolve the issue of significant epitope variation that occurs in viral strains, which could be resistant to anti-retroviral drugs. Predicting these epitope variations could enable the identification of resistant strains and thus facilitate drug engineering to combat against drug-resistant strains. Yu et al. designed a novel "Bayesian machine-learning model that uses information from the HIV-1 envelope protein sequences and foremost approximated glycan occupancy information as variables to quantitatively predict the half-maximal inhibitory concentrations (IC₅₀) of 126 neutralizing antibodies against a variety of cross clade viruses" [63]. The model was subsequently applied to peripheral blood and showed that the predicted broadly neutralizing antibody could achieve 100% neutralization and was able to map the degree of neutralizing resistance.

AI in Haemo-parasitology

Research into machine learning for hemo-parasitological diseases such as malaria and dengue fever has also increased in recent decades. Immunochromatography for plasmodium detection on blood film is a diagnostic approach for laboratory malaria and dengue detection [64]. Algorithms have been developed to diagnose malaria and also distinguish between malaria and dengue fever and other febrile conditions [65]. Previously, this was achieved using percentage of lymphocytes and their standard deviation of conductivity on the LH750 with reported area under the curve (AUC) of 0.893 and evaluated AUCs of 0.931 [66]. However, algorithms such as support vector machine platforms have been explored by HORIBA for malaria classification [67, 68].

In another pediatric cross-sectional study, machine learning was used to predict the stimulation levels of two phenotypes of T-cell activations (T-helper cells and regulatory T-cells)

[65]. Predictive analytics for distinguishing the levels of these various phenotypes between symptomatic malaria patients and asymptomatic patients showed a sensitivity of 86% and a specificity of 94%.

Another area reported is the detection of leishmaniasis and Chagas disease and the need for repeated confirmatory serological assays to identify nonnegative results for blood bank screening and to also identify the degree of agreement between methods of diagnosis [69]. Machine learning has also been applied within this area using discriminant analysis to show higher levels of agreement between (1) the multiplexed flow cytometry anti-T. cruzi/Leishmania IgG1 serology/FC-TRIPLEX Chagas/Leish IgG1 and (2) enzyme-linked immunosorbent assay (ELISA)/immunofluorescent consensus criterion (EIA/IIF). The reported Kappa index (Kappa index = 0.811) and Spearman correlation ($r = 0.6171$; $p < 0.0001$) suggested strong agreement between both techniques, but a superior AUC of 0.91 along with sensitivity and specificity (91% and 90%, respectively) in favor of FC-TRIPLEX [69].

AI for Haemorrhage Prediction and Transfusion

AI for Transfusion and Blood Quality Haemo-diagnostics

Transfusion medicine facilitates the haematological treatment of acute hemorrhagic disorders through valid and safe blood transfusion practices that include grouping, screening, and crossmatching to ensure blood is ready for specialty services including surgery.

Significant harm can befall a patient if transfusion quality assessments are skipped or taken for granted, with death as the endpoint. Blood antigen detection is also paramount in identifying other rarer blood group antigens in the sample that could lead to fatal blood transfusion reactions, and these also need to be identified and mitigated. The blood to be transfused must be assessed for its quality, and machine learning has found use cases within this area as well. As blood can undergo

rapid and progressive vitiation due to long-term storage, there is a need to overcome the challenge associated with at times suboptimal and subjective labelling/identification performed by humans as detectors of degraded blood. Algorithmically, deep learning has been proposed to characterize image flow cytometry for life-saving blood [70].

Similar deep learning approaches like the BMSNet, which leverages You Only Look Once (YOLO) and convolutional neural network architectures, have been used for the quality assessment of 122 bone marrow smears containing 17,319 annotated cells to better identify varying disease morphology [71].

Other areas such as scoring systems for upper gastrointestinal hemorrhage prediction have been augmented through gradient boosting machine learning algorithms with reported AUCs of 0.91 [72].

AI for Postpartum Haemorrhage Prediction

Postpartum hemorrhage can be associated with maternal mortality in both developed and developing countries. Machine learning has been used to predict postpartum hemorrhage, identifying 55 candidate risk factors that were studied to predict maternal risk of postpartum hemorrhage [73]. In a patient study of 152,279 assessed births, 7,279 patients with postpartum hemorrhage were identified using logistic regression, Lasso regression, random forests, and gradient boosting. The models were able to also predict postpartum hemorrhage risk to a significantly high degree based on reported C-statistics ranging from 87% for logistic and Lasso regressions to 93% for the extreme gradient boosting model, which was reported as the model with the best discriminative ability [73].

AI for Bone Marrow Haematopoietic Stem Cell Transplantation

Within the expanding field of haematopoietic stem cell transplantation, machine learning is also evolving rapidly. Sixty thousand procedures of haematopoietic stem cell transplants are

performed worldwide, with an estimated half a million survivors [1]. The process carries a heavy emotional burden involving donor-recipient pair selection, where suboptimally screened human leukocyte antigen locus mismatches could prove detrimental to patient safety and decrease 1-year survival from 53% to 43% in optimally matched pairs [74]. Graft-versus-host disease becomes a problem for donor-recipient mismatching, which can lead to transplant failure.

Machine learning models that have been used for pre-transplantation screening to optimize donor-recipient pairing include random forest and logistic regression used to identify amino-acid substitutions that can lead to mismatches [75]. While these algorithms have been promising during pre-validation, clinical validation has presented with failures. Post-transplantation usually presents with uncertainty for both donors and recipients with prognosis/complications such as graft-versus-host disease and others that influence morbidity or mortality [76]. Machine learning has been applied to identify these complications in big data projects such as the Acute Leukaemia Registry established by the European Group for Bone Marrow Transplantation (AL-EBMT) project – a 2015 initiative using alternating decision tree (ADT) analysis on 28,236 patient characteristics, which pursues multiple paths to predict 100-day mortality following allogeneic bone marrow transplantation for acute leukaemia (AUC, 0.702-ADT vs 0.646-EBMT score; $P = 3 \cdot 10^{-18}$) [38].

AI in Autoimmunity

For a comprehensive review in this topic, the reader is directed to the work by Stafford and colleagues, but it will not be a focus in this chapter as these are very organ-specific and will need a separate dedicated chapter [77]. Reported machine learning approaches to autoimmune disorders such as multiple sclerosis, rheumatoid and psoriatic arthritis, systemic sclerosis, autoimmune liver diseases, coeliac disease, inflammatory bowel disease, and type 1 diabetes have used models including support vector machines, variations of random forest, neural networks, decision trees, natural language processing, and other hybrid models [77].

Point-of-Care Diagnostics, Precision Diagnostics, and Sports Haematology

AI in Point-of-Care and Precision Haematological Diagnostics

This section is specific to haematological diagnostic tests for blood sugar monitoring, hemorrhage and coagulopathy, and septic screening, which need to be rapid for immediate decision support. This can be achieved using direct antigen detection from a very small sample of blood, but devices must be calibrated to reflect the true laboratory values. The principles remain the same as for any diagnostic test; it must be accurate and sensitive, safe to administer, cheap and durable to run, and relatively easy to administer, and in an ideal world it must also be painless or delivered with minimal discomfort to the patient.

In order to fulfill the above criteria, the use of rapid point-of-care diagnostic tests became even more necessary with the recent COVID-19 pandemic, which was also characterized by coagulopathy as well as lymphocytic and platelet count derangements. Social distancing measures and clinician safety meant this became even more of a necessity [78, 79].

HemoScreen is one such technology for point-of-care diagnostics leveraging machine learning algorithms for hemo-cellular-based characterization of blood samples on the operating principles of image analysis, microfluidics, and viscoelasticity [78]. HemoScreen correlates well with laser and impedance methods as well [78, 79].

Another area where precision diagnostics matters is in the oncological disease detection of haematological malignancies. Here too, Watson for Genomics is an exemplar IBM platform that has been designed with cognitive computing in mind to offer precision diagnostics using artificial intelligence as reviewed by Yokohama and colleagues [80].

Advances in mHealth and other areas to facilitate point-of-care testing and result processing and delivery have also seen integration with AI-based platforms that have been developed for diabetes and other chronic disease management. However, this will not be a focus here, and the

reader is thus directed to the relevant chapters to supplement their knowledge.

AI in Sports Haematology

Doping scandals have dominated sports headlines over several decades, as intelligently designed performance-enhancing drugs continue to provide athletes with an unfair advantage. Sadly, more sophisticated methods have been adopted to evade haematological tests and may already be taking advantage of machine learning and artificial intelligence methods for drug design and new ways for athletes to avoid detection. There is therefore a global need to tackle this issue with artificial intelligence, big data, and other approaches. One such International Sports Federation-funded project is the Artificial Intelligence Evoked Target Testing (A.R.I.E.T.T.A) project, which is a platform that aims to develop haematological and performance profile analyses to detect abnormal patterns that can isolate an individual for targeted testing [81].

Future Considerations for AI in Haematology

In this short section, we consider areas that will no longer seem challenging in the coming decades in terms of innovation and where AI and haematology will benefit each other.

Diseases like sickle cell anaemia may be an area that will benefit from genetic engineering to ameliorate crises and will be within our reach in the coming decades. Combining machine learning with CRISPR-like technologies could advance the potential for genetically editing out haematological diseases from the genome and will also be useful for genetically augmenting bone marrow and stem cell transplantation therapies to reduce graft-versus-host disease, etc. An example is in HLA haplotyping, which would benefit from better AI algorithms to augment CRISPR-like technologies in screening for loci sequences that can be edited out or into the genome to facilitate and improve better donor-recipient matching (we may even do without the need for matching in the future). The reader is

directed to other relevant chapters for further inspiration to aid their own knowledge discovery.

Nano-robotics in combination with genetic engineering and machine learning will help us to manage rarer genetic blood disorders with curative outcomes. However, significant advances in our understanding and appreciation for the combinatorial differences in rheological characteristics of an individual's blood must be carefully considered and appreciated.

Abstract

Anemia is a common comorbidity of chronic kidney disease. The abundance of clinical data readily available in electronic medical records facilitates the development of Artificial Intelligence techniques to support the human expert in diagnosis and treatment of this condition.

This chapter reviews applications of various Artificial Intelligence techniques through time to diagnose and treat anemia in patients with declining kidney function. First, Artificial Intelligence tools in this area were reported in the 1980s and focused on building computerized Expert System capable of mimicking human expert in the diagnosis of anemia. With the technological development and the ongoing data growth, more recent applications of Artificial Intelligence to the management of anemia moved from just imitating the human expert toward actively supporting them by elucidating relevant information hidden in the data.

Introduction

The term Artificial Intelligence (AI) and its application have evolved over time as computing capabilities have increased. In 1950, Alan Turing posed the following question: “can machines think?” [1]. He proposed an experiment called “The Imitation Game” where an interviewer will question two individuals to determine which is male and which is female. In the game, one of the test subjects is replaced with a computer, and the goal is to determine how often the interviewer wrongly guesses the sex of the subjects. One might conclude that the machine is “thinking” like the subject that was replaced when the proportions mimic those of human subjects. At the end of this work, he states “We may hope that machines will eventually compete with men in all purely intellectual fields. But which are the best ones to start with?”

In this case, the management of anemia is a perfect test bed in which to apply an AI approach in our own version of “The Imitation Game.” We would hope that we could not only develop a computer that is capable of mimicking the actions of a physician well versed in the management of anemia of chronic kidney disease (CKD) but also exceed the performance of a human expert. Anemia management in patients receiving hemodialysis is a good choice to demonstrate this research due to the nature of the dialysis process and a tightly controlled environment in which it occurs. The inputs to the process (drug dose, hemoglobin, time, etc.) are well captured in this patient population due to reporting and billing requirements and the very nature of the care provided for these patients. The outcome of interest is also well defined as maintaining hemoglobin concentration without exceeding specific upper and lower levels as well as minimizing the number of transfusion events. Errors related to adherence to therapy are minimized since all treatments are captured. The frequency of observation of the process allows us to observe the dynamics of response and provide

timely dose corrections. Although we focus on the use of AI in the management of anemia, it is also used for prediction of the reason for anemia as will be shown.

Artificial Intelligence Tools for Anemia Management

Pathophysiology and Treatment of Anemia in Chronic Kidney Disease

The oxygen-carrying ability of the blood stimulates the release of erythropoietin, primarily by the kidney but also other organs [2]. When patients develop kidney disease and end up on dialysis, the production of and the body’s response to erythropoietin become significantly impaired. Recurring loss of blood during dialysis sessions, reduced red blood cell lifespan, alteration in erythropoietin production and sensitivity, decrease of iron availability, and systemic inflammation lead to anemia in this patient population. In 1989, recombinant human erythropoietin was approved as the first erythropoiesis-stimulating agent (ESA) for treatment of anemia in the United States. Prior to that time, red blood cell transfusions were the primary mode of treatment.

To treat anemia of CKD, human experts attempt to mimic the role that kidneys play in this process by assessing the hemoglobin and iron levels and administering ESA and supplementing iron as needed. Physiologically, this process is precisely controlled at a relatively rapid timescale. Clinically, the precision is limited by the dose availability from the drug manufacturer and longer-time intervals between subsequent dose adjustments. Due to the complex relationship between the ESA dose, red blood cell lifespan, iron availability, and ESA response, as well as the logistic limitations listed above, we contended that an AI-supported approach to dose monitoring and outcome prediction would enable improvements in the treatment of anemia of CKD.

In most dialysis-dependent CKD patients, hemodialysis treatment is performed three times per week. Many therapeutic agents, including those used for anemia treatment, are administered

at that time. Laboratory measurements of hemoglobin and other routinely measured blood parameters are typically performed on a monthly or quarterly basis. Some of these measurements may be performed as frequently as once a week. As a result, data sets exist with very reliable data that can be used for developing AI approaches for monitoring and therapy. Laboratory measurements are usually downloaded into electronic medical record (EMR) database within 48 h of their collection, and ESA and iron doses are entered into the electronic medical record as they are given. Dose recommendations are typically governed by the information gathered by the manufacturer during development of the drug. Drug studies, performed in different patient cohorts, determine both the pharmacokinetic and pharmacodynamic properties of the drug. Knowledge gained during these studies is incorporated into the drug package insert issued by the Food and Drug Administration (FDA). Specifically, the package insert for anemia medications recommends using the lowest ESA dose required to decrease the need for red blood cell transfusions. Dose adjustments should consider the rate of change of the hemoglobin concentration, individual patient responsiveness to the drug, and hemoglobin variability. Doses should not be increased more often than once every 4 weeks, and the rate of hemoglobin rise should not exceed 1 g/dL in a 2-week period. Despite the existence of accurate models of the drug effect in patients, these models are not used in clinical practice in this specific instance and for all drugs in general. Rather, recommendations are given based on the population as a whole and not for an individual. Because of this, dialysis providers often establish their own algorithms guiding initial drug dose selection and the subsequent dose adjustments. In many cases, these algorithms are a form of an Expert System, where a physician expert in anemia management defines rules by which drug dosing performed.

In the United States, approximately two-thirds of dialysis patients receive treatment in one of two large dialysis organizations. The remaining one-third of dialysis patients receive treatment in medium and small dialysis organizations. This can result in different algorithms for the

administration of erythropoietic drugs. While this process may be relatively standardized in the large dialysis facilities, opinions become more varied as we look at smaller facilities. To this end, in partnership with End-Stage Kidney Disease Networks 9 and 10 based in Indianapolis, IN, the performance of six facility-supplied anemia management algorithms was tested in silico with the results shown in Fig. 1 (unpublished data). These results show that individual facility interpretation of the drug dosing guidelines provided in the FDA package insert for ESA can vary significantly and illustrate the nature of the problem.

Application of Artificial Intelligence to Diagnosis and Management of Anemia

Several areas of what one would consider application of AI to anemia management have been explored and will be discussed in the following sections. In addition, other non-AI approaches have been proposed that incorporate pharmacodynamic models for dose recommendation [3, 4]. These alternative approaches are outside the scope of this chapter.

Expert Systems

Expert Systems have been widely used in medicine and are the first form of AI that was applied to anemia treatment. The first reported use of an AI-based Expert System in this area occurred in 1985 with the development of a knowledge-based consultation program called ANEMIA [5–7]. This Expert System was developed to match the cognitive performance of an expert hematologist in diagnosing 65 specific variations of anemia from patient's laboratory results. In validation, using a process akin to Turing's "Imitation Game," the diagnostic performance of ANEMIA was rated as acceptable by expert hematologists in close to 90% of the cases. Similar successful examples of early AI-based Expert Systems for differential diagnosis of anemia are presented in [8–13]. Of

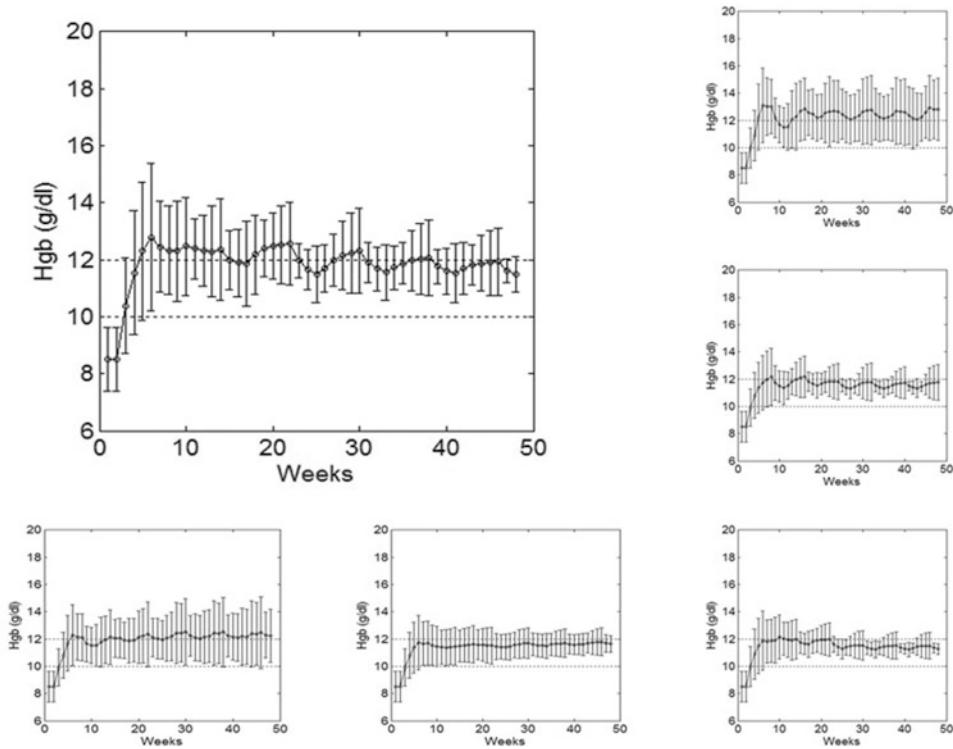

Fig. 1 Simulation of six different anemia management protocols designed by facilities when the hemoglobin target was 10.0–12.0 mg/dL

note, the hybrid Expert System proposed in [14] combined the knowledge-driven rule-based and a data-driven Artificial Neural Network (ANN) approach to AI. The latter will be addressed in greater detail in the following sections.

The first use of an Expert System to provide drug dosing information was tested in a randomized controlled clinical trial [15]. This system was developed by several investigators proficient in the management of CKD anemia and consisted of the following: assessment of hemoglobin concentration every 4 weeks, division of the obtained hemoglobin into three hemoglobin ranges, and for hemoglobin in the lowest range determining if iron stores are adequate, then recommending a step-up in dose, stepping down in dose, dose holding, or administering intravenous iron. This approach represented the computer implementation of a traditional paper algorithm like those used to generate the data shown in Fig. 1. It would meet Turing's definition of "intelligence"

where the recommendations could not be discerned from those made by a practitioner experienced in the treatment of anemia. However, due to the subjective nature of the expert's knowledge, it cannot be guaranteed that the dose recommendations generated by such system are optimal with respect to the published FDA guidelines or best practice.

A similar approach has been proposed by investigators who developed a clinical decision support system for the management of anemia in CKD patients [16]. This system utilizes the concept of threshold values for ESA dose changes in individual patients [17]. This work has resulted in the development of a commercial product called AMIE (Media Innovations, University of Leeds, Leeds, UK). This tool provides not only ESA dose recommendations but also dose for intravenous iron. Testing of the program in a 24-month prospective study in a cohort of hemodialysis patients resulted in a 50% decrease in ESA dose as well as

better iron status management. The decrease in ESA dose administered while maintaining hemoglobin concentrations within the target range is a result that will be seen in almost every other application of AI to support anemia management.

The dose recommendation Expert Systems described above only looked at cross-sectional data and did not benefit from longitudinal data on ESA dose administration and hemoglobin measurements readily available in today's electronic medical records. Dose recommendations were based solely on a single observation. Likewise, these Expert Systems did not address the issue of hemoglobin variability and inter-patient variability in ESA response. Therefore, the impact of these Expert Systems on decreasing individual hemoglobin variability remains unknown [18].

Moving Past Just Imitation

To better leverage the information collected and stored in an electronic medical record, AI approaches have been applied to the anemia of CKD. These approaches attempt to better accomplish the dosing recommendations provided in the FDA-approved package insert. The pharmacologic management of the disease is typically performed in a trial-and-error fashion by physicians. This management can be augmented by therapeutic drug monitoring where the concentration of the administered drug in the blood, or in the case of anemia management of the hemoglobin concentration, is measured, and a new dose is recommended as a function of that measured concentration. Physiologic data is complicated by error and variability. Error can occur in the data in the form of bias in the measurement of the hemoglobin concentration as well as adherence to drug therapy. Fortunately, in hemodialysis, adherence to drug therapy is known. However, there can be considerable variability in the measurement of hemoglobin concentration in dialysis patients due to assay variability, timing of the blood sample during the dialysis session, and dilution of the hemoglobin in the blood due to patient's variable fluid intake prior to the measurement. Physiologic variability can occur due to

differences in the metabolism and elimination of the administered drug as well as differences at the level of the erythropoietin receptor that is responsible for erythropoiesis. A more robust method may be needed to account for all these shifting variables in the prediction problem, and we can see the need to move past basic expert systems to provide optimal therapy.

Artificial Neural Networks

The most frequently applied AI tool in the management of CKD anemia is the Artificial Neural Network (ANN). An ANN represents an empirical, strictly data-driven AI approach. In the context of anemia management, ANNs use large quantities of data to look for associations between patient factors, dose, and response to predict future hemoglobin levels and/or recommend new erythropoietin dose. This approach is most useful when large amounts of data are available, and the dose-response relationship and its predictors are complex and may not be easily understood. In the United States approximately 600,000 patients receive in-center hemodialysis, and most of them receive some form of erythropoiesis-stimulating agent (ESA). Therefore, sufficient data should be available to successfully train an ANN for hemoglobin prediction. Following the work published in the mid-1980s with an Expert System, this was the next form of AI applied to this problem.

Published simultaneously in 2003, two groups researching the use of ANNs presented their results [19, 20]. This initial work focused on developing a pharmacodynamic model representing hemoglobin response to erythropoietin. The work published by Gaweda et al. [19] compared two common types of ANNs, a multilayer perceptron (MLP) network and a radial basis function (RBF) network to a linear auto-regressive model (ARX), and demonstrated the superiority of the MLP network. Martin-Guerrero et al. at the University of Valencia [20, 21] performed a similar study comparing an MLP network and a support vector machine (SVM) to an auto-regressive model. The authors concluded that the results of predicting future hemoglobin were very similar between the MLP

and SVM methods. As presented by these two papers, the very first step in the development of a drug dosing tool is a dose-response model which can be used to in turn calculate ESA dose.

The goal of developing a model for prediction of hemoglobin concentration (pharmacodynamic model) is that one can use that model to advise a medical expert as to the most appropriate dose of erythropoietin needed to achieve target hemoglobin. One must then couple the pharmacodynamic model with some other tool to predict dose or back solve the relationship for the dose needed to see the appropriate change in hemoglobin concentration. One way this can be accomplished is using closed-loop control. Brier et al. report on the use of an ANN-based model predictive control (MPC) to make ESA dosing recommendations [22]. The work represents the use of the gold standard for demonstrating the utility of an intervention, the randomized, double-blind, controlled trial. The study consisted of 60 patients randomly assigned to a control and treatment group, where the control group received treatment guided by the standard of care. Dose recommendations were provided by the ANN-MPC algorithm and a group of nurse practitioners for all study subjects. An unblinded physician entered the appropriate dose for each subject into the electronic medical record based on the subject's group assignment. Subjects were followed for 8 months, and the proportions of measured hemoglobin within the target range of 11–12 g/dL, less than 9 g/dL, and above 13 g/dL were measured. The use of the ANN-MPC resulted in a 50% decrease in outlier hemoglobin values and a decrease in the mean absolute difference between the achieved hemoglobin and 11.5 g/dL. Surprisingly, subjects dosed with the ANN-MPC algorithm had a slight increase in ESA utilization compared to the control group unlike the trial presented above in the expert system section.

A randomized controlled clinical trial is usually statistically powered to demonstrate the impact of a treatment on the primary outcome variable. However, an approach which may be successful in a small, controlled environment may potentially lack external validity. Barbieri et al. [23, 24] used a similar approach as the one

discussed above and developed an ANN-based algorithm using anemia management data from 4135 subjects in a large dialysis organization. Owing to the availability of a large data set, they expanded the inputs used for the prediction to include history of hemoglobin levels and ESA dose, patient characteristics, dialysis prescription, iron parameters, as well as markers of nutrition, infection, and inflammation. The ANN algorithm predicted hemoglobin achieved at 3 months. The prediction made by the ANN model was used to choose the most desirable dose to maintain hemoglobin within the target range. The ANN-driven anemia management protocol that was developed was prospectively validated in three dialysis clinics. The investigators reported a 6% absolute improvement in hemoglobin maintenance within the 10–12 g/dL target range, a decrease in individual hemoglobin variability, as well as 25% dose reduction compared to standard-of-care anemia management used prior to the study [24].

Reinforcement Learning

Drug dosing can be viewed as a form of a trial-and-error learning process within a feedback loop. After the initial drug dose is administered, the patient is observed for specific physiologic responses or adverse events. Subsequently, the practitioner adjusts the dose following the observed state of the patient. If toxicity occurs, the dose amount is decreased. If an inadequate response is observed, the dose is increased. The trial-and-error process continues until a desired response is achieved. Reinforcement Learning (RL) is an AI methodology rooted in the psychological theory of learning that mimics the human trial-and-error learning process [25]. One of the advantages of using this methodology is that some of the RL algorithms could generate decision rules that explain the actions taken. This feature provides an additional source of validation for the expert user. To study the feasibility of the RL approach in anemia management, several investigators tested generating ESA dose recommendations using an RL technique called Q-learning [26–30].

Gaweda et al. [26, 30] first used the RL approach to simulate anemia management in 200 virtual patients including a group of patients who responded normally to erythropoietin as well as a group with an impaired response. Simulation results were compared to a standard anemia management approach showing comparable performance. In the poor responder group, the standard approach typically resulted in the attainment of the target hemoglobin more rapidly. This phenomenon was attributed to the learning occurring at the beginning of the RL-driven treatment and a more conservative initial dose choice compared to the standard approach. To improve the speed and the efficiency of the Q-learning algorithm applied to anemia management, the same investigators proposed a method to introduce the expert knowledge into the learning updates [29].

The University of Valencia group also investigated the use of RL for the individualization of recombinant ESA dosage [27]. The approach used is like that of Gaweda et al. listed above and compares an RL approach to a standard anemia management protocol. These investigators compared standard interactive Q-learning approach to fitted Q-iteration, which is an off-line data-driven modification of the algorithm. In their experience, standard Q-learning resulted in a greater dispersion of hemoglobin values around the target range of 11–12 g/dL, compared to fitted Q-iteration and the standard of care. Several outlier hemoglobins were observed for all three methodologies. In the simulations, the fitted Q-iteration approach resulted in a 27.6% increase in the proportions of hemoglobin values in the target range compared to the standard protocol and a decrease in drug use of 5.13%.

Reinforcement Learning approaches have been investigated in several simulations. Depending on the RL method applied and the learning setup, different levels of success have been achieved. The advantage of the RL approach in the generation of rules that can be explicitly communicated to a practitioner makes this approach intriguing. At this point, sufficient work has not been performed to estimate the impact that the RL approach would have on patient outcomes in anemia management.

Fuzzy Systems

Returning to our discussion on the drug development process and the data and studies used for the registration of a new drug, it is primarily dependent on the manufacture to demonstrate safety and efficacy. Additionally, they are required to provide drug dosing information which usually is population-based with some exceptions for sub-populations. In the case of ESA, in the section on dosage and administration, there are specific recommendations for chronic renal failure, zidovudine-treated HIV-infected, cancer, and surgery patients. The recommendations acknowledge that individual patients are different for several reasons and that “doses must be individualized to ensure that hemoglobin is maintained at the appropriate level for each patient” (EPOGEN FDA product label). Fuzzy set theory may be helpful in identifying patients into groups of similar patients and that membership is not binary (or otherwise).

Unlike a binary factor like sex as defined by XX or XY which is easily ascertained in most cases, drug responsiveness is a blend of genetic and environmental factors. In the case of Mendelian genetics where each inherited trait is defined by a gene pair, this can result in three cases: AA, AB, or BB. Using a genotypic approach, it is easy to assign individuals to specific groups. This is not the case for a phenotypic approach especially when environmental factors come into play. This is where a fuzzy set approach can be useful. As shown in Fig. 2, using a fuzzy clustering approach, patient can be defined as a member of two or more groups with the centroid observed as the peak in the distribution for each cluster. The number of clusters is often determined empirically.

Once again, the goal of information provided to the practitioner in the drug package insert is based on the population than the individual. The clinic is interested in providing dose recommendations for the individual patient. The process by which a dose of drug is determined for an individual patient is typically guided by information contained in the FDA-required drug package insert and supplemented which patient-specific information and the clinician’s best judgment.

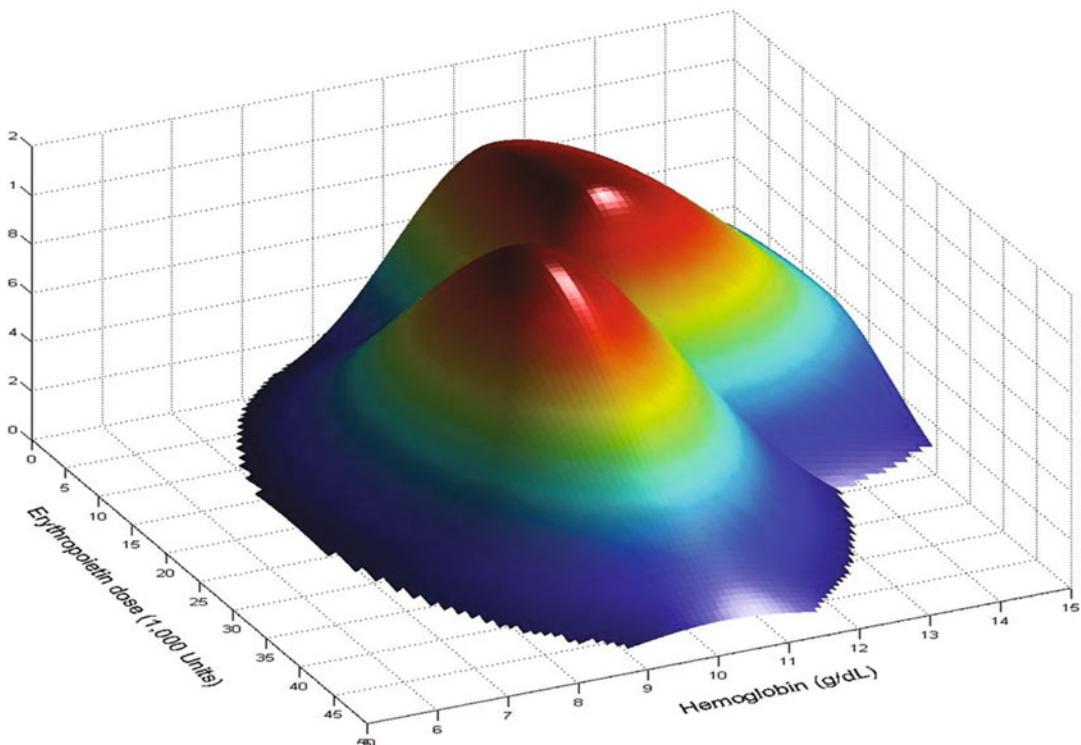

Fig. 2 Fuzzy membership functions representing patient classification as a “good responder” (low erythropoietin dose, high hemoglobin) and “poor responder” (high erythropoietin dose, low hemoglobin)

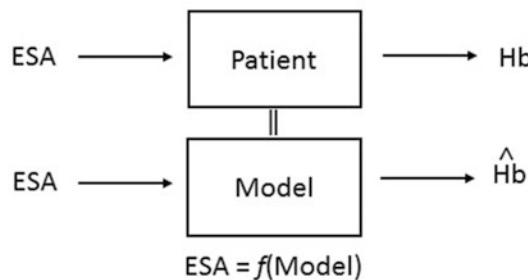

However, these approaches have limitations due to the data used to develop them. An AI-based closed-loop control can be used to account for imperfections in the model of the patient used to predict hemoglobin response. In an open-loop approach, future ESA dose is determined either by a written set of instructions or presenting different ESA doses to a patient model. In closed-loop control, the control system recommends an ESA dose which is given to the patient resulting in a hemoglobin value. This value is then compared to the hemoglobin target, and an error signal is generated. This error signal is fed back to optimize the subsequent ESA dose (Fig. 3).

The closed-loop control was used in the only randomized controlled clinical trials of AI in the management of anemia of CKD [22, 31] where the concepts of a fuzzy classification (Fig. 2) were combined with a model predictive control (MPC). In these two publications, MPC was applied in one instance where the patient model was an ANN and in the second instance where

the patient model was a physiologic model of erythropoiesis. Comparisons were made to a standard anemia management protocol developed by the dialysis facility medical director. Both studies were powered to detect a difference in the hemoglobin variability within and between subjects. As such, the size of the studies is limited to 60 patients. The ANN-MPC approach used only Hb and ESA dose inputs for the prediction of the next hemoglobin value. Future hemoglobin values were predicted over a 3-month horizon. Subjects were followed for 8 months. The Artificial Neural Network-based model predictive control group resulted in decreased hemoglobin variability in fewer observations below 9 and greater than 13 mg/dL. Total ESA dose was increased in the ANN group.

A second randomized controlled clinical trial of MPC-guided anemia management was performed using an AI tool Smart Anemia Manager (SAM). Subjects were followed for 12 months following randomization, and the

Open Loop

Closed Loop

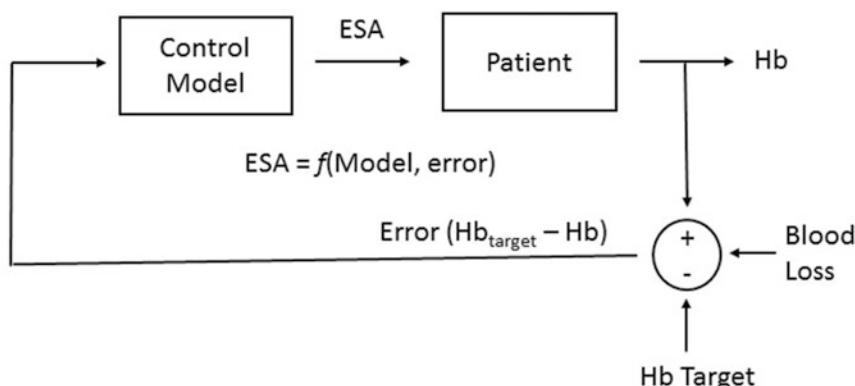

Fig. 3 Comparison between open-loop and closed-loop approaches to anemia management

control group was once again an anemia management protocol developed by the facility medical director. The study was designed to decrease within subject hemoglobin variability. As expected, the hemoglobin variability decreased (from 1.5 to 1.2 g/dL). This decrease led to an increase in the number of hemoglobin observations within the target range of 10–12 mg/dL from 61.9% in the control group to 72.5% in the treatment group. Median ESA and iron dose were not different between the two groups. Secondary analysis of the data observed a 50% reduction in transfusion rate in the treatment group.

Long-term follow-up of the SAM tool was subsequently performed. SAM was adopted as the standard-of-care anemia management protocol for the dialysis facility in which it was developed. Two follow-up periods were defined: (1) those patients on dialysis and treated with a facility-developed anemia management protocol

from September 2009 through August 2010 were compared to SAM dosing from August 2012 through July 2013 and (2) long-term follow-up of all in-center hemodialysis patients from October 2013 through March 2017. The ESA product used in both follow-up periods was epoetin alfa. In the case-control analysis, each patient served as their own control, and a total of 56 patients were analyzed. SAM-guided ESA dosing resulted in a 7% increase in hemoglobin concentrations within the target range of 10–12 g/dL. SAM-guided dosing also resulted in fewer hemoglobin measurements less than 10 g/dL by about 10% and greater than 12 g/dL by about 17%. ESA dose decreased by 62% and iron dose by 63%. The long-term follow-up in 233 patients receiving in-center hemodialysis was performed for 42 months and terminated when the dialysis facility switched to a different ESA product. The percentage of hemoglobin observations within the

target range was maintained between 68% and 77% for the fourth quarter of 2013 through the first quarter of 2017. ESA dose received continued to remain below mean dose established during the control period of 7000 units/week ranging from 2315 to 4176 units/week. Confidence in this technology is further demonstrated by the implementation of the SAM software as a clinical decision support tool and use in a medium-sized dialysis provider using a different, long-acting ESA product, darbepoetin. A total of 3354 patients were available for dosing using the SAM tool. 2946 patients had 3 months of prior dosing data for comparison along with 12 months of follow-up on SAM. These results were published at the 2019 Meeting of the American Society of Nephrology. Mean hemoglobin values in the control for 3 months were 10.3 ± 1.3 g/dL and ranged from 10.3 ± 1.3 g/dL in the first quarter of use to 10.5 ± 1.3 g/dL in the fourth quarter of use. ESA dose fell from a median monthly dose of 87 µg in the control period and ranged from 67 µg to 43 µg in quarters 1 and 4, respectively.

Iron is equally important to erythropoietin in the production of red blood cells. One AI-based approach to diagnose iron deficiency anemia has been presented in this area using an adaptive neuro-fuzzy inference system (ANFIS) [32]. Results obtained by the ANFIS were compared to those produced by an ANN, logistic, and linear regression using receiver operating characteristic (ROC) curve. Diagnostic accuracy improved over logistic regression ($AUC = 0.691$) with both, the ANN ($AUC = 0.982$) and the ANFIS ($AUC = 0.951$). In a total of 54 observations in a test set, the ANN only had 1 false negative and 1 false positive as compared to the logistic regression analysis with 18 false negatives and 2 false positives. This work demonstrates another successful use of an AI approach to diagnose anemia.

Conclusion

Artificial Intelligence tools have been successfully applied to the diagnosis and treatment of anemia. AI has been prominently utilized in the

medical literature for classification. The more novel use is in the treatment of anemia of CKD. The initial uses of AI for treatment were in the form of expert systems which had the advantage of uniformly applying rules to ESA dosing and removing individual practitioner variability from the equation. As individuals acquainted with AI approaches became aware of the unique prediction environment provided by in-center hemodialysis, the use of AI approaches expanded. The most common tool applied to this prediction problem is the Artificial Neural Networks. Other approaches including Reinforcement Learning and Fuzzy Systems have been studied as well. There is now sufficient literature evidence to support the use of AI tools as an addition to standard-of-care approaches to anemia management. These AI tools may not only improve the patient outcomes and the cost-effectiveness of treatment but also reduce and streamline the workload, allowing the medical personnel to better manage their effort.

monitoring equipment in place), which makes it the perfect environment to deploy AI tools. In this chapter, we review in detail the main applications of AI in the operating room, sorted in four main domains: (1) monitoring of the depth of anesthesia, (2) control of administration of anesthetic drugs (hypnotics, opioids, and/or muscle relaxants), (3) hemodynamic control (mostly titration of fluids and vasopressor therapy), and (4) risk prediction and prediction of events (e.g., predict surgery length or postoperative complications). In addition, we analyzed the degree of maturity of these various technologies. While many of these applications can have a large impact on quality and safety of care surrounding anesthesia, the maturity of these technologies is in general very low, and most of the applications published describe tools that have not received prospective evaluation. Only a handful of randomized trials comparing standard of care to the tandem AI doctor could be identified. Finally, we conclude with an assessment of the current practical implications of AI for practicing anesthesiologists.

Introduction

This chapter focuses on applications of artificial intelligence (AI) in anesthesiology. Anesthesiology is the field of healthcare involved with providing a state of controlled, temporary loss of sensation or awareness that is induced for medical purposes such as a surgical intervention [1]. It may include a combination of various components including analgesia (relief from or prevention of pain), amnesia (loss of memory), unconsciousness, and paralysis (muscle relaxation). The two main types of anesthesia that can be provided are general (a medically induced coma) or regional (techniques that numb a large

part of the body, such as an arm, a portion of a leg, or from the waist down). Anesthesiology is mostly a technical field, heavily protocolized and data-intensive (due to all the monitoring equipment in place), which makes it the perfect environment to deploy AI tools [2]. The practice of anesthesiology is of course inevitably dependent upon technology. Anesthetics were first made possible, then increasingly made safer, and now are more innovative and skillful than ever mainly due to advances in monitoring devices and delivery technology.

There are four main domains of applications of AI in the operating room:

1. *Monitoring of depth of anesthesia:* AI is used to quantify the depth of sedation and/or analgesia.
2. *Control of administration of anesthetic drugs:* The administration of anesthetic drugs is titrated by an algorithm to achieve a desired level of sedation and pain control.
3. *Hemodynamic control.* AI is used to titrate fluid and vasopressor therapy, to predict and/or control hemodynamic instability induced by anesthetic drugs, mechanical ventilation, or surgical interventions.
4. *Risk prediction and prediction of events.* Supervised machine learning models are designed to predict patient events and outcomes and generate prediction tools and scores that can be used prospectively with new incoming patients.

The first three domains of applications are building blocks toward automated anesthesia delivery systems, where the task of the anesthesiologist is emulated by machines. Figure 1 depicts an automated closed-loop (feedback control) system, designed to maintain a given target patient parameter into a specified range, without requiring human intervention. These feedback loops achieve their purpose by feeding the measured value of the parameter as well as the target range into a controller that adjusts the rate of drug administration while taking into account patient characteristics (e.g., gender, age, body weight, etc.).

In addition, we analyzed the degree of maturity of these various technologies, by reviewing all

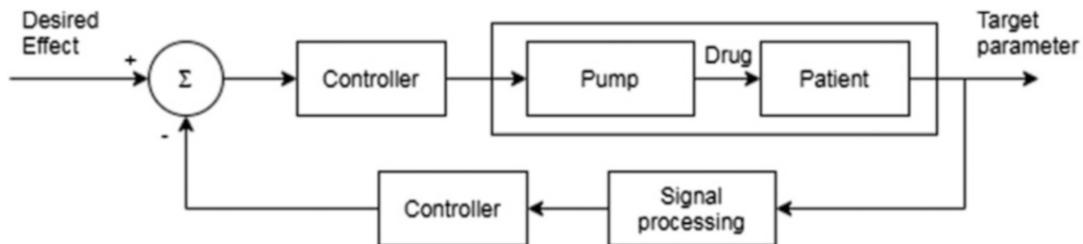

Fig. 1 Principle of a closed-loop delivery system for anesthesia. Drugs can be anesthetic agents, IV fluids, or vasopressors, and the measured target parameter can be an

EEG signal, a nociception monitor, a score of depth of hypnosis, common hemodynamic parameters, etc.

137 publications listed in a recent review of the literature on the topic [2]. While many of these applications can have a large impact on quality and safety of care surrounding anesthesia, the maturity of these technologies is in general very low, and most of the applications published in the literature describe tools that have only been developed on data collected retrospectively, with no prospective evaluation, and very few randomized trials comparing standard of care to the tandem AI doctor. Finally, we propose an assessment of the current practical implications of AI for practicing anesthesiologists.

The Use of AI to Monitor Depth of Anesthesia

The bulk of the literature in AI for anesthesiology relates to techniques trying to quantify the depth of anesthesia or analgesia, with the earliest models now about 30 years old [3, 4]. All these models belong to the realm of supervised learning and attempt to produce a value of awareness (regression models [5]) or classify a patient into being awake or unconscious (binary classification models [6]) or as belonging to a variety of stages of consciousness (multi-label classification models [7–9]). Indeed, machine learning methods are well-suited to analyze time series of data such as electroencephalogram (EEG) signals, either in their raw form (with the use of RNNs and affiliated deep learning models) or following intensive preprocessing and feature extraction.

In many publications, researchers attempted to compare the performance of new algorithms to validated anesthesia depth monitors, such as the

bispectral index (BIS, Medtronic, USA) [5, 7, 10]. More recent papers have used AI to more directly estimate the depth of anesthesia from raw EEG, without feature extraction [6, 9, 11]. Besides EEG, a range of other signals have been investigated: heart rate variability [10], auditory evoked potentials [8], vital signs, and end-tidal carbon dioxide [12]. Another related application relates to the quantification of analgesia and degree of suppression of the analgesic response. This offers the possibility to differentiate analgesia from hypnosis and titrate opioids and sedative agents separately [13–16]. The performance (classification accuracy) of a few of these algorithms was tested against human performance, but there were only a handful of randomized trials comparing patient outcomes when patients were randomized into receiving either standard care or AI-augmented care [17–19]. What these trials showed was that automated adjustment of anesthetics drugs, when compared to human management, better maintained a given target within a narrow range and decreased overshooting and undershooting. The evidence of improved patient-centered outcomes such as neurocognitive recovery remains ambiguous [17–19].

Controlling Anesthesia Delivery with AI

A group of publications focus on the control of drug delivery for anesthesia, including sedative agents, opioids, muscle blockers, and related drugs.

These systems to automate anesthesia delivery require two inputs: (1) a measurement of the depth

of anesthesia (via the use of scores or surrogates of anesthetic depth based on EEG or clinical parameter measurements) and (2) a target level of sedation set by the user (Fig. 1).

Quite logically, several papers proposed to control the delivery of drugs in order to achieve a target value of BIS, either via simple pharmacokinetic models [20] or via machine learning, including reinforcement learning [21–23]. Earlier models proposed to use clinical signs to control the delivery of anesthetics [24, 25]. No paper described the use of direct EEG signal for anesthesia control [2].

Control systems that use machine learning have also been used to automate the delivery of neuromuscular blockade [26, 27], and these systems have also incorporated forecasting of drug pharmacokinetics to further improve the control of infusions of paralytics [28].

Interestingly, the level of maturity of some of these technologies was more advanced than other types of published machine learning research (see section below). The majority of publications described the development and the prospective validation of these tools, albeit in general in pilot studies on a very limited number of patients (around ten for most publications).

Perioperative Hemodynamic Optimization Assisted by AI

Perioperative hemodynamic optimization (a general approach for managing fluids, vasoressors, and inotropes, using advanced hemodynamic monitors, coupled with predefined treatment algorithms to achieve targeted physiological endpoints) has attracted considerable interest within the last three decades due to its potential to decrease postoperative morbidity and reduce hospital length of stay [29–33] and hospital costs [31, 34] and even to facilitate recovery [35] in patients undergoing major surgery when compared to routine care. The beneficial impact of hemodynamic optimization has been shown in multiple RCTs [33], meta-analyses [32], and quality improvement studies [36, 37],

all published in major scientific journals. This has led clinical societies in various countries to publish relevant national guidelines based on expert recommendations. These professional societies now consider this strategy as a standard of care and the best practice for perioperative hemodynamic optimization in high-risk surgical patients. However, despite the benefits, this concept is frequently not well applied at the bedside due to multiple factors including the fact that this practice is relatively time- and attention-consuming, which can jeopardize other clinical obligations and limit the “tight” control required of certain clinical scenarios [38, 39]. To overcome this issue, some teams around the world have developed automated systems to ease the titration of fluid and vasopressor in the perioperative setting. The application of closed-loop automation to better titrate fluid and vasopressor intraoperatively has the potential to benefit both the providers and patients. Figure 2 shows an operating room setup showing a prototype of a closed-loop vasopressor system during a cardiac surgery. The individual components of the system are indicated.

As monitoring systems continue to advance, inevitably the capabilities of autonomous systems will also advance. An ideal hemodynamic management system would be aware of not just vascular tone, but total body water and intravascular volume, the current infusion rates of anesthetic agents, the heart rate, pain levels, and cardiac stroke volume. Moreover, a holistic hemodynamic management system would have the means to modify all of these factors through pharmacologic or similar interventions. Given the complexity of these multiple-input multiple-output systems, the safety concerns, and the regulatory hurdles, it is likely that it will be some time before this type of system becomes commonplace. That said, independent automated systems have indeed been developed to autonomously manage anesthesia [40–42], fluid administration [43–45], and analgesics [46, 47], and recent studies have been published using more than one system simultaneously [18, 48, 49]. It is likely we will see much more such work in the years to come.

Automation for Fluid Therapy

Computer assistance of intravenous resuscitation was one of the first clinical interventions attempted. In the 1970s, a group in Texas developed a closed-loop system for fluid administration based on urine output [50, 51]. In the last 20 years, many measures have been used to direct fluid resuscitation, including mean arterial pressure [52, 53], spectroscopy [54], pulse pressure variation and stroke volume variation [55], or a combination thereof [56].

One of the challenges of fluid therapy is that unlike other measures like heart rate or blood pressure, “optimal” fluid status is neither clearly defined nor easily assessed [57, 58]. Despite these challenges, algorithms can nevertheless be designed to mimic with high fidelity the way that clinicians administer fluid, particularly when guided by established algorithms like goal-

directed fluid therapy [58]. While the question of “optimal” fluid strategy remains open, closed-loop systems may in the meantime ensure that protocols that have been shown effective may be implemented with higher consistency than when implemented manually [36, 59–61]. One author of this chapter review has published numerous human trials using this type of closed-loop goal-directed fluid therapy algorithm and has shown increased protocol adherence [43, 45, 62], decreased length of hospital stay [45], and decreased postoperative complications [63] in patients undergoing major surgery.

Several teams around the world are currently working on closed-loop fluid resuscitation algorithms [64–66]. Moreover, there have been early attempts to look at combining fluid resuscitation with other common resuscitation drugs like vaso-pressors [48, 67]. For the most part, many of these efforts are using independent, noncooperative

controllers, but showing this is safe is a necessary step in the progression of these technologies [48, 67]. Finally, closed-loop fluid delivery systems have also been used as an “unbiased interventionist” in studies examining the effects of different resuscitation fluids [44, 68], and therefore, such automated system can be a very promising tool to better design clinical studies and standardized treatment delivery. Today, two commercially available devices are widely available on the market (Concert and NeuroWave devices).

Automation for Vasopressor Titration

Several retrospective studies highlighted the key role of arterial pressure control in the operating room, and there is published evidence that the titration of vasopressors by hand is inefficient and inaccurate [69]. Thus, the development of a more effective titration system may be particularly clinically impactful and be the future for arterial pressure management in both surgical and intensive care unit patients [70, 71]. Vasopressor administration, having a single “controlled” physiologic variable readily measured (arterial pressure), provides a more direct target than fluid therapy; it is another intervention that earlier researchers attempted to automate [72–74]. However, there was little commercial development – likely due to a variety of factors, not the least of which is regulatory concerns and safety. More recently, some authors believe that such systems have a huge potential for the future [70, 71]. Available prototypes were developed for operating room and intensive care unit use [75–77], obstetrics and spinal-induced hypotension [78–80], and septic shock [81]. A recent paper published this year demonstrated that using such system resulted in a significantly lower incidence of intraoperative hypotension than routine care [82]. Moreover, Libert and colleagues in Paris developed and tested a closed-loop system that can coadminister vasopressors and fluids with good performance metrics [49]. Arterial pressure management, while complex and multifactorial, has great promise as a subject for automated management because of the known link to poor outcomes.

Automation for Inotrope Infusion

Cardiac function has not been studied much for pharmacological closed-loop systems. This may be a natural consequence of the properties of inotropic cardiac medications as well as difficulty in assessing ventricular contractility in an objective and continuous manner. Additionally, many cardiac drugs have nonlinear effects, and ceiling effects are common and often occur at low infusion rates. The obvious exception is the implantable cardiac pacemaker. The most modern pacemakers are quite advanced containing many layers of autonomous systems that combine several algorithms governing their function, but this is an electrical system and not a pharmacologic one [83].

Nevertheless, pharmacologic rate control of heart rate by automated systems has been done in cardiac stress tests [84]. Inotropes have also been studied in at least two published manuscripts [85, 86].

Automation for Vasodilator Infusion

Vasodilators, like vasopressors, have a directly measurable controlled variable and were thus also early autonomous system prototypes [87]. Because of the relative infrequent need for vasodilation drips in clinical care, however, and the risks of overtreatment, there has not been much progression of this research. Two studies did explore titration of vasodilators via closed-loop for neurosurgery [88] and cardiac surgery [89].

Machine Learning for Predicting Hypotension

Arterial pressure is one of the most important determinants of organ perfusion. Perioperative hypotension is frequent in patients undergoing surgery and in critically ill patients. The severity and duration of hypotension are both associated with tissue hypoperfusion and organ dysfunction [90]. Hypotension is mostly treated reactively after low arterial pressure values have already

occurred. However, prediction of hypotension before it becomes clinically apparent is now possible and allows the clinician to treat hypotension preemptively, thereby reducing the severity and duration of hypotension.

It has been clear for some years that machine learning can be used to predict hypotension 10–15 min before it clinically becomes apparent by analyzing subtle hemodynamic changes in the arterial waveform that precede clinical hypotension [90–92].

A hypotension prediction algorithm – resulting in a unit-less “hypotension prediction index” (HPI) – was proposed by Hatib and co-workers [93]. The machine learning algorithm was trained in a cohort of surgical and ICU patients and analyzes characteristics of the arterial pressure waveform. The HPI uses “a MAP of less than 65 mmHg for at least 1 minute” to define hypotension and can take values between 0 and 100, with higher numbers indicating a higher risk of hypotension. The initial validation study showed that the HPI was able to predict hypotension with a sensitivity of 88% and a specificity of 87% 15 min before a hypotensive event [93]. The predictive capabilities of the HPI algorithm were investigated in several studies. In a retrospective study including 23 patients undergoing cardiac and major vascular surgery, Ranucci et al. [94] reported that an HPI value of 85 had a sensitivity of 62% and a specificity of 78% (negative predictive value of 98%, positive predictive value of 13%) to predict hypotension 5–7 min before its clinical occurrence. In a retrospective study in 255 patients undergoing major surgery, Davies et al. [95] showed that the HPI predicted hypotension up to 15 min before its occurrence with a sensitivity of 81% and a specificity of 81%. Recently, the impact of HPI on the incidence, duration, and severity of hypotension was tested in clinical trials. In a single-center prospective interventional feasibility trial in patients undergoing primary hip arthroplasty, Schneck and colleagues [96] randomized 25 patients to goal-directed hemodynamic therapy based on HPI and 25 patients to routine management and additionally compared those groups to a historic control of 50 patients. Goal-directed hemodynamic

therapy based on HPI reduced the incidence, severity, and duration of intraoperative hypotension compared to the control groups. In a small single-center preliminary randomized trial including 68 adult patients scheduled for elective non-cardiac surgery under general anesthesia, Veelo et al. [97] showed that the use of the HPI in combination with a hemodynamic management protocol reduced the time-weighted average below a MAP of 65 mmHg (i.e., the area under a MAP of 65 mmHg divided by the duration of surgery) compared to standard care.

Very recently, Maheshwari and colleagues [98] demonstrated that HPI guidance did not reduce the duration and severity of hypotension in more than 200 patients undergoing noncardiac surgery. One of the hypotheses was that alerts were not followed by interventions, presumably due to short warning time and the complex treatment algorithm or because of clinicians ignoring the alert [99]. Indeed, correction of this new variable is still dependent upon clinician reactivity and intervention. Such indexes may reduce intraoperative hypotension but would be unlikely to reduce hypotensions the way an automated system can. Evidence of this was provided by Sessler and colleagues who showed, for example, that clinicians who had alerts on their hospital phone each time BIS, minimum alveolar concentration (MAC), or MAP was low (“triple low”) did not see any significant reduction in the rate or severity of these measures compared to those who did not [100]. The implication is that lack of awareness of these variables being out of range is not the principle limiting factor, but rather there is a limitation somewhere between awareness and correction. Lastly, we expect that in the future, the optimal hypotension threshold for a given patient might be determined using predictive analytics, further personalizing hemodynamic treatment.

Event and Risk Prediction with AI

A significant fraction of the literature in AI in anesthesiology focuses on predicting events or outcomes related to peri-anesthetic care. Schematically, these can be divided into:

1. *Preoperative tasks*, for example, for prediction of the class of anesthetic risk (using the American Society of Anesthesiologist classification) [101], detection of difficult intubation [102], or assistance in decision-making for the optimal method of anesthesia in pediatric surgery [103].
2. *Intra-operative optimization*, for the prediction of consciousness level in response to propofol boluses [104], prediction of length of surgery [105], or prediction of the rate of recovery from neuromuscular blockade [106].
3. *Postoperative care*, for the prediction of recovery or intrahospital length of stay [107] or for the prediction of postoperative complications such as acute kidney injury [108], delirium [109], deterioration and ICU admission [110], or mortality [111, 112].

While some of these models showed great performance, for example, in predicting postoperative mortality [111, 112], the accuracy of others was more modest. For example, Combes and colleagues used a hospital database containing extensive information on staffing, operating room use per procedure and staff, and postanesthesia care unit use with the electronic health record to train a neural network to predict the duration of an operation based on the team, type of operation, and a patient's relevant medical history; however, prediction accuracy of their models never exceeded 60% [105].

A recent paper published in *The New England Journal of Medicine* assessed for the first time on a large scale the benefit of an automated detection system for general clinical deterioration on the ward across 19 different hospitals, in a cohort of 548,383 non-ICU hospitalizations [110]. While nonrandomized, the authors were able to identify a significantly lower risk of 30-day mortality in hospitals where the AI system was in use (adjusted relative risk, 0.84; 95% confidence interval, 0.78–0.90; $P < 0.001$).

A few of these models were compared to human anesthesiologists. For example, neural networks were used to predict the hypnotic effect (as measured by BIS) of an induction bolus dose of propofol (sensitivity of 82.35%, specificity of 64.38%, and an area under the curve of 0.755) and

were found to exceed the average estimate of certified anesthesiologists (sensitivity, 20.64%; specificity, 92.51%; area under the curve of 0.5605) [104].

Other Applications of AI in Anesthesiology

AI techniques are also proposed in a range of various applications related to the field of anesthesiology, including in the control of mechanical ventilation, in the prediction of pain control requirements, or for ultrasound guidance.

In the field of mechanical ventilation, AI applications have been proposed for a range of tasks [113], including the control of the minute ventilation to achieve a target set end-tidal carbon dioxide [114] or automation of weaning from mechanical ventilation [115, 116].

With regard to pain management, machine learning has been used in various tasks such as identifying objective biomarkers for pain from fMRI [117] or skin conductance [13] or predicting postoperative pain levels or opioid requirements [118, 119]. Research is also ongoing in the domain of genetics of pain, with researchers trying to identify the genetic polymorphism associated with postoperative pain levels [120].

The use of convolutional neural networks for image analysis and classification is now widespread in the field of AI in radiology, with many clinical tools approved by the Food and Drug Administration for clinical use in the United States [121]. Several publications relate to the use of image processing or image segmentation and classification for needle guidance or identification of anatomical structures, including femoral vessels [122], vertebrae, and other anatomical landmarks for epidural placement [123, 124].

Technology Readiness Level of Published Applications

We assessed the degree of maturity of 137 AI applications listed in a 2020 review of the literature [2], after excluding research evaluating

Table 1 Degree of maturity of 137 AI applications in anesthesiology listed in a recent review of the literature [2]. OR, operating room; RCT, randomized controlled trial

Degree of maturity of technology	Depth of anesthesia	Control of anesthesia delivery	Event prediction	Ultrasound guidance	Pain mgmt.	OR logistics	Total
Retrospective model	32	3	41	6	6	1	89
Retrospective model with human comparison	4	0	4	1	0	0	9
Prospective testing on patients but no RCT	2	17	6	5	2	2	34
RCT	0	2	1	0	0	0	3
Evaluation of a certified device	1	0	1	0	0	0	2

existing certified medical devices and reviews (Table 1). What we found is that in agreement with other healthcare domains [125, 126], the maturity of the research is in general very low, with most publications (98/137 or 71%) relating to models that were developed and tested in a single dataset previously collected from a single institution. Only about a quarter of these publications (34/137) included some prospective clinical testing, in general on a very small number of patients (around 10). In this list of studies, we could only retrieve three examples of randomized controlled trials comparing standard of care to decisions supported by an AI tool.

Implications of AI for the Anesthesiologist

This review highlighted some current applications of AI in the field of anesthesiology. With progress in digitization of peri-anesthetic care, clinicians must consider how best to interpret the increasing amount of available data for the delivery of anesthetic and critical care. The application of AI technologies holds the potential to help clinicians maximize the clinical utility of the data that is captured electronically. AI has the potential to impact the practice of anesthesiology in many aspects, ranging from perioperative support to critical care delivery to outpatient pain management.

The predominant focus across most of these studies has been to investigate potential ways that

artificial intelligence can benefit the clinical practice of anesthesiology not through the replacement of the clinician but through augmentation of the anesthesiologist's workflow, decision-making, and some specific elements of clinical care. Thus, although AI is an expansive field, the results of this review demonstrated the literature's focus on the technology of machine learning, which is only one piece of the solution. The technology readiness level of the vast majority of current applications is very low, meaning that applications are nowhere near clinical deployment at scale. Only a handful of systems were tested in new settings or tested prospectively in randomized controlled trials against the standard of care. Of note, the question of the need and rationale for external validation and recalibration itself is debated [127].

Kuck and Johnson have formulated the three laws for automation in anesthesiology: (1) do no harm, (2) be transparent, and (3) reduce the cognitive workload [113]. Indeed, the dangers and risks of using these tools must not be forgotten. Sensor failure, unpredictable disturbances, and software errors remain issues in any automated system, and safety concepts need to be developed to ensure no harm is done to the patient [128]. Another issue to consider with predictive modeling is the discovery of patterns undetectable by the human mind that are not actually causing problems and never will (the problem of overdiagnosis) [129].

A further essential element is that very few systems were fitted into clinicians' workflow and

evaluated in relevant clinical environments. Besides their crude statistical performance, we anticipate that key aspects around usability, interface design, human factors, trust, and acceptability will heavily influence success or demise of these systems [125]. Finally, the scientific community has only scratched the surface on questions related to legal and ethical implications of using AI in anesthesiology and more generally in healthcare.

Because of these factors, we argue that to this day, the threat to human jobs remains distant. We do not anticipate that AI will master all aspects of clinical anesthesiology before a long time. While humans have intuition and the ability to extrapolate from their knowledge base to unknown situations, AI models can only draw conclusions from the data they were trained on [130]. However, as stated by Hashimoto and colleagues: “As more and more elements of clinical practice become digitized and accumulated into databases, and as fundamental algorithmic research keeps progressing, we may one day see the development of AI systems that have a more complete understanding of clinical phenomena and thus greater potential to deliver elements of anesthesia care autonomously” [2].

At this point in time, it is hard to predict what AI application will be the first to be used at scale or will have the most impact for patients and clinicians. From this analysis of the literature, we would cautiously bet on closed-loop systems designed to optimize hemodynamics or maintain general anesthesia and on automated deterioration alerting systems for ward patients.

Conclusion

AI in anesthesiology has the potential to support human decisions and improve outcomes, and some of the research has begun to bear fruit and was translated into commercially available systems. However, most of the current technology is in its early development phase, with very few examples of successful prospective deployment and testing, which should become the focus of teams and institutions involved in this research. In parallel and mirroring a phenomenon seen in

most medical specialties, gaining literacy in the field of AI technology will become inevitable for any practicing anesthesiologist.

Abstract

The hectic domain of critical care is, arguably, one of the most demanding instances of multi-disciplinary medical decision-making. It is also a domain infused with monitoring and life-

sustaining technologies that leave behind the type of digital data trail that is ideal for the deployment of artificial intelligence and, particularly, machine learning methods and analytical pipelines. These data analysis methods should provide medical decision support to intensivists, but there is yet no clear framework or standard set of guidelines on how to do so. In this chapter, we aim to provide readers with information on the current landscape of applications of machine learning in critical care and also with a clear outline of some of the many challenges yet to overcome to guarantee the success of such applications, including the problem of model interpretability and explainability, the technology compliance with current legislation, or the education of medical practitioners in the area of data analytics using open-source software.

Supplementary Information: The online version of this chapter (https://doi.org/10.1007/978-3-030-64573-1_174) contains supplementary material, which is available to authorized users.

Introduction

The critical care domain and, more specifically, the current intensive care unit (ICU) in its different forms (neonatal, pediatric, geriatric, coronary, etc.) rely heavily on technology. All sorts of physiological data from patients at the ICU are gathered in order to inform physicians in a hectic environment in which timely delivered information is paramount to save people's lives. After all, patients in this environment are technologically dependent on life-sustaining devices such as infusion pumps, mechanical ventilators, or catheters, to name a few.

The patient's data captured by the bedside are conditioned by changes in patient status and may consist of electronic health record and monitoring devices data, including, among others, fluid intake and patient output, laboratory blood draw analyses, medical images, demographics, etc. Most of these measurements are electronically stored, generating a digital signature over time of the patients during their stay at the ICU.

The real-time information gathered in this way can be used by the physician as a guide to inform clinical decisions concerning diagnosis, prognosis, and course of treatment. Nevertheless, this information cannot be considered to be knowledge as such, just yet. Knowledge only resides in the physician's biological intelligence, working against a background of expert experience, provided by training and practice. Needless to say, that knowledge is bounded by the limitations of human experience: a physician can only operationalize the knowledge obtained from personal practice, which is augmented by the evidence-based medical protocols and guidelines that result from the accumulated experience of the profession for a given problem.

All the physiological measurements and further information gathered at the point of care conform a true digital signature of the ICU patient. Any clinical environment can thus gather thousands upon thousands of those signatures over time, building databases whose accumulated information is well beyond the reach of the "information-processing capabilities" of any individual medical expert. Extracting useful and actionable knowledge out of these data that go beyond the experience of an individual physician to reach a whole patient population is, instead, the domain of pattern recognition approaches. This is why machine learning (ML) and artificial intelligence (AI) at large are called to play an important role in the ICU: as techniques that can extract knowledge from large, heterogeneous, and complex databases to feed the human knowledge base for specific problems in critical care. Note though that the realization of large inter-center, international critical care databases faces severe challenges. Due to methodological differences in the way critical care is delivered in different medical centers, cultural differences in critical care documentation, and normative disparity, "the development of a system for crosstalk between critical care databases would be a major engineering feat," as argued in [1].

This chapter aims to provide the reader with a landscape of the many opportunities offered by ML and AI to the critical care community, both for research and for point-of-care applications. This will include commentary from a twofold perspective: that of the ML/AI techniques and families of techniques applied in this domain and that of the type of critical care problems that are currently being investigated using ML/AI-based approaches. Beyond that, this chapter addresses several issues concerning the application of ML/AI in critical care whose importance is only now becoming clear in medical applications in general. These issues include the need of interpretable and explainable models; the relevance of designing complete analytical pipelines that are compatible with medical guidelines applied at the point-of-care; and the required compliance of ML/AI methods with boundaries set by ethics and law.

Interpretation, Explanation, Pipelines, and Guidelines

Data dependence is bound to increase in healthcare and medical practice in general and, in particular, in the ICU. As stated in the introduction, this could be seen as an environment ready for data science in general, and ML/AI in particular, to thrive. The fact, though, is that even in this apparently perfect match between an information-rich medical environment and the broad availability of ML/AI data analysis methods, these approaches are not yet universally accepted by the medical community and far from being widely adopted, despite of their maturity, after decades of research and development.

It is argued in this section that the main reasons behind this apparent contradiction have little to do with technological maturity or readiness. Instead, they mostly have to do with difficulties of adoption and implementation challenges that, unless resolved, will not allow ML/AI methods to be adopted in routine medical practice beyond a reduced number of niche applications. One of these challenges is the inherent lack of interpretability and explainability of many ML/AI techniques [2], or, as eloquently expressed in [3], “the need to open the machine learning black box.” This “black box syndrome” has been discussed for decades in the medical domain [4]. Unfortunately, this domain challenge has not entered the mainstream discussion until recently [5], at least partially because of the huge success enjoyed by the current iteration of artificial neural network (ANN) techniques defined as deep learning (DL), which have found their way into biomedicine and healthcare [2, 6] and which are often referred to as an extreme case of model opacity.

This problem should clearly resonate with critical care practitioners: an ML/AI-based system may yield timely results that, despite their accuracy, might not be amenable of comprehensible explication. In an environment prone to swift decision-making such as the ICU, this might pose an insurmountable barrier for adoption, as the medical expert could not trust to implement a decision that cannot be either comprehended or

explained to either the patient or to other medical experts. Despite this, it must be noted that plenty of research has been devoted to imbue ML/AI methods with interpretability qualities, so that complex predictive models can be explained. Most approaches aim to somehow replicate human interpretation procedures, for instance, mimicking the performance of complex models using simpler and therefore more interpretable one; using visual analytics to provide intuitive insights [7]; rule extraction to make model interpretation akin to medical guidelines; or semantic representations that keep interpretation closer to human natural language.

This attempt to provide complex models with interpretability that is compatible with human reasoning brings another side to the argument, which has been broached in [8]: the need to integrate the available human expert knowledge into the ML/AI models. This means that formal frameworks for machine-human interaction that put the medical expert at the core of the process to achieve interpretability and explainability are compulsory [9] and that they should be able to guarantee a fluid exchange of knowledge between the ML-/AI-based decision support systems, the data scientist, and the critical care practitioner.

One of the reasons why ML-based systems need to be interpretable in the critical care domain is closer to the domain itself. It has to do with the idea that interpretability is required specifically when there is incompleteness in the formulation of a problem [5], and such an incompleteness may be the result of a mismatch between the ML-modeling objectives and the critical care goals. The latter are mediated by clinical guidelines. This is not necessarily a bottleneck, especially if we see the achievement of interpretability as the key to make model performance and ICU guidelines compliance compatible. Clinical guidelines at the point of care are nothing but prior knowledge-based procedural decision-making pipelines. The idea of ML/AI data analytics is increasingly being referred to as “analytical pipeline” and, in a related approach, automated machine learning, or AutoML [10], which even addresses the possibility of automated pipeline

optimization. In turn, in the case of medical applications, this is akin to the more time-honored concept of medical decision support systems (MDSS), which have made inroads at least in specific domains [11, 12] and whose barriers to adoption have for long been subject of research [13]. The similarity of ML-based data analytics and medical guidelines conveyed in the concept of pipeline should be the key to stitch the former to the reality of the point-of-care. Note that, in the discussion about the weak levels of MDSS real adoption, it has been argued [13] this might be due to adequate “explanations [not being] given for the system’s diagnosis,” or “the form of explanation [not being] satisfactory for the physicians using the system.”

Where at the ICU Should We Apply AI and ML?

Critical care deals with the seriously or critically ill patients who have, are at risk of, or are recovering from life-threatening conditions. It includes providing life support, invasive monitoring techniques, resuscitation, and end-of-life care. Therefore, most of these patients are both pharmacologically and technologically dependent on the life-sustaining devices that surround them (infusion pumps, mechanical ventilators, external kidneys, catheters, and so on).

Patients are admitted into the ICU if their medical needs are greater than what the general ward can offer. Indications for ICU admission include severe hypertension/hypotension, sepsis, certain cardiac arrhythmias, major trauma, major burns, or brain damage, among others. Other ICU needs include airway or ventilator support due to respiratory compromise, such as severe cases of the COVID-19 pandemic happening at the time of writing this chapter. Patients may also be admitted into the ICU after a major surgery. In summary, critical care deals with the management of organ dysfunction regardless of its source whose cumulative effect is termed as multiple organ failure or multiple organ dysfunction syndrome. Intensive care specialists are also in charge of the “chain of survival” and, thus, apply cardiopulmonary

resuscitation (CPR), defibrillation, and, if necessary, advanced life support (ALS) as stated above. For this reason, beyond managing organ dysfunction, one of the most important needs in critical care is assessing whether a patient will suffer a sudden deterioration that may require resuscitation (i.e., “code blue”). The code blue is typically the result of failed interventions/treatments that eventually result in cardiac arrest and, finally, death.

In developed countries, sepsis (an infection causing organ dysfunction) is the most common immediate cause of death in hospitals [14], and despite decades of research for more effective cures, it affects between 47 and 50 million people every year [15], out of which at least 11 million die (1 death every 2.8 s, on average). Nevertheless, these terrifying numbers fail to convey the magnitude of the effect that the incidence of the new COVID-19 pandemic has generated. Deaths by COVID-19 are cases of viral sepsis resulting from an infection by SARS-CoV-2, which has arisen abruptly while the traditional bacterial sepsis remains in steady state, without real ups and downs in yearly incidence.

Over the last decade, over one hundred Phase II and Phase III clinical trials have taken place including several hundreds of thousands of patients on protocols to modify the systemic inflammatory response in sepsis [16]. Remarkably, none of these studies has resulted in new treatments. The challenges for overcoming sepsis are:

1. Incomplete understanding of the burden of sepsis
2. Absence of national and international guidelines for treatment and follow-up
3. Unacceptable long time to diagnosis
4. Lack of patient trajectory assessment systems for a personalized medicine approach to treatment

The diagnosis of sepsis is only confirmed when the patient is already in organ dysfunction, meaning that there are no established criteria for its early and accurate diagnosis.

Besides sepsis, acute lung injury (ALI) or mild acute respiratory distress syndrome (ARDS) is a diffuse heterogeneous lung injury characterized

by hypoxemia, non-cardiogenic pulmonary edema, low lung compliance, and widespread capillary leakage. Although it can be triggered by a respiratory infection (such as COVID-19 or pneumonia), it is also a result of sepsis and significant trauma. The incidence of this has significantly increased due to the incidence of SARS-CoV-2 infections resulting in the collapse of healthcare and intensive care units worldwide. The main guidelines for managing ALI include mechanical ventilation, pronation, and, in the most severe cases, induced coma.

Mechanical ventilation is not exempt of risks either. It is often associated with major complications. If it can be proven that mechanical ventilation caused an ALI, it is termed ventilator-induced lung injury (VILI). If the mechanical ventilator cause cannot be proven, then it is termed ventilatory-associated lung injury (VALI). VALI is the most common complication since it is virtually impossible to prove the cause of injury. One major causative factor of lung injury is the overstretching of the airways and alveoli (volutrauma). During mechanical ventilation, the flow of gas into the lung will take the path of least resistance. Areas of the lung that are collapsed (atelectasis) or filled with secretions will be under inflated, while those areas that are relatively normal will then become overinflated, which leads to distension and injury. The effect may be reduced by using smaller tidal volumes.

Another possible ventilator-associated lung injury is known as biotrauma. Biotrauma involves the lung suffering injury from any mediator of the inflammatory response or from sepsis. The mortality attributed to VILI has been significantly reduced in recent years, thanks to the protective measures applied to ventilated patients. Weaning from mechanical ventilation is the process of reducing ventilatory support, ultimately resulting in a patient breathing spontaneously and being extubated. The purpose is to assess the probability that mechanical ventilation can be successfully discontinued. Patients who wean successfully have less morbidity, mortality, and resource utilization than patients who require prolonged mechanical ventilation or the reinstitution of mechanical ventilation. The most successful

weaning strategies include a daily assessment of the patient's readiness to wean and the careful use of sedatives. Then, the daily screening of patients who are on mechanical ventilation with the aim of identifying those able to breathe spontaneously is, possibly, the best approach to reduce the duration of ventilatory support and sedation. Unnecessarily prolonging sedation and mechanical ventilation is directly associated with increased morbidity and mortality of critically ill patients as well as the length of ICU stay and a significant increase in costs. Therefore, a strategy to detect at an early stage and in real time the patients able to start weaning leads to a reduction in morbidity, mortality, length of ICU stay, and costs.

The integration of multilevel (i.e., sociodemographics, epidemiological, genetic, systemic, and cellular-level data) and multimodal data (such as patient records, monitoring data, lab tests, biomarkers, and so on) through ML-based solutions provides a valuable opportunity to further understand the mechanisms of organ dysfunction, its phenotyping, and assessing patient responses as well as the clinical response to interventions at the onset (or prior to, when possible) of organ dysfunction.

In this context, the current ML trend in critical care is to integrate multimodal/multilevel data with point-of-care devices for assessing specific protein and metabolic biomarkers to develop clinical decision support systems for diagnosis and early management of organ dysfunction. These solutions shall empower caregivers in the use of novel diagnostic tools, enabling the adoption of more effective management and personalized care by taking a systems-level approach for fine-tuning treatment and vital support. It is expected that these approaches will ultimately lead to a reduction in time to diagnose, days on vasopressor support, days on mechanical ventilation (i.e., early weaning), and, ultimately, mortality. These data modeling-centered integrated solutions aim at ensuring (i) the efficient prediction and assessment of organ dysfunction; (ii) the phenotyping and assessment of patients; and (iii) the timely delivery of treatment recommendations based on the assessment of the clinical trajectory of each patient.

What Sort of AI and ML Can We Apply at the ICU?

Providing an exhaustive summary of AI/ML applications on critical care is beyond the scope of this chapter. For that, the reader is referred to [12] and to a very recent review in [17]. Instead, a more focused review is provided. In a typical ML pipeline, data with available ethical committee approval and consent is collected, processed, pseudonymized, and included into a repository (often cloud-based) with a predefined data taxonomy. In the case of sepsis and ARDS/ALI, special emphasis is given to lactate measurements, C-reactive protein, blood pressure measurements, mechanical ventilation parameters, administration of antibiotics, interleukin blockers, crystalloids, and vasopressors. This basic information is enhanced with data from patient records, medical images, maneuvers, *in vivo/in vitro* tests, functional tests, monitoring data, other lab tests, and biomarkers that may include transcriptomics, proteomics, peptidomics, and metabolomics. In this regard, it is vital to carry out data collection in three main steps: collection and preparation, annotation, and harmonization. It is also important to perform a quality check on the data to assure completeness and absence of bias so that potential data repairs can be arranged.

In the case of sepsis, a major trend today in research is improving the accuracy of its diagnosis. The definition of sepsis was updated in 2016 [18] and advocated to the quick Sequential Organ Failure Assessment (qSOFA), which assesses blood pressure, respiratory rate, and mental status for the diagnosis of sepsis. A major criticism by the medical community of this score lays in its low specificity. For this reason, different research teams are trying to enhance this scale through the addition of bedside parameters (e.g., biomarker data) for enhancing this diagnosis criterion. These enhanced versions of the qSOFA scale are evaluated in the context of all available data at hospital admission through standard ML techniques such as multivariate logistic regression, relevance vector machines (RVM), support vector machines (SVM), shallow neural networks, or random forests (RF), to name a few, taking

the diagnosis of sepsis confirmed through hemocultures as main outcome.

Another key aspect in clinical research is obtaining a set of baseline phenotypes and patient trajectories in the ICU through multivariate analysis techniques such as principal component analysis (PCA), factor analysis (FA), and probabilistic clustering (PC). For example, [19] defines four different phenotypes for sepsis: patients with low vasopressor titration, patients with chronic conditions and lower renal function, patients with high inflammation and pulmonary dysfunction, and patients with liver dysfunction and septic shock through consensus k-means clustering. Another study [20] defines four phenotypes related to predicting ICU outcomes: patients requiring mechanical ventilation support, patients with high organ dysfunction, patients with high severity, and hepatic dysfunction. With the aim of predicting organ dysfunction before its onset, these phenotypes are now being improved through the addition of different clinical traits and biomarkers that become altered before organ dysfunction is detected at a systemic level. Moreover, current initiatives aim at further improving these phenotypes through the application of a generalization of the FA method with deep autoencoders (DAE) to assess the strength of associations between variables and their importance within each patient phenotype.

A common trend between these initiatives is that they all pave the way to study patient trajectories in the ICU. Patient trajectory assessment includes studying the prevalence of each phenotype as well as their impact on other clinical outcomes such as long-term survival (i.e., 100-day survival rate), pressor resistance, and days on organ support. Deep reinforcement learning (DRL) has also become an important line of research for assessing the continuum of organ dysfunction in sepsis. For example, [21] proposed a continuous state-space model for the management of sepsis in a twist that goes beyond the more traditional development and use of discriminative classifiers. Other studies have used Bayesian networks and Random Forests [22] for assessing patient trajectories of septic and septic shock patients in the acute phase. It is also expected

that with the inclusion of biomarker data from the complement cascade, platelet degranulation, acute inflammation response, negative regulation of endopeptidase activity, and blood coagulation, it is possible to further assess the continuum of organ dysfunction with high accuracy through the development of comprehensive, interpretable, and mathematically rigorous graphical model embeddings through deep learning techniques such as DRL and standard ML techniques such as conditional independence maps and generative kernels [23]. These techniques are not only expected to improve the accuracy in diagnosis and trajectory prediction and, in particular, long-term survival but also should set the basis for the personalized treatment of organ dysfunction.

A Further Few Things About the Use of AI and ML in Medicine that Merit Discussion

Most of the discussion so far in this chapter has revolved around the critical care areas to which AI and ML can be applied and about the type of AI and ML models that can be more suited to the analysis of the data generated by specific critical care problems. The use of AI for critical care is also mediated by a few other practical challenges. After all, we should wonder why this type of approaches has not really permeated medical practice yet, despite their technological maturity.

The use of AI and ML methods to assist decision-making in the critical care domain is, for instance, also likely to concern practitioners in terms of legal boundaries and their implications. In Europe, this directly relates to the recent implementation of the European Union directive for General Data Protection Regulation (GDPR), which mandates a “right to explanation” of all decisions made by “automated or artificially intelligent algorithmic systems” [24]. Article 13 of this directive indicates that a designated “data controller” is legally bound to provide requesting citizens with “meaningful information about the logic involved, as well as the significance and the envisaged consequences of such processing [automated decision making, as described in its Article 22] for

the data subject.” As stated in [25], at least part of the problem has to do with data pseudonymization and anonymization. If proper anonymization is in place, data sharing and analysis should, in principle, not collide with legal privacy issues. The paradox is that ML, particularly in the form of deep learning, has been shown to be able to challenge medical data anonymization procedures [26]. Note also that there is a subtle and somehow related problem: the fact that ML and related methods often require substantial databases in order to extract useful and generalizable knowledge; gathering such databases faces non-trivial challenges, because it would require linking databases across clinical centers and countries (i.e., it would require the use of multi-center, international databases). As discussed in [27], this might boil down to another issue also brought up in [25]: the matter of data property. Who holds the data ownership at the ICU? Is it the patients? The professionals who have collected these data or the medical institutions they belong to? The external companies developing medical software used at the point-of-care? [28] If anonymized data are going to be used for ML-based analysis, does it require patients’ informed consent in all cases? The problem here, clearly expressed in [27], is the heterogeneity with which ethics committees at clinical centers deal with the requirement for consent for secondary uses of health data (semi-automated analysis in this case) provided certain conditions are met. And we are not talking only about the whim of particular ethics committees but also about the fact that these committees might be bounded to comply with heterogeneous local, national (such as the US HIPAA), or even transnational legislations (like GDPR). Such heterogeneity precludes the existence of high-quality databases for ML analysis, and the way forward is unclear but would entail either legislative harmonization or, perhaps in a more feasible manner, achievable in a shorter term, negotiation of codes of conduct related to data handling between professional bodies.

Note that GDPR legislation, in any case, is only partially about data rights as such and requires something very specific from the people implementing and using ML systems: the

aforementioned “right to explanation”: this leads back to the interpretability and explainability issues discussed in previous sections.

Most of the discussion so far in this chapter has revolved around the critical care areas to which AI and ML can be applied and about the type of AI and ML models that can be more suited to the analysis of the data generated by specific critical care problems. There is a further underlying problem that is not often broached [29] in relation to the previous: the use of open-source software (OSS) in the implementation of ML-based analytical pipelines and the potential benefits and risks of endowing critical care practitioners with the skills required to use such software.

Over the last few years, there has been a very swift transition from the predominance of proprietary software for the development of ML-based data analysis to the expansion of the use of non-proprietary software for such development, not only in the academic domain but also in applied domains traditionally reluctant to the use of OSS. From this, we can interpret that the advantages of OSS have proved to be more than those of the proprietary counterparts and that their inconveniences and barriers-to-use have been limited, if not vanished. It can be argued that the medical domain in general has been more impervious to these changes but also that [30] software vendors have failed to provide stable technical partnerships with the clinical domain in terms of medical informatics. Proprietary data management and processing also limit the reach of standardization of proprietary technology, therefore limiting as well the ability to take full advantage of patients’ population data analytics. OSS eliminates licensing costs, promotes compatibility, and allows customizing the software tools to the medical domain and its requirements [31], encouraging collaborative innovation and shortening software development cycles [32]. Why should not the critical care domain take full advantage of OSS for the development of ML-based MDSS? This coalesces with the recent research push for the development of automated ML or AutoML tools in medicine [33], despite existing and nontrivial barriers related to potential unreliability and unwanted variability of

the data, potential inadequacy to large-scale datasets, and also the lack of interpretability and explainability of many ML methods that we have earlier discussed in this chapter [10].

Conclusions

Should intensive care physicians care about AI and ML in their application to their domain of expertise? Arguably not. Should a data analyst specialized in medicine and clinical applications care about the application of AI and ML in critical care? Arguably yes. This asymmetry is a sobering reminder that there is plenty to do before these new technologies become a full-time companion for medical decision-making in critical care. We have provided in this chapter a general overview of how AI and ML can contribute in different problems of the domain, but, perhaps more importantly, we have highlighted the characteristics of many of the challenges yet to overcome.

As stated from the onset, the data wealth provided by the necessary use of digital equipment at the point of care, coalescing with the use of omics data, makes the intensive ward the perfect environment to take advantage of advanced data analytics. As we have argued, only by achieving a seamless integration with medical guidelines, by taking on board the human expertise, and by facilitating personalized medical treatment will AI and ML deliver on the great expectations that have been placed upon them.

Abstract

Cardiac arrest is one of the major causes of death worldwide. There is a significant clinical and economical need to prevent cardiac arrest.

The risk of cardiac arrest increases with age and comorbidities such as hypertension or other cardiovascular diseases. As the average life expectancy is increasing, the number of people

predisposed to cardiac arrest is increasing globally. Moreover, cardiac arrest can also occur in the young, healthy population and may result in sudden cardiac death due to hereditary diseases. The clinical and societal needs to prevent cardiac arrest continue to grow.

The recent development of artificial intelligence (AI) has shown potential for improving clinical techniques in the field of cardiovascular medicine. There are three important phases of interventions to prevent cardiac arrest: (1) early recognition of high-risk populations, (2) active interventions and follow-up according to individual estimated sudden cardiac arrest risks, and

H. Makimoto (✉)

(3) continuous monitoring in daily life and subsequent interventions. AI technology has been introduced in each phase. In this chapter, we discuss the recent achievements of AI in medicine (AIM) related to cardiac arrest and discuss its potential future uses.

Sudden cardiac death · Heart failure · Ventricular tachycardia · Wearable devices

Introduction

Cardiac arrest is defined as the cessation of heart function resulting in ineffective pumping of the heart and possibly leading to death. A typical cause of cardiac arrest is acute myocardial infarction. Chest pain, faintness, and nausea are possible symptoms that can occur shortly before cardiac arrest.

Sudden cardiac arrest (SCA) is an abrupt form of cardiac arrest. In developed countries, SCA is considered a major cause of death, accounting for 15% of all deaths [1]. Although acute myocardial infarction is well known for occurring during hard exercises or when the body is rapidly and intensely cooled, for example, in winter, there are many cases of SCA in which the normal heart beats suddenly cease without any obvious pathology. SCA is a life-threatening condition and can be difficult to predict. Therefore, it is a major clinical concern.

The most typical and direct cause of SCA is a ventricular arrhythmia. Risk factors of ventricular arrhythmias include age and baseline cardiovascular diseases, particularly ischemic heart diseases such as angina pectoris, myocardial infarction, heart failure, and various cardiomyopathies [2]. Some hereditary arrhythmic diseases have also been reported to cause SCA in relatively young patients. Bradycardia, in which the heart rate is slower than expected, such as in atrioventricular block, can also cause SCA.

The current standard medical treatments for high-risk patients who are exposed to SCA are implantations of medical devices such as implantable cardioverter-defibrillator (ICD) or

pacemakers [2, 3]. These devices can detect pre-defined heart rhythms that may be harmful to the patient. This detection leads to heart stimulation or shock delivery through electrical signals to retain an appropriate rhythm. The intracardiac electrodes are placed on the atrial or ventricular myocardium, and the generator is placed subcutaneously or submuscularly in the pectoral region of the anterior chest wall. The main function of the ICD is to detect ventricular arrhythmias and subsequently terminate them using stimulation or electrical shocks. Pacemakers stimulate and maintain heart beats if the heart rate is slower than predefined rates.

Currently, these medical devices are the most effective preventions against SCA. However, there are shortcomings of these devices, including higher risks of infections locally and intracardially and the risk of inadequate or inappropriate intervention of the devices (e.g., electrical shocks due to erroneous detection of abnormal heart rhythms) [4]. Thus, the necessity and suitability of these devices must be carefully examined before implantation, considering each patient's risk of SCA. Unfortunately, it is difficult or nearly impossible to accurately predict if the concerned patient will experience SCA. Artificial intelligence (AI) technology may supplement this decision-making process with its high performance in memory, recognition, and analysis. Some studies have reported the use of AI to prevent SCA more efficiently. In this chapter, we discuss some achievements of SCA prediction and prevention using AI and discuss further possibilities for the use of AI in medicine (AIM).

Cause of Cardiac Arrest: Ventricular Arrhythmias

The typical cause of cardiac arrest is a ventricular arrhythmia, most of which are ventricular tachycardia or ventricular fibrillation. Ventricular arrhythmias lead to ventricle trembles, resulting in a loss of the pump function of the ventricle, leading to circulatory collapse and cardiac arrest. Ventricular bradycardia can also result in circulatory collapse and cardiac arrest if the heart rate is extremely slow.

Ventricular tachycardia is defined as rapid and regular heartbeats (≥ 100 bpm) generated in the ventricular myocardium, contrary to normal heartbeats generated in the right atrium of the heart (at the sinus node). Ventricular fibrillation is a faster and finer trembling of the ventricular myocardia.

Ventricular bradycardia is defined as a heartbeat ≤ 60 bpm, and severe cases of bradycardia (heartbeat ≤ 30 bpm) can lead to circulatory collapse.

Baseline Cardiovascular Diseases Leading to Ventricular Arrhythmia

These ventricular arrhythmias rarely occur in healthy young adults who do not have an underlying cardiovascular disease. Ventricular tachycardia and fibrillation can be more frequently observed in elderly patients with a history of myocardial infarction or heart failure [5]. Various cardiomyopathies and inherited cardiovascular diseases have also been reported to be risk factors for these ventricular arrhythmias [2].

In the acute phase of myocardial infarction, myocardia undergo necrosis due to an abrupt disruption of the oxygen supply [6]. A typical cause of this is the obstruction of the coronary artery that supplies oxygen to the myocardium by a thrombus generated from the rupture of atherosclerotic plaques. Patients with hypertension, diabetes mellitus, dyslipidemia, renal dysfunction, and atrial fibrillation are considered to be high risk, with a predisposition for acute myocardial infarction [6].

Heart failure is broadly considered to be a condition in which cardiac dysfunction causes symptoms such as dyspnea. When the pump function of the ventricles is severely reduced, the patient may develop heart failure. Heart failure can result from primary myocardial damage due to dilated cardiomyopathy or hypertrophic cardiomyopathy as well as from secondary myocardial damage due to myocardial infarction or subsequent ischemic cardiomyopathy.

Some hereditary arrhythmic disorders are frequently seen in relatively young patients who experience ventricular tachycardia or fibrillation. These hereditary disorders involve myocardial ion channels that contribute to myocardial action

potentials and include Brugada syndrome, long QT syndrome, and catecholaminergic polymorphic ventricular tachycardia.

From Ventricular Arrhythmias to Cardiac Arrest

Patients with a prior history of myocardial infarction or heart failure have injured myocardium that no longer functions normally. These injured myocardial tissues are termed “arrhythmogenic substrates” and can generate ventricular tachycardia or fibrillation. In the case of hereditary arrhythmic disorders, myocardial ion channels harbor genetic dysfunctions, and these abnormalities precipitate ventricular arrhythmias.

When the heart loses its pump function due to ventricular arrhythmia, the blood pressure falls, resulting in circulatory collapse. In most cases, patients lose consciousness 10 s after the ventricular arrhythmia.

The Current Clinical Treatment to Prevent Cardiac Arrest

The current standard treatment for SCA due to ventricular arrhythmias is implantation of an implantable cardioverter-defibrillator (ICD). ICDs can detect the occurrence of the ventricular arrhythmias based on predefined settings and terminate arrhythmias through electrical stimulation and shocks. ICD implantation is the standard treatment to prevent SCA due to ventricular arrhythmias [2]. There are two basic indications for ICD implantation. Primary prophylactic ICD implantation is indicated in patients with highly reduced left ventricular function who have had no prior sustained ventricular arrhythmias. Secondary prophylactic ICD implantation is indicated in patients with a history of ventricular arrhythmia events. The latter patients have a naturally higher incidence of subsequent ICD interventions (stimulation/shocks) compared to the former patients.

For patients with bradycardia, the implantation of a pacemaker can maintain the heart rate and contribute to the prevention of cardiac arrest through direct myocardial stimulation [3]. The

necessity of pacemaker implantation should be determined by the patient's symptoms and the specific type of heart block.

The implantation of these devices also has disadvantages. In patients with implanted devices, especially for primary prevention, ventricular arrhythmia does not always occur following implantation. It is difficult to identify patients who will benefit from implantation prior to the procedure as future ventricular arrhythmias leading to cardiac arrest are difficult to predict in these patients. The implantation of these devices may also accompany long-term risks of complications [4]. The device itself causes discomfort and, furthermore, may give inappropriate shocks when the device misdiagnoses arrhythmias. Moreover, stimulations or shocks to terminate ventricular tachycardias have been reported to predict higher mortality, whether the interventions were appropriate or not, although ICDs effectively terminated life-threatening ventricular arrhythmias [7, 8].

To overcome these shortcomings of implantable devices, a more reliable and efficient method of estimating the risk of future ventricular arrhythmias is needed to determine the necessity of ICD implantation.

The Possibility and Advantage to Introduce AI Technology

AI technology may be a more efficient way to predict and prevent cardiac arrest. In theory, AI is not only able to gain knowledge via a learning process, similar to humans, but also to recognize information in a more efficient manner than human physicians. Furthermore, AI can manage large data simultaneously at high speed due to the development of computational technologies in the last decade. AI technology has begun to be utilized to prevent cardiac arrest.

Overview of Researches to Prevent Cardiac Arrest Utilizing AI

Machine learning has been a mainstay technique to build AI for cardiovascular data. In recent years, more researchers have adopted deep

learning models instead of conventional algorithm-based models.

Electrocardiogram (ECG) data are most commonly used as input data as the ECG is one of the major examinations used in cardiovascular medicine. Other medical data including blood tests, blood pressure measurements, and video or photographs of the face have also been used to build the AI for cardiovascular medicine. Simple data are preferred as input data, as the priority for preventing cardiac arrest is to determine or predict lethal ventricular arrhythmias as soon as possible, rather than to predict an exact diagnosis. For example, the ECGs used in some reports were recorded using a single lead, in contrast to the 12 leads used in the clinic. The quantity of data used for AI building ranges from that of several hundreds to tens of thousands of patients.

The target cardiac diseases to be identified by AI include myocardial infarction, cardiac dysfunction (heart failure), and arrhythmias, all of which are related to cardiac arrest. AI has been used to detect anomalies or diagnose these cardiac diseases.

For the prevention of cardiac arrest, there are three important phases of intervention:

1. Early recognition/detection of high-risk patients
2. Active interventions and follow-up according to individual estimated SCA risks
3. Continuous monitoring in daily life and subsequent interventions

Here, we present the achievements of AI at each phase to date.

Early Recognition/Detection of High-Risk Patients

It is important to identify high-risk patients as early and precisely as possible to prevent cardiac arrest. A history of sustained ventricular arrhythmias (i.e., previous aborted sudden cardiac arrest) and highly reduced left ventricular function are the most reliable risk predictors for cardiac arrest. Left ventricular function is determined comprehensively using echocardiography and cardiovascular magnetic resonance (CMR) [2].

Researchers in the United States have reported that patients with highly reduced left ventricular function can be detected with ECG data only by AI built using deep learning [9]. The researchers reported that a convolutional neural network (CNN) with nine layers was trained with ECGs from 44,959 patients and tested with ECGs from 52,870 patients. This CNN could distinguish patients with severe left ventricular dysfunction using only raw ECG data with an accuracy of 85% (area under the curve = 0.93). Interestingly, some patients classified as severe left ventricular dysfunction by the CNN but whose cardiac function had not deteriorated significantly according to echocardiography developed a severe decline in cardiac function upon follow-up. Therefore, this CNN identified the current high-risk patients as well as the potential high-risk patients using only ECG data.

There have been attempts to build AIs using video capturing with smartphones. Researchers in China reported an AI program built via deep learning to predict blood pressure using videos of the human face obtained with a smartphone [10]. Based on transdermal optical imaging from 2-min-long videos, the blood pressure could be predicted through the multilayer perceptron in the error range of 5 ± 8 mmHg. Higher blood pressure is correlated with a higher incidence of acute myocardial infarction or heart failure leading to cardiac arrest. This program may result in the very early discovery of patients with the potential to be at high risk for cardiac arrest.

The smartphone videos were also used for the detection of arrhythmias [11]. A CNN that could detect atrial fibrillation from video data with an accuracy of more than 95% both in sensitivity and specificity (AUC = 0.99) has been reported. These reports suggest that AI can currently recognize information that human physicians cannot.

Active Intervention and Follow-up

The risk of cardiac arrest often increases if patients are affected by certain cardiovascular diseases, such as myocardial infarction. In these patient populations, medical interventions should address long-term care and subsequent possible

cardiac arrest risks in addition to providing direct medical therapy for cardiovascular diseases. AI technology has started to be used to efficiently identify these patients.

Risk scoring systems are currently used to estimate the mortality or rehospitalization risk of patients with cardiovascular diseases. It has been reported that a machine learning algorithm built using a large amount of electronic health record (EHR) data can predict mortality and rehospitalization more precisely than the current risk scoring system [12]. Utilizing the EHR data in combination with other clinical data, the mortality of patients with heart failure could be predicted more precisely than with the Seattle Heart Failure Model (SHFM), which is the clinical index used to determine risks for patients with heart failure. Another study reported that AI built on a machine learning algorithm can use EHR data to precisely predict the onset of heart failure in a span of 12–18 months [13].

Torsade de pointes, a specific type of lethal ventricular tachycardia, can be induced by the administration of medications, which was predicted during a simulation using machine learning [14]. This study reported that a computer model was built based on the electrophysiological characteristics of cardiomyocytes and their reaction to drugs. This computer program was able to predict the risk of an order-made medication according to the electrophysiological properties of the patient.

Continuous Monitoring and Subsequent Interventions

Patients considered to be at high-risk for cardiac arrest are monitored and protected everyday by implanted devices (ICDs or pacemakers). Noninvasive monitoring devices, such as handheld ECG equipment for single-lead, 3-lead, or 6-lead ECG, are also used. The algorithms of these devices, built using machine learning, can detect atrial fibrillation (AF), including subclinical AF. Subclinical AF may lead to a higher risk of stroke and myocardial infarction if not detected. The diagnosis of subclinical AF enables the initiation of anticoagulant therapy earlier to prevent subsequent attacks.

In the iREAD Study [15], the ability of single-lead handheld ECG equipment (KardiaMobile Cardiac Monitor (KMCM)) to detect AF was verified. This study reported that the KMCM detected AF as accurately as the physicians who interpreted single-lead and 12-lead ECGs (KMCM sensitivity, 100%; specificity, 89.2%).

Recently, more and more wearable devices with cardiac monitoring functions are being used by patients with cardiovascular diseases as well as the healthy population. Most of these devices work in conjunction with smartphones, where applications are developed to obtain and manage the healthcare data from the wearable devices. Some devices are equipped with algorithms built through machine learning, one of which was tested for its detection capability of AF [16]. The Apple Heart Study included 419,297 owners of Apple Watches and iPhones, and their pulse analysis was verified. According to the investigation of 86 cases in which an irregular pulse notification on the apple watch and the ECG monitoring could be collected simultaneously, the positive predictive value for the AF detection based on the irregular pulse notification of the apple watches was 84%.

Data from implanted medical devices such as ICDs or pacemakers can also be continuously gathered and analyzed in the background. This data has been used for the early detection of heart failure [17]. It has also been suggested that the mortality of patients with heart failure can be predicted more precisely by combining intra-device variables with other medical data [18].

Discussion

Cardiac arrest remains as a major cause of death worldwide. AI technology has great potential and is expected to improve the methods of cardiac arrest prevention. Healthcare data and medical data are mainly objective and easy to digitalize, which are appropriate for building an AI algorithm. Input data will continue to accumulate with the widespread use of wearable devices and smartphones. It is expected that the quantity of input data will increase due to the era of big data,

enhancing and improving AI constructions. AI can handle enormous amounts of data, such as genetic information, suggesting the possibility of applying it to the treatment of hereditary diseases and to individualized medical therapies. Researchers have reported that the onset of asthma can be predicted based on genetic data (a single-nucleoside polymorphism (SNP)) using machine learning [19]. This strategy may also be applied to cardiovascular diseases, for example, hereditary arrhythmia syndromes.

However, there remain problems and possible weakness in using AI technology in cardiovascular medicine. First, AI programs could not provide reasoning for their conclusions, making it difficult to determine if the AI has correctly learned by machine learning or deep learning methods. As suggested in Nature (2019) [20], AI algorithms may be easily deceived by data corruption that human physicians cannot perceive. AI technology is incomplete and must be carefully introduced in the medical field to ensure patient safety. Whether AI can be relied upon is dependent on technical development as well as political and legal factors. Furthermore, to build a better AI program, the quality of input data is crucial. Medical data are typically collected at hospitals by certified medical staff; however, healthcare data obtained by wearable devices are not verified by trained individuals. To build an AI, the quality of these input data must be well considered.

Cardiac arrest is a life-threatening condition with a significant effect on quality of life and healthcare costs. There is a need for a more efficient and simple way to predict and prevent cardiac arrest, and for this aim, AI technology may play a key role. It is strongly expected that systems or devices with AI technology will soon be put into practical use as an aid to human physicians.

Abstract

Artificial intelligence (AI), mainly machine learning and deep learning algorithms, have advanced remarkably in the multiple domains of medical sciences. Clinical toxicology is a branch of toxicology that explores the adverse effects resulting from exposure to the various

harmful chemicals on humans. In this chapter, we explored a broad understanding of AI methods with a special focus on their applications in clinical toxicology. The future of clinical development hugely relies on the convergence of the latest digital data resources as well as the advanced computing capabilities by efficiently utilizing AI and machine learning algorithms. The advancement of computational and AI-based methods for virtual screening and *in silico* drug design has made significant progress over the last decade. Also, the use of the deep neural network in conjunction with data-driven and mechanistic modeling for clinical toxicology evaluation has emerged as a promising field for research and development. We describe the fundamental concepts of clinical toxicology and AI in this

chapter. Machine learning architectures are used to analyze and learn from publicly accessible biomedical and clinical trial datasets, real-world information from sensors, and health records are briefly covered. Recognition of complex patterns in toxicological data using advanced AI methods and its assistance in detection, characterization, and monitoring of clinical diseases are also elaborated. The future of AI and its impact on clinical toxicology is also discussed and summarized in detail.

Introduction: Clinical Toxicology

The amplified urbanization, industrialization, and technological advancement are among the key sources of environmental health hazards [1]. Human beings are increasingly exposed to

tens of thousands of individual or mixtures of chemicals, out of which only 10% have been tested for safety [2]. It is important to understand which environmental chemical poses a risk to human health. Clinical toxicology is a sub-discipline of toxicology that emphasizes and explores the harmful effect of chemicals which are both used for therapeutic and nontherapeutic purposes [3]. It is a discipline concerned with diseases and illnesses associated with acute and chronic toxicity of chemicals. It deals with the diagnosis, treatment, and management of patients including the toxicological estimation of mildness/severity and prolonged prognosis, as well as selecting the most suitable treatment for each patient. Clinical toxicology is an amalgamation of internal medicine, pharmacology, and toxicology. Though pharmacology may deal with thousands of chemicals with therapeutic uses, clinical toxicology encompasses tens of thousands of chemicals (Fig. 1) such as bacterial toxins, phycotoxins, mycotoxins, phytotoxins, animal venoms, household toxicants, pharmaceuticals, alcohol and drug abuse [4], air/water/soil

Fig. 1 The broad umbrella of clinical toxicology, depicting the wide range of products that induce toxicity starting from the naturally occurring toxic products (produced by bacteria, fungi, algae, plants, and animals) to the synthetic chemicals (pharmaceuticals, drugs, or household chemicals). It also includes illicit and psychedelic drugs and other chemical agents that induce acute inhalation toxicity

pollutants, chemical and biological warfare agents, and many more [5, 6]. Hence clinical toxicology is branched now to its subdisciplines, including the latest toxicodynamics. This new subdiscipline is developed aiming at assisting emergency physicians with a more systematic description of the effects of the chemicals on the patients [7]. Progress in clinical toxicology is strongly interdependent on related aspects of medical disciplines and studies. Hence, the focus of a clinical toxicologist is generally on the key points that are: the importance of toxins, their corresponding toxic response, and the molecular/cellular mechanisms involved in the response. The toxic response is either imparting reversible or irreversible injury on living cells and hence itself; a detailed study to understand the mechanism of toxicity and the critical molecular interaction involved is a matter of great interest to understand the etiology. The branch of clinical toxicology has progressed immensely in the past couple of decades due to the enormous developments that happened in the field of advanced computing as well as in the advanced imaging and visualization capabilities on cellular and molecular biology. An enormous amount of chemicals could have harmful effects on human health. But not all the adverse effects of exposure to chemicals are fatal, they can be mild and therefore do not require medical attention. Diagnosis of any form of intoxication can be difficult, particularly when there is a lack of exposure history. To detect certain toxins, analytical treatments are conducted, although their diagnostic utility is often constrained. However, general medical care is often considered adequate to successfully treat asymptomatic patients [8].

The Importance of Toxicovigilance

The concept of toxicovigilance involves the early and precise detection of toxin exposure followed by the clinical validation and follow-up of toxicology and immune response in human beings. Toxicology evaluation centers are important nodal centers in this complex clinical process as the collection of primary evidence and poisoning statistics

are very critical to define the cause, incidence, and severity of poisonings occurring in the general population. The active detection of clinical adverse events related to toxic exposures can be achieved either from single case reports or by database mining. Both approaches proved effective ways to detect clinical adverse events induced by pharmaceutical products in the post-marketing phase. Toxicovigilance is essentially based on the medical assessment of acute or chronic intoxications on an individual basis, which requires validated information that epidemiologists either do not look for or cannot analyze as comprehensively on a large scale. During these years, clinical toxicologists are prioritizing their focus on early identification and risk assessment in cases of environmental and occupational toxic exposures in human beings rather than simply focusing on causative treatment and management of affected patients. Toxicovigilance is this branch of precise clinical evolution that is now accepted widely as a useful complement to other modalities of risk assessment, especially in experimental toxicology, exposure analysis, and epidemiological validation.

Clinical toxicologists include medical practitioners and scientists working in hospitals, research centers (pharmacology and toxicology departments), government agencies, or industries [9]. Clinical toxicologists have a pivotal role in the detection, prevention as well as in the treatment of chemical intoxications. The clinical expertise of a toxicologist is extremely critical in providing suggestions of treatment to patients who have been exposed to any toxic chemical, either accidentally or voluntarily. They may be consulted on any environmental, occupational, and legal aspects of any harmful chemical exposure. They are involved in collecting, assessing, and interpreting the results of the analysis performed on the poisoned patient [10]. It is also expected that clinical toxicologists will be engrossed in developing methods to manage major chemical disasters, for determining antidotes administered against chemical warfare agents [11], or even for evaluating adverse effects of pesticides and fertilizers, by determining the level and dosages as like single exposure or chronic low-level exposures. Even though some clinicians are assisted by the

conventional prediction models, yet these clinicians should have a thorough understanding of theoretical and experimental laboratory studies and must have research enthusiasm to participate in reforming their primitive clinical evaluation methods. This is an extremely daunting task, as performing clinical evaluations on environmental and chemical toxicities include:

1. Determining the patient's intrinsic vulnerability to hazardous chemicals and environmental toxins thorough evaluation and understanding of their family record, nutritional and genomic profiles, demographic peculiarities and ethnicity, etc. [12].
2. An exposure history that includes a complete overview of food and drinking water, prescribed and recreational medications, and other consumer and personal care products.
3. A brief place history that includes both the residence and workplace. It also covers the assessment of the living conditions of patients, including their exposure to traffic and other sources of air pollution.
4. Evaluation of biomarkers in different body organs to measure the long-term and short-term exposures of toxicants.
5. A detailed medical evaluation to monitor any physical symptoms and comorbidities of metabolic, neurological, reproductive, or other illnesses.

Predicting Clinical Efficacy and Drug Toxicity

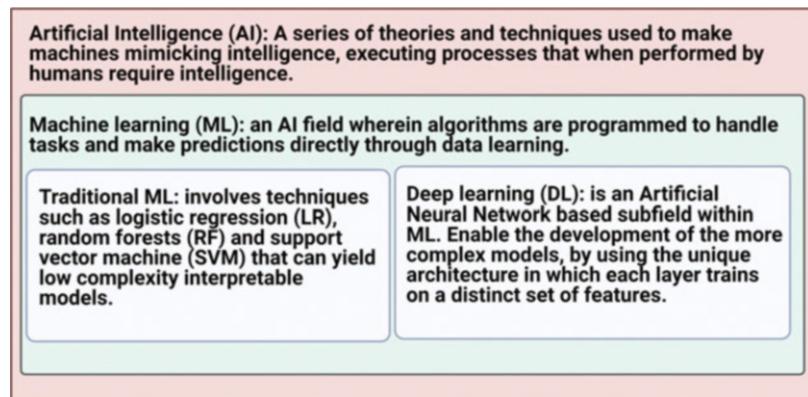

Noncompartmental analysis (NCA) is the conventional pharmacokinetic modeling tool. NCA is an experimental model that does not have a physiological interpretation component. Generally, NCA assumes whether the dose administered is distributed uniformly throughout the body and predicts the elimination of the drug through a rate constant that does not consider physiology barriers. This modeling approach definitely has some advantage like rapid generation of PK parameter estimates, but a major drawback of not considering any physiological mechanisms or biological processes that

naturally involved and influencing the actual PK dynamics. Population pharmacokinetic analysis (popPK) is yet another computational tool to determine the PK dynamics of a drug. Typically, population PK models are also experiential in design, but are different from PCA because being semi-mechanistic. There is also a PBPK model that estimates drug toxicity on the basis of physiology, biological processes, enzyme/transporter abundance, organ function, and even blood flow functions. PBPK modeling and simulation involves physiologically important parameters that are responsible for PK variability in patients.

Artificial Intelligence

Artificial intelligence (AI) is an advanced branch of computer science that deals with the realization of cognitive skills and it generally aims to mimic human intelligence with computer systems. In recent times, AI-based initiatives have attracted growing attention and acceptance in clinical evaluations like any other health care disciplines and industries [13]. The techniques of AI are widely used nowadays to improve clinical care, diagnosis, treatment, and follow-up of patients. The two subareas of AI are machine learning (ML) and deep learning (DL). ML is a subset of AI that utilizes advanced arithmetic algorithms that provide computers with the ability to automatically learn and make predictions on data without being explicitly programmed. This ability of algorithms are exploited using iterative, complex pattern matching, usually at a rate that exceeds human capability [14]. Deep learning (DL) is also a division of AI that is inspired to behave in a way similar to the human brain. It is related to understanding from examples. DL helps usually assists to filter the input data within layers and helps to predict and arrange information [15]. Recent developments in predictive DL techniques make it an ideal and useful tool on a large-scale analysis and arrangement of the newly available data; advanced storage technologies can also save significant amounts of data with advanced computing capabilities, as it can deal massive amount of data and information (Fig. 2).

Fig. 2 Distinguishing artificial intelligence (AI), machine learning (ML), and deep learning (DL). AI encompasses ML and DL wherein ML is a subset of AI and DL is a subset of ML

Deep learning appears to be more promising in terms of efficiency and precision, as it can accommodate a larger volume of data [16]. During the ML process, there is one input, one output, and one hidden layer. It requires feature extraction to train the model. On the other hand, DL uses the concept of multiple layers to adequately train the system, without the use of feature extraction. DL consists of one initial input, quite a few fully connected hidden layers, and one final output layer. Each layer represents a series of neurons and extorts higher-level features of the data, until the final layer effectively decides what the actual input shows. The additional layers the deep neural network has, the better the training of the features would be. The ability to interpret datasets differently is given by the various layers. Input data is converted by each layer into abstractions. The output layer merges those features to generate predictions. DL eventually comes into action when the required objective requires analyzing a huge number of factors correlated by unidentified and intricate interrelationships [17] (Fig. 3).

Machine Learning Algorithms

In toxicology, machine learning can be used for determining and understanding the toxicological effects of chemicals on humans [18]. These approaches provide evidence to be more beneficial as toxicity endpoints are widely heterogeneous, complex, and mostly not completely understood. Earlier several machine learning research were

mostly associated with small or nondiverse datasets that resulted in overfitting and unreliable prediction models that makes them undesirable for toxicology prediction [19]. Until recently, however, in silico approaches are considered extremely prevalent because of the advancements in computational hardware and significant concepts in techniques (like deep learning and natural language processing). The majority of these approaches have not only concentrated on using chemical structural and functional features to test chemical toxicity but have also started to implement outsized and more dissimilar sample sizes toxicity datasets that include data from both high-throughput screening (HTS) and toxicogenomics assays to supplement and explore machine learning processes appropriate for toxicology evaluation (Fig. 4).

Training and prediction are the two phases of the ML process. In the boot phase, the ML process is fed with unique datasets as input. This input dataset is separated into independent datasets:

- The training dataset: for training/learning the model. The model observes the data values/features carefully and learns from this data.
- The test dataset: for an unprejudiced evaluation of the ending model that fits on training dataset. The test set is generally a well-curated dataset that is used only after a model is fully trained. This is used for assessing the quality performance of the model (Fig. 5).

It is always beneficial to separate the datasets for the varied analysis using training

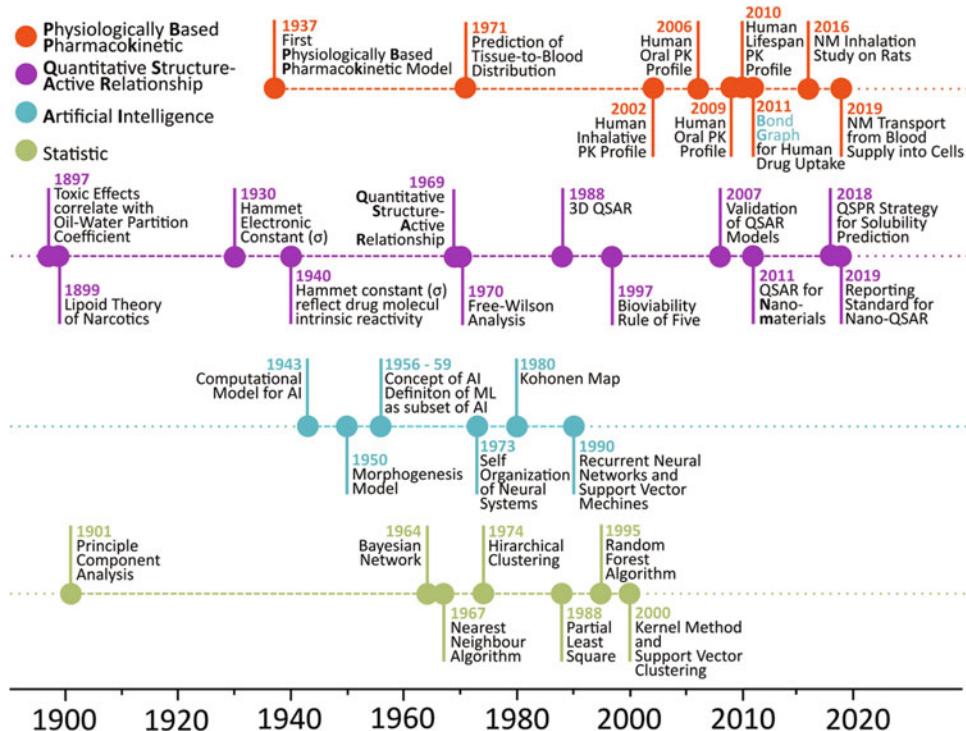

Fig. 3 Timeline of significant advances in the use of machine learning (ML) to aid in quantitative structure–activity relationships (QSAR) and Physiologically based Pharmacokinetic (PBPK) modeling and toxicity prediction of drugs and other substances. and testing models. The training dataset should not be used to validate the precision and accuracy of the model because then the model

would not generate accurate outputs if it is used in the training phase. The test dataset consists of strategically chosen data that covers

the different class types of the original data. A typical suggested ratio to break the dataset is found to be more (nearly 70%) for the training set and almost 30% for the testing set. This splitting data method in ML is also called the “lockbox approach.” This plays a critical role in every ML project as it a determining factor of success and failure of the project. The machine learning algorithms are further divided into two forms of learning: supervised and unsupervised.

Supervised Learning

In supervised learning, predictive models are developed using a labeled training dataset (Fig. 6). To map an input to output, a supervised learning algorithm is used which learns to predict an accurate output when a new unknown input is provided. In view of toxicology, supervised learning algorithms can look over various toxicity endpoints related with chemicals as input features to classify output as toxic or nontoxic. Thus, toxicological data must be known to train the model.

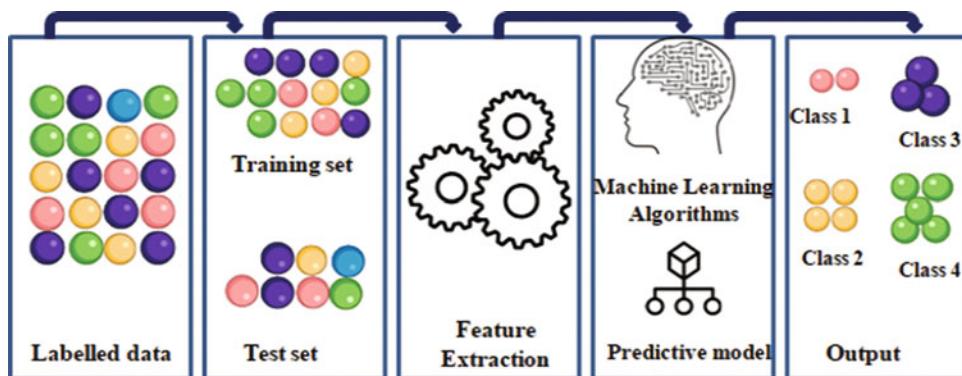

Fig. 6 Overview of the workflow of supervised machine learning

Supervised learning comprises classification and regression methods to predict qualitative or quantitative outcome, respectively. Qualitative output such as drug efficacy, organ toxicity, and disease diagnosis are streamlined using supervised classification methods, while computable output such as ADMET prediction and liver mass are modulated using supervised regression methods.

Table 1 enlists few extensively used supervised learning algorithms to test chemical toxicity. It comprises of Naïve Bayes, k-nearest neighbor (k-NN), support vector machines (SVMs), and random forest algorithms [20].

Unsupervised Learning

In the context of toxicity, unsupervised learning is useful when there is limited or almost no information available on the chemical's toxicity or non-toxicity. The purpose of the algorithm in unsupervised learning is to identify and learn representations and patterns from the unlabeled input data (Fig. 7). Unsupervised learning is very well established for the features mining, whereas supervised learning is ideal for predictive modeling by defining certain relationships within chemical characteristics as input and the result of interest as output [24].

Methods of unsupervised modeling are also used to minimize sets of feature-rich data, a feature of several sets of toxicity data, and to pick the most important predictive modeling feature or group of features. Unsupervised learning methods, for example, have been exploited to map molecular chemical bonds to generate

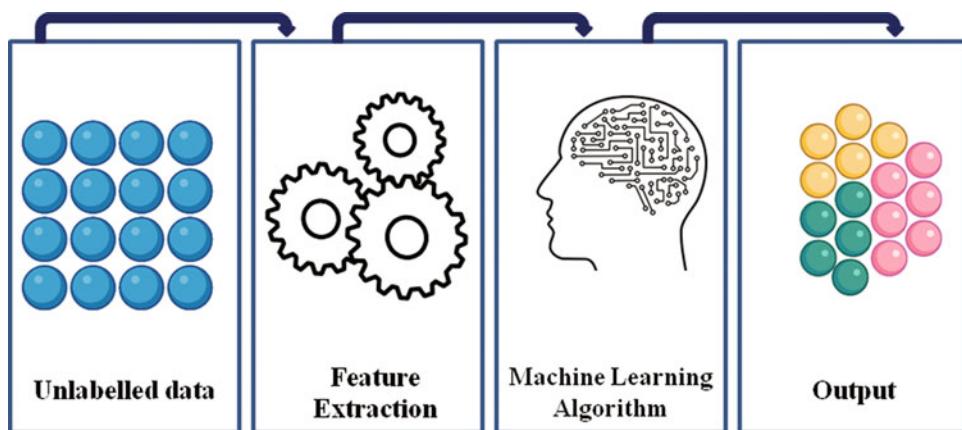

series of descriptors that are further used in combination with supervised learning to predict advanced toxicity. Clustering and dimension reduction are two major unsupervised learning methods. Table 2 enlists few of the unsupervised learning algorithms [25]. Clustering algorithms group similar characteristics into clusters together. Common clustering algorithms like k-means clustering, hierarchical clustering, and fuzzy clustering are used to cluster categorical and quantitative datasets. Another set of well-known unsupervised learning algorithms is principal component analysis (PCA) that is a well-known reduction technique used to visualize chemical patterns, reduce dimension, detect outliers, and particularly used when a trait is evaluated over a large number of dimensions, like number of genes in a genome-wide population or similar association studies.

Artificial Neural Networks (ANNs)

Artificial neural networks or connectionist systems are computing systems inspired by the biological neural networks that constitute animal brains. ANNs are a part of machine learning algorithms that mimic/replicate the learning process of neurons in the brain. ANNs consist of input, output, and a hidden layer to connect the input and output layers. However, each connection in ANN has a weight, which changes during training phase to link the input and output data. The combination and number of nonlinear connections enable ANNs to learn relatively highly complex functions to map the input and output data. This

Table 1 Description and applications of supervised machine learning algorithms

Name	Description	Applications
Naïve Bayes classifier	Based on the probabilistic Bayes theorem that is used to execute classification with a naive independence supposition between datasets It is suitable to use when the input dimensionality is high	Prediction of activity spectra for substances (PASS), an online tool, uses naïve Bayes classifier to predict various biological events, including toxicological endpoints such as carcinogenicity, mutagenicity, and developmental toxicology [21]
k-NN	A nonparametric algorithm where samples are characterized in a high-dimensional attribute by assuming that similar sets are in close proximity Selection of the feature is an imperative aspect in building k-NN models	A study by Amie D. Rodgers et al. (2010) used K-NN algorithm to predict chemical-induced hepatotoxicity. They observed that selection of total hydroxyl groups of aromatic rings had significant impact on the toxic effect of the model [22]
Support vector machines	SVM is a discriminative classifier that applies a linear or nonlinear utility to map chemical characteristics into a high degree of space and construct the best possible hyper-plane boundary which is defined by support vectors, and also helps to categorize the chemical toxicity	e-Doctor is an online application based on support vector machine that makes automatic diagnoses about health problems [23]
Random forest	It is a combined learning method where multiple resolution trees are randomly generated and combined with the majority voting schema It is more complex and less interpretable; this model performs well with large datasets and is more resistant to outlier effects and overfitting	These methods are used to categorize a broad range of toxicological endpoints such as estrogen receptor binding, cytochrome P450 inhibition, and kidney toxicity

**Fig. 7** Overview of the workflow of unsupervised machine learning

algorithm has been widely used but can suffer from overfitting [26].

The unique objective of the neural network technique is to resolve crisis in a similar process as the human brain works. During the years of advancement, importance of this technique was given to match and study specific mental abilities/illness. Divergence from biology has happened as now

capabilities are gained to acquire data on back propagation, or transition of information in the reverse direction and even to adjust the network of learning for reflecting the information. Neural networks have been used on a variety of tasks, including computer vision, speech recognition, machine translation, social network filtering, playing board and video games, and medical diagnosis.

Table 2 The learning categories and definitions for basic unsupervised learning algorithms

Algorithms	Definition	Learning category
Fuzzy clustering	A clustering method in which each data point can cluster more than once. It is a coefficient computing method that clusters for each data point	Clustering
Hierarchical clustering	A method to cluster hierarchies by combining two similar data clusters. The algorithm terminates when single cluster is left	Clustering
Principal component analysis (PCA)	A nonparametric statistical technique that utilizes an orthogonal method to convert a set of correlated features into new independent variables called principal components	Dimensionality reduction
Independent component analysis	A statistical approach for distinguishing statistically distinct additive components from a multivariable output	Dimensionality reduction
Self-organizing map (SOM)	A competitive learning network that represents the input distribution as a map by reducing the input dimensionality	Dimensionality reduction

Deep Learning Algorithms

Deep learning (also known as deep structured learning) is a type of machine learning method that uses artificial neural networks to learn representations. DL algorithms are prepared to handle very large, unstructured, and complex feature-rich toxicity data. DL supports analysis of large datasets such as high-throughput sequencing (HTS) data, toxicogenomics, microarray analysis, and image-based content [27]. Following are some of the studies conducted which have shown how deep learning models have achieved best performances in comparison to other machine learning algorithms.

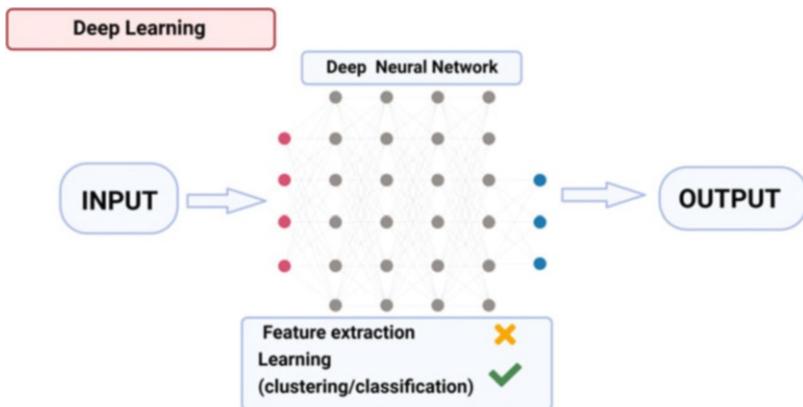

- Korotcov et al. found that deep neural network (DNN) models performed the best in a study comparing six different machine learning models among various toxicity-related endpoints for pharmaceutical research [28].
- Wang et al. assessed hepatotoxicity for biliary hyperplasia, liver necrosis, and liver fibrosis and observed that a DNN model performed better than SVM and RF models [29].
- During the Tox21 data challenge where various computational approaches for toxicity assessment was compared, a DeepTox pipeline that uses deep learning outperformed conventional machine learning methods [30].
- In a similar study that analyzed over 10,000 compounds with HTS data from Tox21, DNNs was used for predicting whether these

compounds exhibited agonistic or antagonistic activity in the androgen receptor pathway.

The majority of recent deep learning models are built on artificial neural networks, especially convolutional neural networks (CNNs), but they may also have propositional formulas or latent variables arranged layer wise in deep generative models like deep belief networks' nodes. Yoshua Bengio, Geoffrey Hinton, and Yann LeCun were most recently awarded the Turing Award in March 2019 for conceptual and engineering breakthroughs that have rendered deep neural networks a key component of computing. Hochreiter's team won the NIH's "Tox21 Data Competition" in 2014 by using deep learning to track off-target and harmful effects of environmental chemicals in foods, household goods, and medications. In 2012, a team headed by George E. Dahl won the "Merck Molecular Activity Challenge" by predicting the bimolecular target of one drug using multitask deep neural networks (Fig. 8).

An artificial neural network (ANN) with several layers between the input and output layers is known as a deep neural network (DNN). Neural networks come in a number of shapes and sizes, but they all share the same fundamental components: neurons, synapses, weights, biases, and functions. These components operate in the same way as human brains and can be conditioned much like every other machine learning algorithm.

Fig. 8 An overview of workflow in deep neural networks: DNNs are typically feed-forward networks in which data flows from the input layer to the output layer without looping back

Advances in Computational Toxicology

In the era of big data, significant advancements in computational toxicology have created an opportunity for potential toxicity research, which would have a profound effect on public health. The emergence of artificial intelligence techniques in computational toxicology is facilitating clinicians and public health professionals in bringing new research methods into practice. The latest terminologies used in the current big data era are “volume, velocity, and variety” to describe the currently available *in vitro* and *in vivo* chemical data for toxicity modeling purposes. Traditional modeling experiments consider only one entity (e.g., a single toxicity endpoint) and one set of attributes (i.e., chemical descriptors). There are several databases (e.g., PubChem, ChemIDplus, ChEMBL, DRUGBANK, T3DB, etc.) that provide a wide range of data for compounds of concern, including quantitative data directly from assays and qualitative data as the screening readout, which necessitates various data processing strategies [31].

Big Data for Toxicology Interpretations

The term “big data” refers to structured or unstructured datasets that expand exponentially and are so vast and complex that they are difficult to manage with personal computers and conventional computational methods. Big data has now become a

reality in chemical risk management. They offer multiple opportunities to transform this field of research and boost chemical risk management prospects. Big datasets necessitate specialized tools like heterogeneous and cloud computing, which go beyond traditional data collection and handling approaches, as well as complex data curation and sharing using algorithms like those used to manage data streams. The number of data is a key feature, as the term “large data” implies. The age of major toxicological evidence correlates to the evolving model of toxicology in the twenty-first century, which is turning away from apical effects research and observation and toward mechanistic toxicology. In the context of systems toxicology, the current direction of toxicology is focused on a better understanding – and continued elucidation – of the mechanisms that contribute to negative effects, and it reflects more on the individual relevance of the assessments. The number of data related to different toxicity end points is high due to the quality of the data. Combinatorial chemistry advanced quickly in the 1990s, resulting in vast chemical repositories for drug discovery screening. Automatic data mining and the use of robotics to replace humans in laboratory operations reduce the expense of testing a compound and help to quickly expand the new big data sources. Big data has thus brought major advancements to toxicology, but it has also posed significant difficulties, both on the technological side of integrating and interpreting their information, and on the general difficulty of not getting overcome by the

volume of data and being able to assess its significance. The handling, collecting, saving, combining, and reviewing of these data has become possible thanks to advances in data sciences, and data sciences has become an important part of contemporary toxicology. The distinction between experimental research and computational modeling has blurred in recent years, with the study and evaluation of certain types of data, such as omics data, necessitating the use of bespoke computational algorithms on a regular basis. In this context, predictive toxicology refers to more than just the use of statistical predictive modeling.

Physiological-Based Pharmacokinetic (PBPK) Modeling

Physiological-based pharmacokinetic (PBPK) modeling and simulation is a computer modeling technique that takes into account blood flow and organ tissue structure to determine drug pharmacokinetics (PK) [32]. The ability of PBPK models to solve ethical and technical challenges associated with pharmacokinetics and toxicology trials for various populations explains the increased reliance on PBPK models to answer regulatory and clinically relevant questions. The advantage of PBPK modeling is that it is a cost-effective and reliable statistical method that does not come with the ethical issues that come with clinical trials in vulnerable populations (e.g. cancer patients, pediatrics, pregnant women, etc.). The use of PBPK models in combination with in vitro–in vivo extrapolation (IVIVE) of absorption, distribution, metabolism, and excretion (ADME) in drug development and regulatory evaluation has grown significantly in recent years. This can be due to the creation of user-friendly platforms with high computational power that can handle this complexity and enable users to concentrate on the models' applications (Fig. 9).

Conclusion

Artificial intelligence (AI) and deep learning (DL) are gaining momentum into clinical medicine and clinical toxicology. These technologies enable to

strengthen the decision-making systems by enhancing the human intelligence. Clinicians, toxicologist, and AI developers should collaborate to take an active role in evolving their approaches and developing technology to minimize the potential adverse effects of AI in health care [33]. Integrating these programs into clinical care necessitates the formation of a mutually beneficial relationship between AI and clinicians, in which AI provides clinicians with improved efficiency and less expensive methodology, and clinicians provide AI with the clinical experiences necessary to learn complex clinical case management [34]. It will be an important task to ensure that AI does not outweigh the human face of medicine, as the public's reluctance to accept a profoundly controversial technology will be the greatest impediment to AI's widespread adoption in the future [35]. Recent advancements in AI are paving the way for proactive consultations that assess a patient's chances of acquiring a disease or other complications. Since AI can track millions of inputs at the same time, it will play a vital role in preventative health care. From a patient's digital records, AI can extract vital details. This will initially save time and increase model performance, but after proper research, it will also explicitly guide patient management. For instance, consider a consultation of a patient with an unknown complication: Currently, a physician spends a considerable amount of time reading past prescription letters, and reviewing pathological test results. Provided the patient's health record and exposure history, AI may, on the other hand, automatically plan the most critical threats and actions. It could also turn the consultation's registered conversation into a summary letter that the clinician may accept or amend. Since AI support rather than replace doctors, these applications would save a lot of time and could be introduced easily. Similarly, an AI-based mobile app capable to identify a skin lesion and diagnose its etiology, directly from the image captured, is also a future of AI in clinical toxicology. Artificial intelligence (AI) has made a lot of progress in the last decade, but it is still uncertain if these cutting-edge computing technologies will keep up with the hype. This chapter provides an

interdisciplinary review of the current state of the art in using AI-based methodologies to address various clinical toxicological issues. Clinical toxicology is one field of medicine where AI systems have the ability to revolutionize the process. Researchers can use AI to predict possible toxicity or off-target outcomes in a variety of workflows, as well as process the heap of data produced from the experimental analysis quickly and efficiently in a way that is meaningful and free from human biasness. AI and machine learning (ML) algorithms can help scientists learn more about the mechanisms that cause toxicity, biomarkers, and the subtle differences in genetic makeup that affect the maximum tolerated dose or drug efficacy in different people. Finally, AI will help companies speed up preclinical growth, save time and money, and get to market faster. Apart from demonstrating superior effectiveness, emerging medical developments must also integrate with existing procedures, secure regulatory approval, and, perhaps most importantly, encourage medical personnel and patients to engage in a new paradigm.

Abstract

In recent decades, advances in image-based assessment of stroke have enabled highly effective treatments to be deployed clinically, greatly improving stroke outcomes. However, the current model of stroke care still leaves many patients without treatment for numerous reasons, including the rigid treatment time window that is often applied. Additionally, many people do not live in the range of specialist care, leaving them at greater risk of a poor outcome. Currently, artificial intelligence (AI) carries the potential to optimize stroke care by automating diagnostic processes and delivering individualized outcome predictions that can guide health care decision-making. Accordingly, there are many advances underway to implement AI into stroke care. In this chapter, a summary of

AI applications to stroke medicine is presented and the challenges facing clinical deployment of AI into stroke care are discussed. Among those are data security and privacy, interpretability of algorithms, and standardization of outcome metrics. These challenges should be addressed by regulatory bodies in order to progress the field of AI in stroke.

Introduction

Stroke is characterized by the sudden onset of neurological symptoms and is the leading cause of adult disability in the developed world. Stroke may be further classified as either ischemic or hemorrhagic. Ischemic stroke occurs when a vessel supplying blood to the brain is obstructed by a clot, or thrombus, and accounts for approximately 85% of all strokes, with a lower proportion in Asian countries. Hemorrhagic stroke occurs when a blood vessel ruptures, bleeding into the surrounding brain tissue.

Emergency care for hemorrhagic stroke focuses on management of bleeding, by keeping blood pressure down and sometimes removing parts of the skull to allow room for the brain to swell. Surgical repair may also be necessary at a later stage.

The goal of acute ischemic stroke (AIS) therapy is to either pharmacologically or mechanically remove the clot in order to restore both patency to the artery occluded by the thrombus (recanalization) and blood flow (reperfusion) to the surrounding tissue that is ischemic but still salvageable (the ischemic penumbra). The current standard of care for AIS patients is intravenous (IV) thrombolysis with recombinant tissue plasminogen activator (tPA or alteplase), restricted to less than 4.5 h from symptom onset. In addition to thrombolysis, endovascular clot retrieval (ECR)

has been strongly validated as therapy for ischemic stroke in a large vessel, typically the internal carotid artery and the middle cerebral artery, greatly improving patient outcome. ECR has one of the strongest treatment effects in modern medicine, doubling the likelihood of an individual patient living disability free after stroke [1–6].

Imaging plays an essential role in acute stroke management. Thrombolytic agents were identified as a treatment for AIS in 1958, although they were associated with a high risk of hemorrhagic complications. However, advances in neurological assessment by computed tomography (CT) scanning throughout the 1970s and 1980s led to the ability to rule out hemorrhagic stroke before the administration of thrombolytic therapies, leading to their approval by the Food and Drug Administration (FDA) in 1996 [7].

Today, most acute stroke research focuses on ischemic stroke partly due to the diagnostic dilemma present in identifying the ischemic penumbra and core, as well as the need for patient selection for ECR. With guidance from neurological imaging, clinical trials have shown that some patients benefit from reperfusion treatment up to 9 h for IV thrombolysis or 24 h for endovascular clot retrieval (ECR) [8, 9]. These advances support a more individualized form of patient assessment, rather than applying a rigid time window to all patients. By integrating artificial intelligence (AI) into image-based assessment of stroke, it may be possible to advance these diagnostic techniques to offer more optimal stroke care.

This chapter will present a summary of artificial intelligence application to stroke medicine. In section “[AI Applications to Acute Stroke Medicine](#),” the applications of AI in stroke is discussed. In section “[Challenges for AI in Stroke Medicine](#),” the challenges of AI in stroke are explored.

AI Applications to Acute Stroke Medicine

Patients presenting to a capable center with dedicated wards and specialized staff are shown to have twice the chance of an excellent clinical outcome than patients that are not admitted to stroke wards

[10]. Specialist neurologists are less likely to be recruited to remote and regional areas, putting patients in regional and remote areas at higher risk of death or severe disability from stroke [11, 12]. The most significant role of AI in stroke is to deliver the highest possible standard of care to patients, regardless of their proximity to a specialist treatment center. In seeking to do so, AI applications can be fed the same data as would be a stroke specialist, process the information and provide an output or treatment recommendation, or a recommendation to connect to a stroke specialist as a means of triage. The applications of AI for acute stroke medicine are therefore divided into three categories: *Diagnosis* (section “[Diagnosis](#)”), *Prediction* (section “[Prediction](#)”), and *Integration* (section “[Integration](#)”). Section “[Diagnosis](#)” describes methods that focus on detection of stroke and section “[Prediction](#)” addresses algorithms which serve to assist clinicians in the decision-making process by generating an individualized outcome prediction. Finally, section “[Integration](#)” discusses the integration of AI into stroke care.

Diagnosis

While histology is unparalleled as means to confirm cell death in brain tissue, MR and CT imaging is used to identify cerebral infarct in patients presenting with stroke symptoms. The gold standard for the diagnosis of a cerebral infarction is widely considered to be by an expert assisted by magnetic resonance imaging (MRI) diffusion-weighted image (DWI-MRI), which measures cytotoxic oedema [13], shown in Fig. 1. However, during an emergency MRI imaging is not always available, and computed tomography (CT) acquisitions are commonly used to diagnose by attending clinician. CT scanners are cheaper—hence more ubiquitous—and have become increasingly more compact, and mobile [14]. CT imaging modalities relevant to stroke may be summarized as follows:

- Noncontrast CT (NCCT) is a standard tool for stroke assessment. Due to increased water content, severely ischemic brain tissue appears

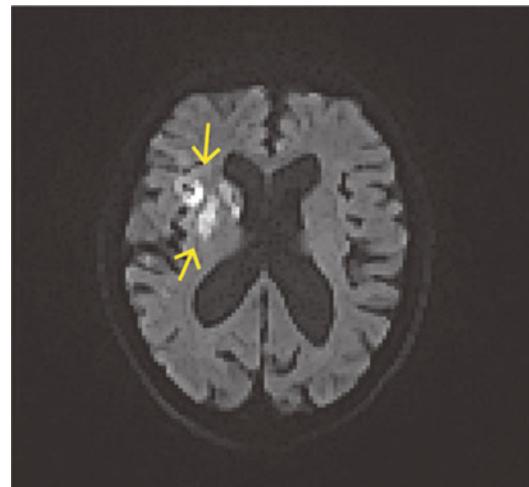

Fig. 1 MR-DWI imaging. Hyperintense regions (indicated by the yellow area) correspond to brain tissue that constitutes part of the ischemic core

hypodense on a NCCT image. This lies in contrast to intracerebral hemorrhage (ICH), which appears hyperintense on NCCT due to the high density of blood. NCCT can therefore be used to distinguish between hemorrhage and infarct.

- CT angiography (CTA) uses an injection of contrast into the blood vessels to find the precise location of the clot. This often informs treatment decisions. CTA also assists in ECR.
- CT perfusion imaging (CTP) estimates tissue response to reperfusion therapy by evaluating blood flow within the brain. Several CTA images are acquired in a short time frame and contrast concentration of tissue is measured over time. Hemodynamic maps are derived using post-processing methods that differ among software vendors [15]. Ischemic core (estimated infarction) and penumbra constitute the perfusion lesion. CTP is illustrated in Fig. 2.

Lesion Segmentation

Accurate measurement of a cerebral infarction is crucial for evaluating patients and guiding treatment. However, especially in the hyperacute phase, stroke presentation images can be subtle and often require an experienced clinician to interpret.

Manual demarcation of a stroke lesion on NCCT images is subject to inter- and intra-rater

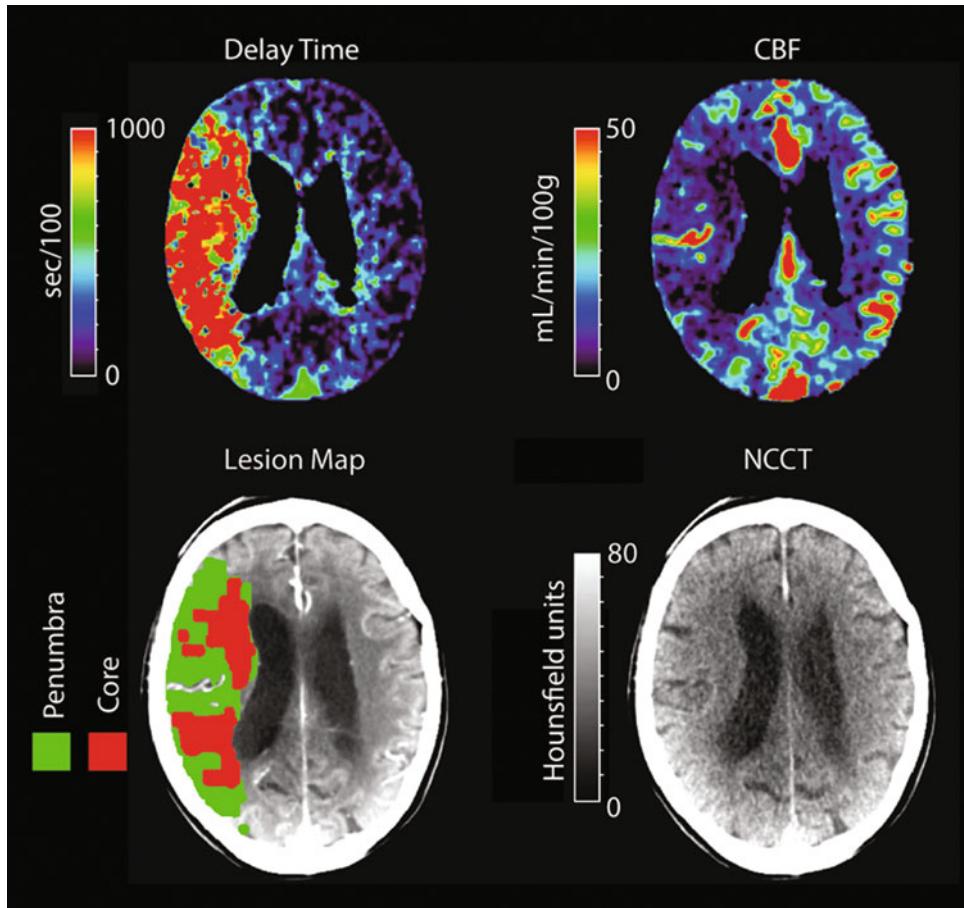

Fig. 2 CTP images. The delay time and cerebral blood flow (CBF) hemodynamic maps (generated by *Auto-MIStar*, Apollo Medical Imaging Technology, Melbourne,

Australia) provide an estimation of the ischemic core and penumbra. The corresponding noncontract CT (NCCT) is shown for the same patient

variability [16]. While a DWI hyperintense signal is visible within minutes of stroke onset, many infarcts are not visibly hypodense on a NCCT until hours after stroke onset, if at all [17]. This is partly due to the low signal-to-noise ratio which makes it more difficult to detect structural changes early on. Tissue intensities are also subject to variation due to acquisition parameters, which are not standardized. An added problem lies in the practice of windowing, done to highlight hypodense regions for easier demarcation; there is no standard placed on window levels.

CTP imaging is more sensitive to ischemic tissue. By extracting hemodynamic properties from time series data, tissue that is experiencing a deficit of blood flow can be identified. The

ischemic core identifies the region which has a degree of deficit which implies infarction and may be quantified by a 30% or more reduction in cerebral blood flow (CBF) [16]. However, other factors such as white matter disease and old infarcts have been shown to confound this thresholding approach [18, 19]. There is room for a robust method for automated lesion detection and measurement in CT-based images, validated against expertly segmented DWI.

Automated lesion segmentation is a classification problem, where each voxel (three-dimensional pixel) is classified as lesion or otherwise. Classification problems in AI may be categorized as supervised or unsupervised machine learning (ML). If annotated data (or *ground*

truth) is supplied to train a model to classify voxels into two or more known classes, the system is supervised, whereas an unsupervised model will locate patterns in the data without being supplied a ground truth. Unsupervised methods can be slow, especially over large datasets. There are also segmentation methods that combine elements from both categories, as well as those that are semi-supervised, or weakly supervised [20, 21].

The general formulation of a supervised ML classifier involves using input channels—features—to accurately predict the supplied ground truth. The objective function defined by the algorithm—which evaluates the loss accumulated by errors during a pass through the classifier—is minimized until the highest accuracy is achieved. Best practice dictates that data is divided into *training*, *testing*, and sometimes *validation* cohorts. By testing the trained model on new, unseen data, the model is prevented from overfitting to the data it was trained on.

There are several modes of approach for obtaining the necessary voxel-wise information—or features—that are used to classify the image voxel, some of which are listed here:

- *Physiological properties.* Physiological features known to be relevant—e.g., hemodynamic properties, white matter content, and NCCT hypodensity—can be quantified and calculated/extracted from images as feature maps [22, 23].
- *Template matching.* If templates are available, images can be registered to template space where deviations from template can be calculated [22, 24].
- *Statistical properties.* Information about the grey values of voxel as well as the distribution of values may be calculated [25].
- *Automated feature extraction via deep learning (DL).* Feature extraction and segmentation are combined into one end-to-end model [26].

Traditional segmentation methods characterize a voxel’s class based on the features associated with that voxel alone. In contrast, there are several methods for including spatial context into AI models—such as the location of the voxel within

the brain or in relation to other voxels—that improve the quality of the classifier.

Classifier methods such as random forest (RF), logistic regression, gradient boosting, support vector machine, or neural networks may adopt a format whereby features associated with a single instance or voxel are combined into a one-dimensional array and stacked with features from other instances to form a two-dimensional training matrix. To include spatial context with this approach, neighboring voxels can be concatenated along the feature axis. Figure 3 illustrates this patch-based approach. The voxel at the center of the patch is the target of the classification and neighboring voxels are included as additional features [24, 27].

A neighborhood analysis takes only immediately surrounding voxels into consideration and not the location of the pixel within the brain. Fully convolutional neural networks (FCNs) improve on this by forwarding the entire image through a DL network, allowing *dense inference*. Figure 4 illustrates a simplified version of the architecture described by [26]. A series of convolutional layers automatically extract features from the image. Each layer successively downsamples the image to extract features on different scales. Both fine and coarse layers are used to make predictions that respect global structure. A classification layer upsamples the image to provide a segmentation output.

The International Conference on Medical Image Computing and Computer-Assisted Intervention (MICCAI) has hosted the ISLES (Ischemic Stroke Lesion Segmentation) challenge since 2015, setting various tasks relating to stroke lesion segmentation. The 2018 ISLES challenge was to segment stroke lesions based on acute CTP data. The top four finalist all proposed solutions based on U-Net architecture, which adopts the FCN and modifies it to work with very few training images [28, 29]. A simplified illustration of U-Net architecture is shown in Fig. 5. The U-Net possesses an upsampling section which is more symmetric with the contracting/downsampling path, rather than the FCN’s single upsampling layer. Features from the downsampling path are concatenated with those from the upsampling path

Fig. 3 Voxel-based data with neighborhood analysis. A training matrix is constructed out of features and the ground truth class label corresponding to each voxel. The neighboring voxels are here concatenated onto the feature axis for each voxel providing spatial context

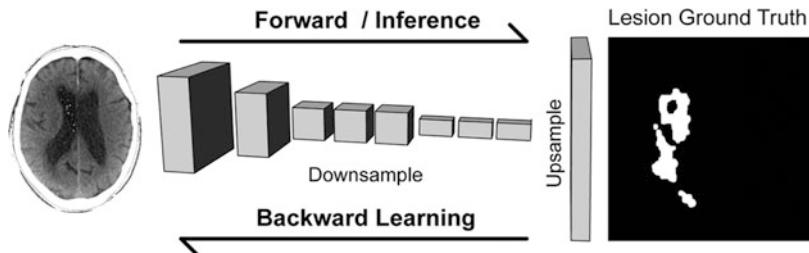

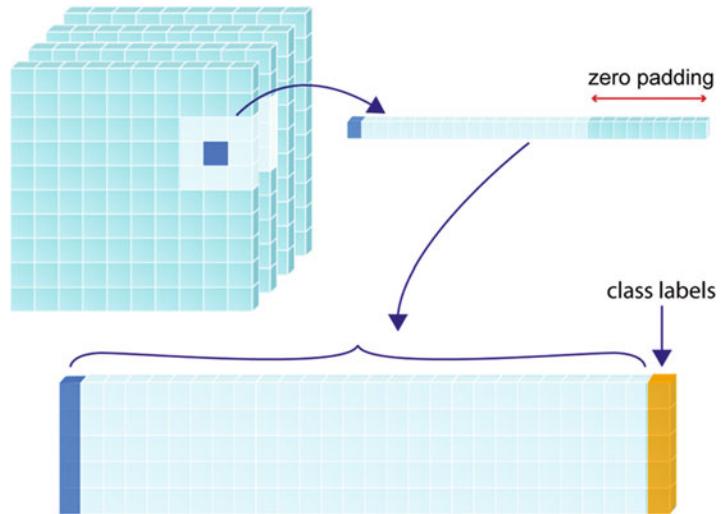

Fig. 4 A fully convolutional neural network (FCN). The entire image is forwarded through the network, allowing for *dense inference*. The process of downsampling as the images passes through convolutional layers provides a

high degree of spatial context. Features are automatically extracted over multiple scales. The image is then upsampled to provide a classification against the ground truth. Feature hierarchy is determined via back propagation

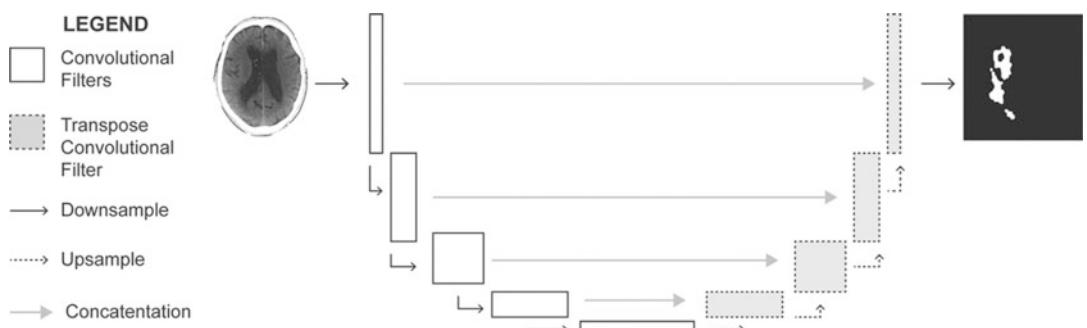

Fig. 5 The U-Net builds of the architecture of the FCN. The contracting network is supplemented by additional convolution layers, where the downsampling operators are replaced with upsampling operators, creating a symmetric U-shape. The resolution of the output is increased as

a consequence. In addition, high-resolution features from the downsampling path are added to the upsampled path, providing a more precise output. These modifications allow the U-Net to be trained by very few images

to give a high resolution and structured output. Variations on U-Net continue to be developed for the segmentation of both hemorrhagic and ischemic stroke (e.g., [30]).

Dense inference using whole images is challenging due to the computational expense. As an alternative, FCNs can be adapted to patches. Figure 6 illustrates a multiscale 3D CNN which uses two convolutional pathways, simplified from [31]. One pathway takes as its input a patch at normal resolution, and the other a larger patch at a lower resolution. Both are centered on the same image location. These two parallel convolutional pathways (each 11 layers deep in [31]) are combined and passed through two full connected layers to allow for structure prediction.

Clot Detection

Automated clot detection in CTA can be approached in several ways. Using supervised ML, a CNN may be taught to recognize a clot using annotated training data. There is FDA-approved software that reports using CNNs to detect LVOs with a sensitivity of 96%, although the details of the methods are not available due to commercial interests [32]. This approach depends

on access to a large, high-quality dataset which often has been highly selected and is not likely representative of a typical image for accuracy.

Template matching may also be of benefit to clot detection [33]. However, a CTA template relies on a high volume of high-quality images to create a generalized view of cerebral vasculature, and so this approach has a similar need for a large, high-quality dataset. It would also have difficulties due to anatomical variants that exist in brain vasculature. For example, the division of the MCA is variable after the horizontal (M1) segment, with 22% of cases branches into more than two divisions rather than a bifurcation. MCA duplication is another anatomical variant, seen in approximately 1.5% of the population [34, 35]. Nonetheless, the use of a template would allow for the automated identification of the occluded vessel by name. Stroke location together with lesion volume rather than lesion volume alone is a better predictor of functional outcome [36]. Treatment decision may be impacted if a clot lies in a region of the brain such that an infarction there would result in considerable loss of function. Small strokes in eloquent areas such as the brainstem can induce sever

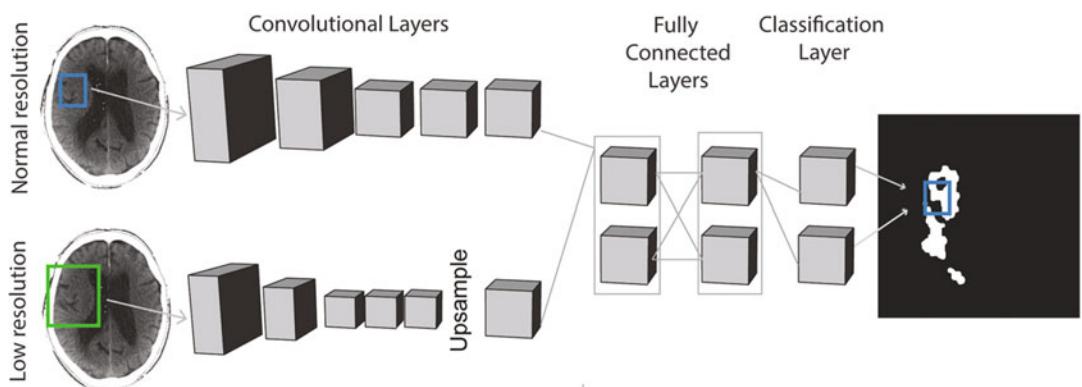

Fig. 6 3D CNN with two multiscale convolutional pathways, simplified from [31]. Using entire images as with Figs. 5 and 6 introduces issues of class imbalance and carries computational expense. This architecture adapts dense inference to patches which are randomly sampled into a training batch. To include spatial context, an additional lower-resolution patch (centered on the same image

location) is forwarded through a parallel channel. Both channels undergo a series of convolutional filters for automated feature extraction. The lower-resolution channel is upsampled to match the higher resolution. Both channels are then combined in full connected layers for structured prediction. Finally, a single classification layer provides the output

deficits comparable to those associated with a large hemispheric stroke [37].

Prediction

As stroke progresses, brain tissue that is ischemic may evolve to become infarcted and irreversibly damaged. As the volume of ischemic tissue increases, so too does the breakdown of the blood-brain barrier which increases the likelihood of hemorrhage after reperfusion. Treatment decisions may therefore be framed as a matter of risk over reward and should be made individually based on the characteristics of each patient. In Australia, only 10% of stroke patients receive IV treatment, partly due to many patients arriving at stroke centers outside the 4.5 h treatment window [38]. Therefore, there is incentive to develop AI algorithms that predict the outcome of clinical decision for individual patients so that patients can be effectively selected for treatment.

Imaging Outcomes

The volume and location of an infarction is correlated with patient outcomes and thus predicting infarct core growth can be key in clinical decision-making [39]. Penumbra imaging such as CTP provides an estimate of core growth under the assumption that the penumbra will go on to infarct if blood flow is not restored. The volumetric difference between core and penumbra, defined as the *mismatch*, is the therapeutic target and therefore drives clinical decision-making.

Although CTP imaging has been successful in selecting patients for treatment that would otherwise go untreated under the current standard of care, the therapeutic target is estimated under the assumption that treatment is provided without delay. In reality, patients may have to be transported to a treatment center before undergoing reperfusion therapy, and delays may occur within a hospital setting as well. This may lead to the growth of the infarct core, altering the core/penumbra ratio. Therefore, to have robust prediction for final infarct core, the impact of time delays should be modeled. However, infarct growth over time cannot be modeled based on a baseline

perfusion lesion alone as characteristics such as age and sex impact disease progression [22]. Additionally, fluctuations in collateral flow are known to occur, and failure of collaterals is itself associated with core growth, establishing a complex nonlinear relationship between time and infarct core growth [16, 40].

The idea of patient selection based on mismatch is also predicated on the assumption that reperfusion therapy will result in full recanalization of the affected vessels. However, treatment can also result in degrees of success [41]. Singular events such as hemorrhagic transformation may also result from treatment. There may be higher-order interactions (more than two) between characteristics that are predictive of treatment outcome which are not yet known. These complexities must be accounted for to provide robust core prediction.

It has already been established that DL can provide a more robust means of segmenting the ischemic core than with univariate thresholding. Another vital contribution of DL to stroke research is the ability to automatically examine and model complex nonlinear relationships and higher-order interactions [42, 43]. This lies in contrast to conventional statistical models, the vast majority of which rely on linear interactions. ML systems that are based on linear models, such as logistic regression, may also be too simple to predict lesion outcome [44]. The design of statistical models is also dependent on the perspective of the user, which is an obstacle if one wishes to advance beyond their understanding of a system [45]. The hidden layers of a DL network, and a well-chosen activation function (the function which determines the output of each layer) can trigger the extraction of latent (hidden) features. Complex interactions among latent features of a system can be explored to predict tissue fate.

Multiscale 3D CNNs, similar to the diagram shown in Fig. 6, can be adapted from lesion segmentation tasks to formulate lesion outcome prediction models. The dual-channel architecture described by [31] can be expanded to include additional channels for patient or clinical data that is relevant to the predicted outcome such as age, sex, time to treatment, and degree of

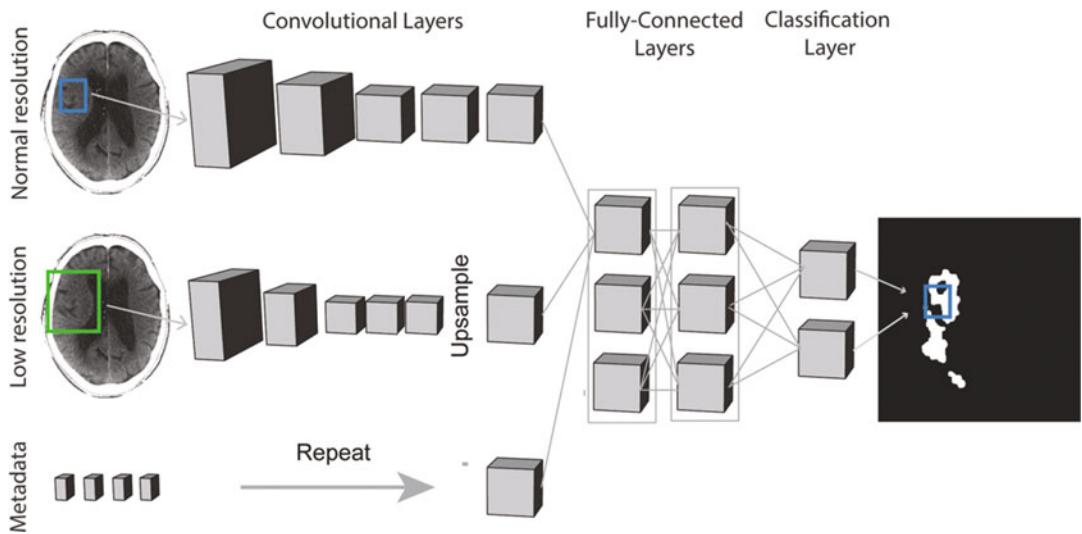

Fig. 7 Dual channel architecture (simplified in Fig. 6) may be expanded to include additional channels. Here, a third channel inputs metadata, which is repeated in an array to match the size of the normal resolution patch. All feature

channels are concatenated along the same axis and passed through fully connected layers for structured prediction. Simplified from [41], who include time and treatment success as predictors of outcome

recanalization [41]. Figure 7 shows a simplified version of the multichannel architecture described by [41].

Clinical Outcomes

While lesion properties may be associated with clinical outcomes, it is not necessarily so. The relationship between structure and function is impacted by elements beyond lesion characteristics, such as the existence of previous infarcts and white matter hyperintensities [46]. Age and stroke severity, measured by the National Institutes of Health Stroke Scale (NIHSS) score, along with other clinical variables, have significant impact of post-stroke outcomes as well [47]. Therefore, as most stroke trials use long-term functional outcomes as the primary end point, it may be suitable to directly predict a functional outcome rather than final infarct [37].

One such outcome is the modified Rankin Scale (mRS), a clinician-reported descriptor of global disability. The mRS is used often in clinical trials due to its accepted inter-rater reliability and straightforward application [48]. Briefly: mRS ranges from 0–6, where 0 is no impairment, 5 is severe disability requiring constant care; 6 is death. The mRS at 90 days after stroke is commonly used

to parameterize clinical outcome. Many AI algorithms developed to predict clinical outcome of stroke use a binarized mRS as ground truth, e.g., where $mRS < 2$ may denote a good outcome.

There are various scoring systems—based traditional statistical analysis which have been adopted by medical communities to predict the clinical outcome of acute ischemic stroke. The Totalled Health Risks in Vascular Events (THRIVE) score uses preadmission information to predict clinical outcome on a nine-point scale. It is designed to help clinicians understand a patient's chance of a good outcome. The ten-point Houston Intra-Arterial Therapy (HIAT) score uses clinical variables as well as imaging variables to patient outcome as 90 days. HIAT includes the Alberta Stroke Program Early CT score (ASPECTS), a ten-point score designed to evaluate NCCT images of patients with MCA stroke. Both THRIVE and HIAT assume a linear relationship between variables and outcomes [49]. As mentioned earlier, subjective design is a disadvantage to statistical models such as THRIVE and HIAT and that high-level ML models can investigate interactions between feature that have not considered by the user. Further, these statistical scoring methods are fixed and are not designed to adapt to added

information. ML models, on the other hand, can continue to learn and improve predictions as data examples accumulate.

ML models can adapt the nuances of patient outcome by including more features and exploring interactions between them. The 2016 ISLES challenge focused on outcome prediction, tasking challengers to predict both the lesion *and* the follow-up mRS score using 35 training cases and approximately 40 testing cases. Variables used to formulate a prediction include the time since stroke (TSS, time between stroke onset and imaging), the time to treatment (TTT, time between imaging and treatment), and degree of recanalization, parameterized by the Thrombolysis in Cerebral Infarction (TICI) score. Two out of the top three model for predicting clinical outcome adopted random forest, a high-level ML technique also capable of modeling the relevant complex interactions [44]. RFs consist of an ensemble of randomly trained decision trees, designed to increase predictive accuracy and avoid overfitting. The decision trees are trained in parallel, thus RFs train very quickly. Although most used for classification, RFs can also be formulated for nonlinear regression based on multidimensional input features [50].

There are other clinical outcomes that an algorithm can be trained to predict, depending on the application of the algorithm. Examples of clinical outcomes that are relevant to clinical decision-making include hemorrhagic transformation or successful recanalization after thrombectomy or thrombolysis [51, 52]. For patients suffering from ICH, the ability to estimate the risk of hemorrhagic expansion is valuable when selecting patients for surgical interventions. The methods that have been discussed may be capable of modeling the complex interactions between variables that lead to these outcomes and providing a prediction. There is ongoing development of techniques to predict stroke outcomes.

Integration

It has been mentioned several times already that the relevance of these algorithms will depend on the way they can be integrated into the stroke care

continuum and patient pathway. Technology has already been integrated into the stroke care workflow via the introduction of Telestroke. Rapid and reliable diagnosis can be delivered via Telestroke through remote consultation with highly trained clinicians [12]. In addition, mobile stroke units (MSUs) are being deployed in various countries throughout the world [53, 54]. These units update and equip patient transport vehicles with the tools necessary to assess for stroke, including imaging tools. Patients can therefore be provided with pre-hospital stroke care and thrombolysis.

These advances are especially relevant to areas that do not lie within proximity to stroke treatment center. Moreover, there is a growing shortfall in neurologists that is expected to rise and so there may be a growing percentage of the population that does not have access to expert stroke assessment [12]. Ageing populations will also contribute to a higher rate of stroke occurrence. Therefore, it is highly relevant to develop and optimize automated diagnostic and predictive AI algorithm so that they can be integrated into the stroke care workflow.

There is also opportunity for AI integration to assist in centers that already provide specialized stroke care. Even in stroke centers, communication remains a burden to physicians. However, with a messaging system that is integrated across all stages of patient processing—advanced emergency care, patient transportation, emergency department, and finally stroke treatment center—physicians can be alerted in advance of an incoming patient. Patient information can be collected and sent by the same messaging system. If the patient has existing electronic medical records, this additional information can be made available as well. Historical and pre-admission data, MSU imaging, and additional information such as the estimated transport time may be used by AI to assist in diagnosis and determine outcome prediction [12].

Currently, AI is already deployed clinically into Telestroke in a triage system [32]. There, all patients with suspected stroke will have their details reviewed by a neurologist. However, if the clinical and/or imaging data of a patient is first passed through an AI algorithm, their place in line can be updated based on the results of the

algorithms. For example, a positive result for a suspected LVO will place a patient ahead of others which have returned a negative result. This process has been shown, in a limited study, to reduce patient processing time.

Challenges for AI in Stroke Medicine

The Black Box Problem

A great barrier in the application of AI is its interpretability, or the degree to which the internal mechanics of a machine can be understood. The deployment of AI often invokes black box toolkits—whereby the user applies an input to retrieve an output—which is not problematic provided the algorithms in use are highly interpretable, such as decision trees or logistic regression. Neural networks, on the other hand, have a problem with interpretability. A deep neural network has a complex hidden structure such that it may be difficult to understand and interpret the internal processes and explain why a decision was made. An associated problem for AI is *explainability* which is the ability to explain to a human audience what is going on. When it comes to AI in stroke, this is troubling on two fronts.

First, there is the issue of trust. For AI processes involved in decision assistance or outcome prediction, it does not seem feasible or ethical for clinicians to rely on algorithms which have processes that are mysterious to them. This may not be a problem for AI algorithms that assist in or automated of processes that would otherwise remain as time-costly and labor-intensive work for radiologists or neurologists (e.g., denoising and segmentation). In those cases, the decision-making of clinicians is expedited. This is highly valuable in the time-pressured environment of acute stroke medicine and allows for more time with the patient and their family, to consider complex or delicate aspects of the decision-making process that are not captured by AI (e.g., cultural and financial). However, for predicting outcome and aiding in decision-making, doctors and medical boards may remain skeptical.

Secondly, there is the matter of legal responsibility if uninterpretable AI generates an incorrect

output. If one cannot understand the hidden processes of a neural network, one cannot predict how the AI will continue to develop as it learns and whether that would lead to an unexpected result. In fact, it is more or less inevitable that if AI is deployed clinically, and continues to learn with more data, it will eventually produce a decision that is inexplicable. It is important to understand how to manage that inevitability and more AI-based tools are deployed.

There are solutions to both issues of explainability and interpretability. For the former it is important that strong collaborative ties are made between developers and the eventual users of algorithms. Poorly communicated ideas result in skepticism and dubiousness. For the latter, it may be necessary for developers to add steps in the deployment of AI that render the process more transparent to both the developers and toward the users once they have been properly visualized and explained. There are many developing solutions to DL interpretability [22, 55].

Evaluation of AI Models

As it stands, there is no standard in the use of accuracy metrics to report on the performance of an AI model. Receiver-operating characteristics (ROC) are widely used to evaluate binary classification systems in medical research and are therefore often applied to evaluate the performance of such AI models in medicine. Illustrated in Fig. 8, the ROC curve plots true positive rate (TPR; also called *sensitivity*) against false positive rate (FPR; *specificity* is $1 - FPR$), and the area under the curve (ROC-AUC) often represents the overall performance of a model. The success of otherwise of the derived model in predicting a binary outcome for a new patient defines the ROC-AUC.

The interpretation of ROC performance metrics for ML models is subject to some nuances and so can be highly subjective. For instance, a binary classification, while convenient for constructing a model, may be artificial and impractical. As discussed earlier, predictive models may define a binary outcome as ground truth, such as with the binarized mRS. However, it may not be useful to know that a patient is at risk of an outcome

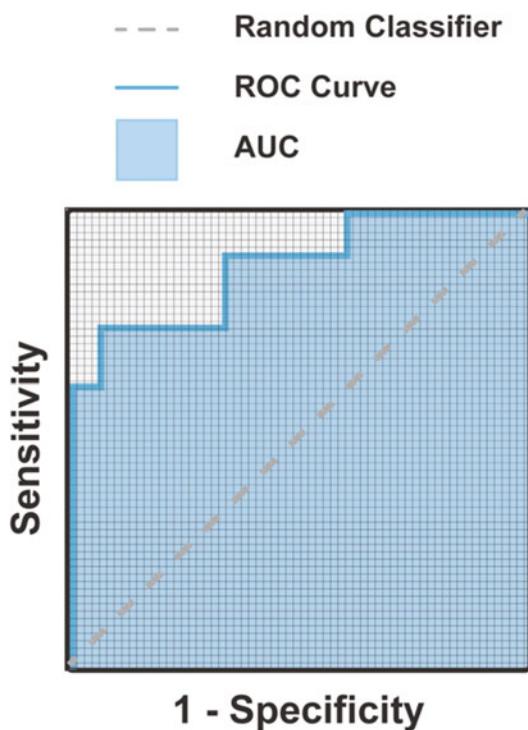

Fig. 8 Receiver operating characteristic (ROC) curve. For a binary classifier, the area under the ROC curve (AUC) determines the overall performance of the model. The broken line represents the ROC curve of a random classifier

encompassing both moderate disability (mRS = 3) and death (mRS = 6). Instead of classifying patients into simple categories to simplify a model and increase predictive values, it is more clinically relevant to precision medicine to predict a continuum of risk [56]. Similarly, diagnostic or predictive models are more applicable to clinical medicine if they can identify a multitude of classes, rather than being limited to making only one distinction [57]. Binary outcomes are not necessarily a requirement of ML models. Discriminative models can provide a multiclass rather than a binary output via *one-hot encoding* (Table 1); however, again, there is no standard in how to represent the accuracy of a model capable of predicting multiple outputs.

When interpreting the reported accuracy, the training cohort should also be considered carefully. The accuracy of a model may differ depending on characteristics of the study

population. Many AI algorithms are trained on limited or highly selective datasets, such as patients with confirmed LVOs, which constitute only 14–16% of all stroke cases. When applied to a more general population, or under different conditions, the model may not perform with the same accuracy. A model that performs with high accuracy but only under certain unrealistic conditions is of little relevance to clinical practice [56].

Related to training population is the particular matter of class imbalance within classification training data. Generally, for a classification problem, training data should have close to equal class representation so that the algorithm does not favor the majority class and learns to be accurate in its prediction of the minority class as well. However, medical image segmentation problems are typically highly unbalanced because the frequency of healthy pixel greatly outweighs that of unhealthy pixels. There are numerous solutions to this problem, such as patch sampling from each class or weighting the loss associated with the minority class [26, 31]. However, there are no clear guidelines with how to manage class imbalance.

Nevertheless, for scenarios with a large class imbalance where there are excessive number of correctly classified background voxels, the Dice similarity coefficient (DCS), Jaccard index (JI), or Hausdorff distance (HD) are popular as accuracy metrics to replace the ROC-AUC. DCS and JI are calculated based on the amount of overlap between the predicted and measured areas, while HD computes the maximal displacement between the two areas. Figure 9 illustrates the difference between DCS and JI. These reflect both size and location agreement and so are better reflective of the quality of the prediction than a pixel-wise ROC-AUC accuracy. However, these metrics are also highly dependent on the test set. Without standardized reporting parameters, it is difficult to ascertain the excellence of AI models [58].

Data Registries

There are many AI algorithms that depend on the existence of large high-quality, annotated, unbiased datasets. As mentioned in section “Evaluation of

Table 1 An illustration of one-hot encoding for four classes. Each class is translated into a binary string

Class	Codes			
1	1	0	0	0
2	0	1	0	0
3	0	0	1	0
4	0	0	0	1

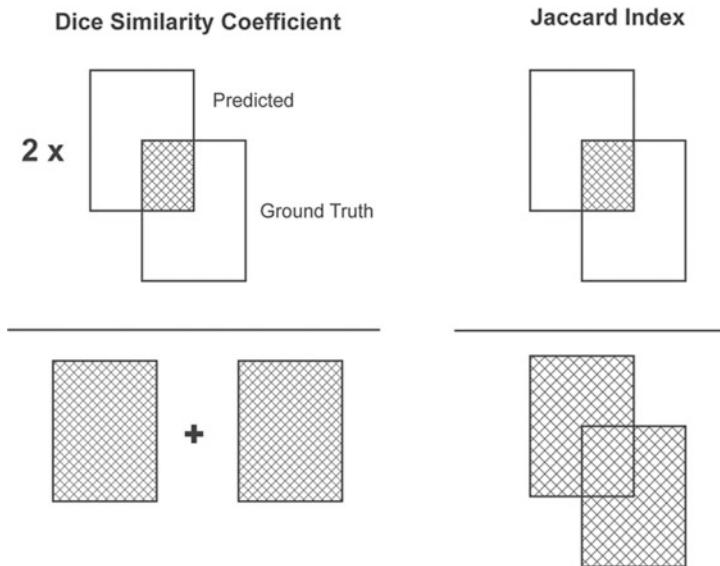

Fig. 9 The Dice similarity coefficient (DSC) and Jaccard index (JI). Both are more suitable methods to evaluate image segmentation problem as they do not weigh negative background pixels in performance evaluation. Whereas JI is Intersection over the Union (IoU) of the two areas, DSC

is twice the Intersection over the sum of the two areas. A perfect prediction gives $\text{DSC} = \text{JI} = 1$. JI is more sensitive to changes in shape. While they are positively correlated, JI penalizes incorrectly classified pixels more than DSC

AI Models,” if a dataset is too small and lacks diversity, the model may suffer from overfitting. To make a model robust, it is important to develop data sources that are as diverse as possible. However, image acquisition practices and data protocols vary among institutions, and within institutions over time due to practice changes, making it difficult to combine data sources [58]. Organizations such as ISLES supply publicly available annotated datasets for developing and evaluating AI algorithms for stroke but growing and maintaining these datasets to reflect practice changes is difficult. To do so, large numbers of images need to be scrutinized by experts, which is burdensome.

However, when discussing the need for large, readily available datasets, it is necessary to also discuss issues of data security and patient privacy.

It is seen in other areas of data-driven AI that the high quality of predictive algorithms tends to come at the cost of privacy. Because the health care industry is implied to face the highest number of data breaches among all sectors, it can be assumed that as patient data is used more frequently, privacy will become a significant issue [59]. Considerable steps will need to be taken to protect data from both external cyberattacks and internal breaches.

There are methods to adapt to limited data registries. Mentioned previously, the U-Net provides a framework that adapts to fewer training examples. Another interesting solution is the use of generative adversarial networks (GANs), which are capable of generating or augmenting data that can be used to supplement training

examples [60]. Generative models are a form of unsupervised ML, designed to automatically learn characteristics of input data such that it can produce new examples of data. By combining this with a discriminator, whose job is to classify the generated examples as “real” or “fake,” GANs can produce plausible examples of data. GANs are an exciting field which promises wide-ranging applications.

Finally, there exists a fundamental challenge in using data registries to develop predictive outcome model. As discussed throughout this chapter, ML models are structured to identify the predictors of an outcome. However, even when they are highly interpretable, ML predictive models make no assumption about *causality*, and do not enable conclusions about causality to be determined without strong assumptions [61]. To establish causality, it is necessary to estimate what would happen under another set of conditions, e.g., if a different decision was made [62]. Randomized controlled trials are designed to allow for causal inference to be established by randomizing decision-making. Both the causal pathway where the decision is made and the pathway where the decision is not made are investigated. Data registries, on the other hand, act as evidence of medical decision-making that is not randomized but based on underlying factors that may or may not be reflected in the data that is available. (For several reasons, including privacy, information may be withheld or omitted from a data registry [63]).

Discussed here, one of the strengths of high-level ML models such as RF and CNNs over traditional statistical frameworks is the ability to extract latent features not subject to user input which predict an outcome. This stands at odds with a causal model-building process, which is driven by *a priori* theory, investigating particular causal pathways that are of interest. One cannot infer causality from a model if it has not been built on an explicit causal framework. Therefore, the purpose and context of a predictive model should be specified from the outset so that it can be implemented for decision assistance.

Conclusion

The diagnostic complexities of acute ischemic stroke favor solutions that are powered by artificial intelligence. However, there are some challenges that should be overcome so that AI can be deployed effectively into clinical environment. The AI applications described here provide a service that would require extensive training when administered by a clinician. The standard to which AI is to be held will heavily impact whether these challenges are met and overcome, and it will be the role of regulatory bodies to address these challenges by enforcing standards.

Abstract

Artificial intelligence (AI), in particular deep learning (DL), has gained significant interest recently from healthcare systems. DL has been widely applied to detect and classify major diseases in ophthalmology, including diabetic retinopathy (DR), age-related macular degeneration (AMD), glaucoma, and retinopathy of prematurity based on fundus photographs; cataract and anterior segment diseases, glaucoma, and retinal diseases based on optical coherence tomography (OCT) scans; and glaucoma progression based on visual fields. The substantial progress of AI in ophthalmology has involved the identification of clear public health (e.g., DR screening) and clinical (e.g., prediction of the need to treat AMD) unmet needs, the targeted development of the AI algorithms using both retrospective and prospective clinical and imaging data, and designing the application interface for clinical deployment. In ophthalmology, there has also been significant experience of applying AI algorithms in “real-world” clinical situations, as well as the submission and approval by governmental regulatory agencies (e.g., Food and Drug Administration). Future research is warranted to address not only technical issues (e.g., explainability of the “black box”) but also a range of nontechnical challenges, such as increasing the awareness and acceptance of physician and patient, issues relating to global collaboration and data sharing, medical ethics, financial and reimbursement systems, and

integration of AI algorithms in clinical settings with diverse electronic health records.

Introduction

Artificial intelligence (AI) has gained remarkable traction in different segments of society, including healthcare, in recent years. This is made possible with the convergence of several interrelated technologies, such as availability of graphic processing units (GPUs), advances in computer science and mathematical models, and the increasing access to big datasets [1]. In particular, deep learning (DL), a subtype of AI, utilizing multiple processing layers to learn representation of data with multiple levels of abstraction, has shown substantial promise [2]. In some areas, DL has shown performance significantly superior to humans [3, 4] and thus DL is now widely adopted in image recognition, speech recognition, and natural language processing [1].

In ophthalmology, there have been three major areas of progress in which AI and DL algorithms

have been developed successfully. First, DL systems have been shown to accurately detect diabetic retinopathy (DR), [3–6] glaucoma, [5, 7] age-related macular degeneration (AMD), [5, 8, 9] retinopathy of prematurity (ROP), [10] predict refractive error, [11] and papilledema [12] from digital fundus photographs. Systemic diseases such as risk factors of cardiovascular disease have also been accurately predicted from fundus photographs [13, 14]. Second, there is major progress in applying DL to another imaging modality, the optical coherence tomography (OCT) scans, to detect subgroups of retinal conditions such as choroidal neovascularization (CNV) in neovascular (“wet”) AMD and diabetic macular edema (DME) [2, 15, 16]. Third, there are cases of DL algorithms used in “real world,” such as in DR screening programs and approval by regulatory agencies (e.g., FDA) in using AI for clinical care. Nevertheless, significant challenges remain. Future research is important not only to address the technical issues (e.g., explainability of the AI “black box”), but also a range of nontechnical challenges in increasing physicians’ and patients’ awareness and acceptance, and issues relating to global collaboration and data sharing, medical ethics, financial and reimbursement systems, and integration of AI algorithms in clinical settings with diverse electronic health records. This chapter provides an overview of the developments of AI in ophthalmology, highlighting major progress and future directions, including global guidelines.

Essential Concepts and Components in an AI System

AI research can be broadly divided into the clinical and technical components (Table 1). First, it is important to understand the specific clinical or research question, and then apply the appropriate AI technical methodologies to address the question [17]. For example, most AI systems in medicine have been designed to address a public health, clinical, or healthcare systems gap. AI could improve access to screening (i.e., addressing public health need), improve the diagnostic accuracy of detecting a disease or predicting the outcome of a new treatment (i.e.,

clinical needs), or relieve the shortages of specific healthcare manpower (i.e., healthcare system needs).

There are a number of factors affecting how an AI system is built. Clinical datasets and technical architectures are the two core components required to build an AI system. For clinical datasets, it is important to pay attention to the image-related factors such as types of devices (fundus photographs or OCTs), image quality, number of fields, width of field, color vs monochromaticity, classifications, reference standard, and number and experience of graders. For technical architecture, the operational flow diagram, types of input data, convolutional neural network (CNN), pre-image processing steps, and classification output and visualization map (Figs. 1 and 2) are important components.

To ascertain the diagnostic performance of an AI system, the operating threshold needs to be fixed using the training datasets. For the testing datasets, it is important to perform the power calculation by taking into account alpha and beta errors, confidence intervals, and prevalence rate to ensure that the sample size required is sufficient to confidently differentiate positive versus negative cases. The operating threshold is determined based on the universally accepted standard, tailored to the local population need. Using the same operating threshold determined from the training datasets, the area under the receivers’ operating curve (AUC), sensitivity, and specificity (with 95% confidence interval) can be determined.

Application of AI and DL Algorithms in Ophthalmology Using Different Devices

Retinal Fundus Photographs

Diabetic Retinopathy

DR is a major public health challenge [18, 19]. One-third of people suffering from diabetes is projected to develop DR, resulting in an estimated 250 million patients with DR by 2035 [20]. The early detection of DR associated with timely treatment has been largely shown to have

Table 1 The important components of an artificial intelligence system for ophthalmology [143]

Introduction	Validity of the research question Comprehensive literature search of similar technologies related to the specific disease Clinical unmet need “Value-add” of the proposed AI system
Methods	
Core components	Clinical datasets and technical network
Clinical datasets	Division of training, validation, and testing datasets
Dataset descriptions	1. Number of images, eyes, and patients 2. Inclusion and exclusion criteria for these patients 3. Study design (prospective vs retrospective) and patients demographics (optional) 4. Recruitment methods (consecutive and randomized) and sites 5. Prevalence of positive vs control cases 6. Types input data – clinical data, imaging test, or others
Technical methodology	1. Technical approach (deep learning, machine learning, or statistical approach) 2. Types of neural network 3. Operational flow of an AI system
Assessment of the diagnostic performance	1. Power calculation of the testing datasets 2. Receivers' operating curve (AUC), sensitivity, and specificity (with 95% confidence interval) 3. Accuracy, positive predictive, or negative predictive value 4. Cohen's kappa
Reference standard	Numbers and experience of graders (e.g., graders from reading centers, retinal specialists, etc.) Disease classification system
Statistical analysis and results (all with 95% CI)	1. Area under receiver's operating curve (AUC) 2. Sensitivity and specificity 3. Accuracy, positive predictive value, and negative predictive value 4. Cohen Kappa 5. Mean absolute error (continuous variables) 6. Dice coefficients (for segmentation tasks)
Discussion	1. Clinical application of the AI solution
Clinical translational value	2. Limitation of the AI systems 3. Potential deployment methods

the potential to prevent vision loss through population screening [18]. Nonetheless, the implementation of DR screening programs faces challenges related to long-term financial sustainability, as well as availability of experienced human assessors [18]. To tackle this growing crisis, a DR screening tool capable of dealing with high workload in a quick manner is critical to overcoming the limitations of DR screening programs [21]. Many computer-aided algorithms for automated detection of DR from retinal fundus images have been explored, representing potential cost-

effective alternatives to DR screening if coupled with telemedicine [22]. However, diagnostic performance comparable to humans have been reached only with DL technology [1].

Many studies using DL technology have shown robust diagnostic performance in detecting referable DR, defined as worse than mild non-proliferative DR (Table 2). For DL systems, Abramoff et al., [23] Gulshan et al., [4] Ting et al., [5] and others [6, 24, 25] have reported AUC of >0.90, and sensitivity and specificity of >90% in detecting referable DR in multiethnic

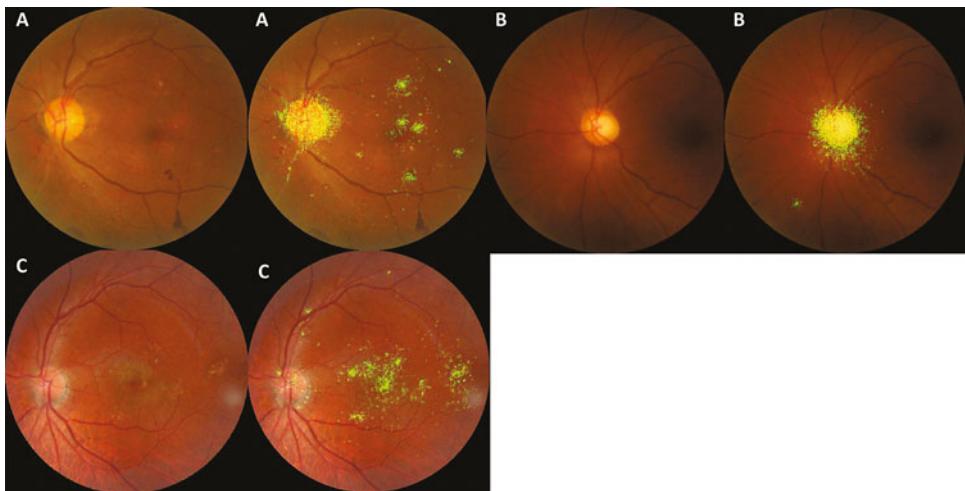

Fig. 1 Visualization techniques on fundus photos: A) proliferative DR; B) glaucoma; and C) advanced age-related macular degeneration

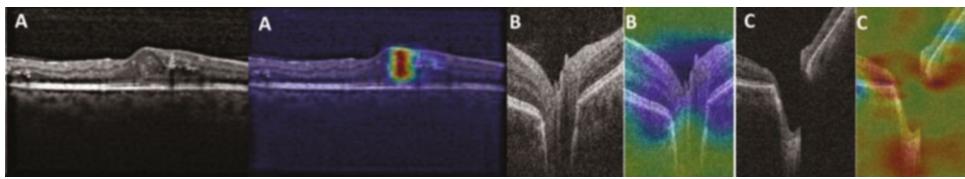

Fig. 2 Visualization techniques on OCT: A) fovea-involving DME with cystoid macular edema and hard exudates on OCT; B) normal OCT nerve fiber layer; and C) OCT nerve fiber layer with advanced glaucoma

populations with diabetes, using publicly available retrospective datasets and numerous clinic-based and population-based datasets. Following this, Abramoff et al. conducted a preregistered prospective clinical trial on a DL system, achieving 87% sensitivity and 90% specificity in detecting referable DR (worse than any DR) and subsequently obtaining US FDA approval [26]. In Australia, Keel et al. [27] also showed excellent result on a prospective AI study for DR screening in two urban endocrinology outpatient services, not only with a good diagnostic performance – 92% sensitivity and 94% specificity in detecting referable DR, but also well received by the patients (96% of participants were satisfied with the AI algorithm). Real-world performance of a DL system on detection of referable DR in prospective datasets was examined recently by Bhuiyan et al. Using nonmydriatic retinal images collected from 974 patients with diabetes in

primary setting, the DL screening system achieved a sensitivity of 82.6% and a specificity of 93.7%, which meet the requirement of FDA approval of a screening program. This DL system was also integrated with a telemedicine platform, capable of generating a report on the referral decision automatically within one minute [28]. Besides detection of referable DR, DL algorithm has been utilized to predict OCT-derived DME from two-dimensional (2D) fundus photographs with an AUC of 0.89, sensitivity of 85%, and specificity of 80%, whereas retinal specialists had similar sensitivity but only half of the specificity [29].

At the global eye health setting where screening expertise is limited (e.g., India and Thailand), DL tools were shown to be a great alternative, or even more superior, to human graders to screen for DR. In Thailand, Ruamviboonsuk et al. reported promising sensitivity (97%) and

Table 2 The summary of all the artificial intelligence systems with the respective training datasets and diagnostic performance for different retinal diseases using fundus photographs

AI systems	Year	Disease	Imaging modality	Race	Clinical validation	Independent testing datasets (retinal images)	AUC	Sensitivity	Specificity

specificity (96%) of the DL system in a national screening program, with AUC of 0.99 [30]. In India, the DL system achieved a sensitivity and specificity of 89% and 92%, respectively (AUC of 0.96), in Aravind Eye Hospital, and 92% and 95%, respectively (AUC of 0.98), in Sankara Nethralaya Hospital [31]. In Africa, Bellemo et al. reported promising sensitivity (92%) and specificity (89%), with AUC of 0.97 for the diagnostic performance of a DL system in Zambia, a low middle-income country with the ratio of 3 ophthalmologists to 1000,000 population [32]. Although DL technology may have a great potential to help improve the access to DR screening for the under-resourced countries, the supporting infrastructure and availability of the tertiary care services are particularly crucial to support such technology.

For epidemiology, a DL system was also reported to accurately estimate the prevalence of DR and related systemic cardiovascular risk factors, as compared to the human graders, using a much shorter time frame (1 month vs 2 years) [14]. These findings suggest the potential role of DL systems to serve as the grading tool for many large-scale epidemiology or population-based studies. In addition, DL has been applied for the prediction of DR progression. Using color fundus photographs from 575,431 eyes with no DR, Bora et al. from Google Health created a DL system to predict the progression to mild or worse DR within 2 years, which achieved AUC of 0.79 and 0.78 on internal validation dataset for the three-field and one-field model, respectively. This DL system retained high prognostic value after adjusting for available risk factors, such as the HbA1c level, years with diabetes, and insulin use [33].

Of all the AI algorithms in ophthalmology or medical fields, the DL systems for DR is probably at the closest stage for clinical translation. To achieve such success, it is critical to build a surrounding ecosystem to support the deployment of DR systems in the real-world practice, including IT systems and integration with the electronic health records, medical ethics, safety regulations, financial and reimbursement systems, tailoring to the respective healthcare system regulations, medical expertise, and patients' demographics.

Glaucoma

Glaucoma is a chronic progressive optic neuropathy with characteristic visual field (VF) loss associated with intraocular pressure elevation, leading to irreversible vision loss without early diagnosis and prompt treatment [34, 35]. The global prevalence of glaucoma is 3.4% for people aged 40–80 and it is projected to be approximately 112 million by 2040 [36]. Therefore, screening and monitoring for glaucoma are of paramount importance and AI applications might play a pivotal role in diagnosis and surveillance of this condition. The DL systems are broadly divided into the fundus photos, OCTs, and Humphrey VF-based algorithms in detecting glaucoma suspect, glaucoma, or glaucoma progression. This section will focus on the fundus-based glaucoma AI algorithms.

For glaucoma suspect detection, two DL systems, tested on >10,000 retinal images, reported to have AUC of >0.90, sensitivity >90%, and specificity >80%, [5, 7] although the definition of cup-to-disc ratio was slightly different between the two studies (Li et al. -0.7 or worse; Ting et al. 0.8 or worse). Tested with three independent datasets, the DL algorithm developed by Phene et al. using fundus images alone achieved AUC for referable glaucoma of 0.945, 0.855, and 0.881 in dataset A, B, and C, respectively [37]. The decrease in performance with datasets B and C was attributed to the differences in reference standard, in which the graders had access to additional clinical data, such as a full glaucoma workup. Using smaller testing datasets (<500 fundus photos), Shibata et al., [38] Masumoto et al., [39] and Ko et al. [40] reported AUC >0.85 in confirming the diagnosis of glaucoma, using the diagnosis made on clinical examination and VF.

The development of glaucoma AI algorithms is often challenged by the inconsistent ground truth, and lack of consensus on the definition of glaucoma suspect or definite glaucoma. In addition, the diagnosis of glaucoma requires not only multimodal imaging, but also time sequence to confirm the glaucoma progression. Thus, it is hard to conduct a head-to-head comparison between different glaucoma AI algorithms, as each of them may be built to answer different research questions. While the optic disc fundus imaging of the retina is the least expensive imaging modality to

conduct structural assessment of the optic nerve, glaucoma detection consists of combined structural and functional assessments, using more sophisticated imaging devices, such as OCT [41–43]. Further details will be discussed in the latter section.

Age-Related Macular Degeneration

By 2040, 288 million patients may have some forms of AMD and approximately 10% may be affected by intermediate AMD or worse [44]. With aging population, DL algorithms could be deployed as alternative tools to aid diagnosis and disease surveillance, tackling the urgent clinical need to screen these patients for further evaluation in healthcare centers. Similar to DR and glaucoma, most DL algorithms have reported robust diagnostic performance in detecting AMD.

The majority of the AMD algorithms reported in the literature were developed using the Age-Related Eye Disease Study (AREDS) with different clinical questions, given that it is available to public request with the AREDS committee approval [45]. Using the best training model, Burlina et al. reported excellent diagnostic accuracy and AUC (both >90%) in detection of referable AMD (defined as intermediate AMD or worse based on AREDS classification), [8] and accuracy of >80% in estimating 5-year risk of developing advanced AMD [46]. Using different technical methods, Grassmann et al. [9] reported 100% sensitivity and 96.5% specificity in detecting late AMD, although the performance in detection of early AMD is suboptimal. Peng et al. [47] reported that the DL system could perform better than the retinal specialists to determine the AREDS grading (accuracy 67% vs 60%), and specific AMD lesions (e.g., large drusen and pigmentary abnormalities) (AUCs of 0.94 vs 0.93). Groups studying the automated detection of geographic atrophy (GA) also demonstrated high accuracy and noninferiority to human graders [48, 49]. Using multicenter datasets, Liefers et al. [49] developed a DL model for automatic segmentations of GA, which identified nine automatically calculated structural biomarkers being significantly correlated with GA growth rate.

Besides detection of AMD from fundus images, AI has been applied for predicting risk

of progression to late AMD. Using fundus photos and demographic data from over 1800 AREDS subjects, Bhuiyan et al. developed a logistic model tree machine learning (ML) algorithm to predict the risk of an individual with early or intermediate AMD progressing to late AMD within 1 or 2 years. By combining the AMD 12 level severity score and sociodemographic clinical data, the ML model could predict the risk of AMD progression with accuracy of 86.36%, sensitivity of 92.42%, specificity of 84.39% for 2-year incident late AMD, and similar performance for predicting the incidence of late AMD in 1 year [50].

At present, the application of fundus-based AMD algorithms is yet to penetrate the clinical space due to the following reasons. First, although the American Academy of Ophthalmology (AAO) guidelines recommend regular follow-up once every 2 years for patients with intermediate AMD or worse, not many countries worldwide are currently practicing this exercise, given the resultant of unnecessary referrals to the tertiary eye care settings. Second, there is no effective treatment to delay or prevent progression to advanced AMD, although various interventions were attempted (e.g., AREDS2 formulation and smoking cessation). Third, to accurately diagnose active choroidal neovascularization, it is more accurate to perform OCT scans for diagnosis and disease monitoring during the treatment course [15, 51, 52]. More details are discussed in the section under OCT AI algorithms.

Retinopathy of Prematurity

ROP is characterized by the growth of abnormal fibrovascular structures at the junction between vascularized and avascular peripheral retina. Globally, approximately 19 million children are estimated to suffer from visual impairment, [53] with ROP accounting for up to 18% of childhood blindness [54]. Given that ROP clinical examination can be technically challenging, many countries, unfortunately, do not have such expertise to perform ROP screening. In the USA, a DL system for ROP was developed using approximately 5500 Retcam retinal photographs collected over a 5-year period from eight US academic institutions for training and testing [10]. Compared to

the ROP clinical experts, the DL system demonstrated robust sensitivity (>90%) and specificity (>90%) in detection of plus and pre-plus diseases, [10] and excellent AUCs (>0.90) in detecting type 1 ROP and “clinically significant ROP” that warrant an urgent referral to a specialty center [55]. This DL system was further evaluated retrospectively using an operational ROP telemedicine program. With limited sample size (81 infants, 613 eye encounter images), Greenwald et al. reported that the AUC of the vascular severity score for the detection of referral-requiring ROP was 0.99, with 100% sensitivity and 90% specificity [56]. In New Zealand, using 6974 Retcam retinal images from infants, a DL algorithm was developed to detect plus disease with AUC of 0.993, sensitivity of 96.6%, and specificity of 98.0% [57].

Future research is of great value to test these ROP systems in different population, in order to increase the generalizability of such system. In the developed countries where there are established ROP services, the bar of having AI algorithms replacing clinicians in ROP screening may be reasonably high, provided that there are always potential occasions where the DL systems could misdiagnose or underdiagnose ROP cases that may carry clinical, medico-legal, and psychosocial implications. On the other hand, although the ROP DL systems are extremely useful in countries without existing ROP screening services, it may still be challenging to deploy such technically demanding system as the Retcam imaging. This, again, highlights the need of having a robust healthcare ecosystem to support the deployment of any AI algorithm in clinical care.

Papilledema and Optic Disc Abnormalities

Examination of the optic nerve head is an important component of the clinical examination when indicated, but general physicians and nonophthalmic specialists may lack confidence in using direct ophthalmoscopy, especially without pharmacologic pupillary dilation [58, 59]. Alternative use of nonmydriatic ocular fundus photography has been adapted in the emergency departments and outpatient clinics [58, 60,

61]. However, these fundus images need to be interpreted on-site by physicians or remotely by ophthalmologists via telemedicine, which may not be always feasible. Several groups have evaluated the performance of AI systems in detecting papilledema and optic disc abnormalities from fundus photographs. Using 15,846 fundus images from multiple ethnic groups in 11 countries, Milea et al. developed a DL classifier to discriminate papilledema from normal discs and other disc abnormalities (e.g., anterior ischemic and inflammatory optic neuropathies, optic atrophy), achieving AUC of 0.990, sensitivity of 93.5%, and specificity of 96.2% [12]. Similarly, the Brain and Optic nerve Study with Artificial Intelligence (BONSAI) DL system, which was developed with multiethnic and multicenter datasets, demonstrated similar or even superior performance in classifying optic disc appearance when comparing to neuro-ophthalmologists. For classification of papilledema, the BONSAI system achieved AUC of 0.96, sensitivity of 91.5%, and specificity of 94.3% [62]. Using a smaller dataset, Ahn et al. reported that the ML classifier could differentiate pseudopapilledema from normal discs and discs with other abnormalities with an accuracy of 95.89% and AUC of 0.992 [63]. Introducing these DL models to the routines in emergency departments and outpatient clinics does not replace human experts, instead it may facilitate effective triage and management of patients, in particular when experts are not available.

Systemic Diseases

Besides retinal diseases, a number of DL algorithms have been developed to detect systemic diseases from fundus photographs, with cardiovascular disease (CVD) being the mostly studied. CVD is a major cause of morbidity and mortality globally [64]. It is now recognized that microvascular pathology plays a key role in processes leading to the development of subclinical vascular disease and clinical CVD events [65–67]. In the past, physicians perform a fundus examination in patients with hypertension and follow classification system to determine the presence and severity of retinal vascular damage, such as retinal arteriolar narrowing, arteriovenous nicking, retinal

hemorrhages, and cotton-wool spots, as a mean to estimate CVD risk [68–73]. Together with left ventricular hypertrophy and renal impairment, most international hypertension management guidelines include the retinal vascular changes (or hypertensive retinopathy) as an indicator of target organ damage, and that its presence should be an indication for a more aggressive approach in managing these hypertensive patients [70–73].

Broadly speaking, there are three basic approaches to predicting systemic diseases from a retinal image (Table 3). First, DL algorithms could be applied for estimating systemic risk factors based on fundus photographs. Using two large databases (48,101 patients from the UK Biobank and 236,234 patients from EyePACS), Poplin et al. have developed DL models using retinal fundus images to predict multiple CVD risk factors simultaneously, including age, gender, smoking status, blood pressure, body mass index, HbA_{1c}, and major cardiac events [13]. The reported AUC of the DL model (AUC = 0.70) for predicting CVD events was comparable to that of the composite European SCORE risk calculator (AUC = 0.72). In a further validation using an Asian dataset, the performance of the DL models was similar [74]. A surprising finding from this study was the ability of the DL algorithm to accurately predict the gender of a patient from fundus image, with AUC of 0.97, and this has certainly generated widespread discussion among the ophthalmology community. In addition, Rim et al. evaluated 47 DL algorithms in predicting 47 systemic biomarkers based on fundus photographs, with use of 236,257 images from diverse population datasets. The DL systems were shown to quantify body composition indices (muscle mass, height, and bodyweight) and creatinine from fundus photos alone, while 37 biomarkers could not be predicted well from retinal photographs ($R^2 \leq 0.14$ across all external test sets) [75].

Second, DL models have been developed for the purpose of replacing another biomarker with findings from retinal images. Cheung et al. evaluated the correlation between retinal-vessel caliber and CVD risk factors, using multiethnic multi-country datasets of over 70,000 images to develop a DL system, the Singapore I vessel assessment-

DL system (SIVA-DLS). [76] High agreement was achieved by the SIVA-DLS and human graders in measuring central retinal artery equivalent (CRAE) and central retinal vein equivalent (CRVE), with overall interclass correlation coefficients of 0.82–0.95. Figure 3 demonstrates the prediction of retinal-vessel caliber by the SIVA-DLS. The model showed superior or comparable performance than expert graders in identifying the relationships between measurements of retinal-vessel caliber and CVD risk factors. Furthermore, the SIVA-DLS measured retinal-vessel caliber was associated with incident CVD events. Using 15,408 fundus images, Chang et al. built a DL model to predict carotid artery atherosclerosis, named deep-learning funduscopic atherosclerosis score (DL-FAS), with an AUC, sensitivity, and specificity of 0.713, 58.3%, and 89.1%, respectively. The DL-FAS was used as the main exposure to follow patients for the primary outcome of death. They found that participants with DL-FAS greater than 0.66 had higher risk of CVD deaths compared to those with DL-FAS less than 0.33 (hazard ratio: 8.33) [77]. To estimate coronary artery calcium score (CACS) from fundus photographs, Son et al. built a DL algorithm using 44,184 images, which could recognize subjects with CACS over 100 from those of no CAC, with an AUC of 0.823 for unilateral fundus images and 0.832 for bilateral ones. However, whether the CACS could predict clinical CVD events remains to be explored [78].

Finally, DL techniques could be used for detecting specific diseases based on fundus photographs, such as hypertension, hyperglycemia, dyslipidemia, anemia, and chronic kidney disease. With use of over 2000 vessel-segmented retinal photographs, Dai et al. developed a DL model to generate heat maps for predicting hypertension, with an AUC of 0.651, an accuracy of 60.94%, and a specificity of 51.54% [79]. Another DL framework built by Zhang et al. using 1222 fundus images was shown to predict hypertension, hyperglycemia, and dyslipidemia with an AUC of 0.766, 0.880, and 0.703, respectively [80]. Mitani et al. developed ML algorithms that could detect anemia from retinal fundus photographs alone with an AUC

Table 3 Three basic approaches to predicting systemic diseases from a retinal image and the relevant studies

1. AI-DL algorithms to estimate systemic risk factors from retinal fundus images							
AI systems	Year	Disease	Imaging modality	Race	Clinical validation	Independent testing datasets (retinal images)	Results

						AUC — — —

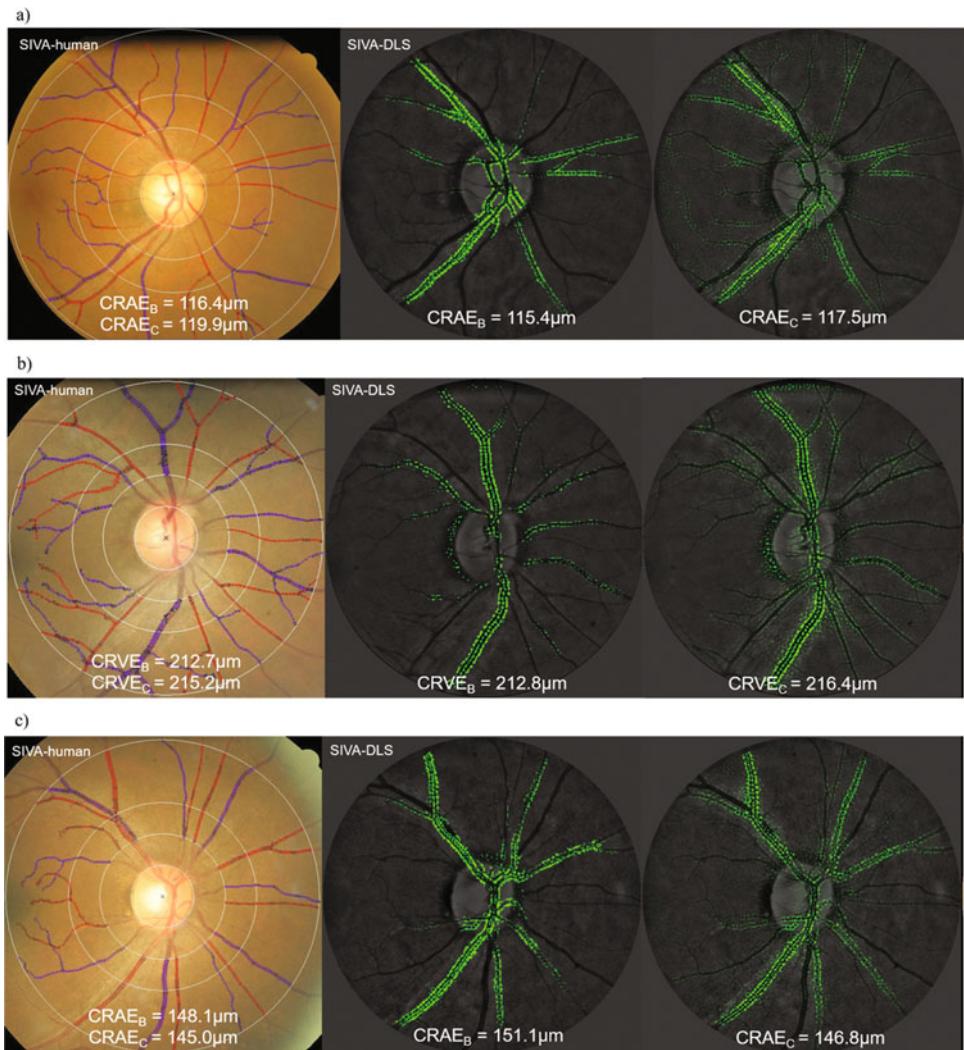

Fig. 3 An example of CRAE and CRVE prediction using SIVA-human and SIVA-DLS. The retinal-vessel calibers were calculated at two regions: one from 0.5 to 1.0 disc

diameter away from disc margin (zone B: CRAE_B and CRVE_B) and one from 0.5 to 2.0 disc diameters away from the disc margin (zone C: CRAE_C and CRVE_C) [76]

of 0.74. The ML model achieved higher performance in study participants with self-reported diabetes, as evidenced by an AUC of 0.89 in predicting anemia [81]. Sabanayagam et al. built a DL framework using fundus images of over 5000 patients from multiethnic, population-based datasets, which demonstrated good performance in predicting chronic kidney disease from fundus photographs, with an AUC of 0.911 in the validation dataset, and 0.733 and 0.835 in two external testing datasets [82].

Although it is interesting to predict systemic diseases with DL using retinal imaging, the clinical relevance and impact is yet to be defined. For example, to impact patients' management outcome, future research is of great value to explore using the retinal imaging CVD scores to stratify patients with CVD into high, moderate, or low risks, in addition to all the existing CVD risk calculator parameters, and this will require close collaboration between ophthalmologists and cardiologists in development of such tools.

Optical Coherence Tomography

OCT, particularly high-resolution spectral domain OCT (SD-OCT), is now the dominant imaging modality in ophthalmology, with more than 30 million OCT scans being acquired per year worldwide – more than all other modalities combined [83]. OCT is of particular value in the diagnosis and management of retinal diseases such as CNV in neovascular AMD and DME, the commonest causes of irreversible vision loss in many countries [84, 85]. In fact, the use of OCT to allow personalized treatment of retinal diseases has allowed cost savings estimated at \$9 billion, a 21-fold return on initial US government investment in developing this technology [86].

To date, the OCT-based DL systems focus on three major areas, namely the segmentation, classification, and predictive tasks. In segmentation tasks, DL has been adopted to segment “fluid” within the retina, both intraretinal fluid (IRF) and subretinal fluid (SRF). The automated quantification of these fluids could be used to guide anti-vascular endothelial growth factor (VEGF) treatments in retinal diseases [87, 88]. Using the OCT data of 1127 eyes from the AREDS2 10-year follow-on study, Keenan et al. reported that the Notal OCT Analyzer (NOA), a ML classifier, could detect retinal fluid with higher accuracy and in particular higher sensitivity than expert graders (accuracy of 0.851 vs 0.805, sensitivity of 0.822 vs 0.468, and specificity of 0.865 vs 0.970) [89]. A novel, alternative approach has recently been suggested for detecting early AMD biomarkers, via annotation of OCT scans for biomarkers at the B-scan rather than pixel level, with subsequent training of a DL system to classify the scans. Class activation maps can then be used on each scan to provide approximate delineation of the biomarkers in a quick and entirely automated manner [90]. The classification and predictive tasks will be discussed in the following section.

DL Algorithms for Retinal Diseases Using Macula-Centered OCT

Using close to 100,000 OCT scans, Lee et al. reported excellent AUC and diagnostic accuracy

(>90%) in discriminating “normal” versus neovascular AMD patients (Table 4) [51]. Kermany et al. subsequently reported a robust diagnostic performance in discriminating DME, drusen, neovascular AMD, normal, with an accuracy of 96.6%, a sensitivity of 97.8%, and a specificity of 97.4%. In addition, this study also showed that transfer learning could potentially reduce the need of having large training datasets to train a robust AI algorithm [15]. Developed with OCT scans from a Korean dataset, Rim et al. demonstrated that the DL model could be generalized onto an external validation dataset of 91,509 OCT scans from American population, with AUC of 0.952 at individual level [91]. De Fauw et al. developed a two-stage DL framework by decoupling the segmentation and classification network, using 14,884 OCT scans. The DL system was able to detect those who require urgent referrals with excellent performance (AUC of >0.90), using two different OCT systems (Topcon and Spectralis) [16]. This DL algorithm utilized nine contiguous OCT scans, a three-dimensional U-net architecture, and intermediate tissue representation to output-automated segmentations across 15 different label classes. These labels encompass a range of novel OCT biomarkers, including three forms of pigment epithelial detachment (PED: fibrovascular, serous, and drusenoid) and sub-retinal hyperreflective material. The authors also highlighted the need to perform domain adaptation to fine-tune the DL algorithm for a new device, which brought down the total error rate for referral suggestions from 46.6% to 3.4%.

DL has also been shown to be useful in assisting the management of neovascular AMD with OCT measurements. Schmidt-Erfurth et al. applied a DL framework for automated detection and quantification of IRF, SRF, and PED before and after anti-VEGF treatment, which revealed that higher dose and more frequent dosing correlated with least residual fluid volumes [92]. DL model may become a more reliable and reproducible tool to quantify the response to anti-VEGF treatment, comparing to the qualitative assessment currently used in clinical practice. For the predictive tasks, Schmidt-Erfurth et al. used the HARBOR data to

Table 4 The summary of all the artificial intelligence systems with the respective training datasets and diagnostic performance for different retinal diseases using optical coherence tomographs

develop ML models to predict visual acuity (VA) in patients receiving ranibizumab for neovascular AMD [93]. They applied automated segmentation algorithms (using both graph-based and DL approaches) to the OCT scans, allowing segmentation of total retinal thickness, IRF, SRF, and PED, using random forest regression to predict VA at baseline and at 12 months. In the study, they found that the patients with good VA at baseline, and then at each follow-up for 3 months, were likely to have good VA at 12 months. In addition to the prediction of treatment results, Yim et al. built a DL system to predict the progression to exudative AMD in fellow eyes of patients with exudative AMD in the other eye, by combining 3D OCT images and corresponding automatic tissue maps, which outperformed five out of six experts. This DL system achieved sensitivity of 80% at specificity of 55% and sensitivity of 34% at specificity of 90% in predicting the conversion to exudative AMD within 6 months when compared with the ground truth of “conversion scan” rather than injection, corresponding to false positives in 9.6% of scans at the 90% specificity point [94]. These risk stratification and prediction models may have significant potential in the management of AMD by critically identifying the point of conversion from early or intermediate to exudative AMD, allowing timely follow-up and treatment.

A recent study adapted multimodal retinal image analysis consisting of fundus photographs, OCT, and OCT angiography scans, for the detection of intermediate AMD. Despite a relatively small training dataset of 75 participants, Vaghefi et al. demonstrated that the DL system accuracy increased from 91% to 96% in detecting intermediate AMD by combining multiple modalities, comparing to using OCT alone [95]. It is therefore crucial for the future research to evaluate the generalizability of these DL systems in a larger international multiethnic cohort, incorporating multimodal approach with clinical data, fundus photographs, and OCT scans. Apart from screening purposes, it will be of great value to generate new algorithms to predict and prognosticate the functional, structural, and treatment outcome for AMD patients, with appropriate stratification of the risk profiles.

DL Algorithms for Glaucoma Using Optic Disc-Centered OCT

Glaucomatous optic neuropathy (GON) is characterized by thinning of the retinal nerve fiber layer (RNFL) and optic disc cupping, in connection with loss of retinal ganglion cells (RGCs). Assessment of peripapillary RNFL thickness by OCT is now commonly used to detect GON for diagnosis and management of glaucoma, especially mild to moderate glaucoma. OCT has also been proposed to be used for screening GON in high-risk communities (e.g., elderly people, people with high myopia, people with a family history of glaucoma, or people with high intraocular pressure) [96, 97]. However, experienced glaucoma specialist or highly trained assessors are required to interpret the OCT results. Thus, AI algorithms may play an important part in detecting and managing GON.

Besides fundus-based glaucoma AI algorithms as discussed earlier, several groups have explored the use of OCT measurements for the training of a DL system to quantify GON on 2D fundus images [98, 99]. Using a total of 32,820 pairs of optic disc photographs and OCT RNFL scans, Medeiros et al. showed that the prediction of RNFL thickness from optic disc photos are similar to the OCT findings (83.3 μm vs 82.5 μm , $p = 0.164$). The AUC in differentiating GON from health eyes were 0.944 [98]. In addition, a DL model recently reported by Medeiros et al. demonstrated the ability to discriminate glaucoma progressors from nonprogressors, based on quantitative estimates of RNFL changes from fundus photographs, with an AUC of 0.86 [100].

Several DL frameworks have been developed to detect glaucoma using OCT measurements such as the RNFL thickness and ganglion cell complex (GCC) images [101, 102]. Asaoka et al. built a classifier by first pretraining with 4316 OCT images and then further training with 178 images obtained with a different OCT instrument. This transform model achieved AUC of 0.937, sensitivity of 82.5%, and specificity of 93.9% in differentiating early glaucoma eyes from normal eyes [101].

Subsequently, Ran et al. developed a three-dimensional (3D) DL system from 4,877 volumetric OCT scans for automated detection of GON, aiming to utilize the GON features of 3D

volumetric OCT cube that are not shown in 2D fundus photographs [103]. In the primary validation, they showed that the 3D DL algorithm outperformed the 2D DL algorithm trained on fundus images (AUCs 0.969 vs 0.921, $p < 0.001$). In the external validation, the 3D DL algorithm was tested in three other independent datasets and showed good performance, with AUCs of 0.893–0.897, sensitivities of 78–90%, and specificities of 79–86%. This study suggests that screening with the 3D DL system is much faster than conventional glaucoma screening methods (i.e., by experienced specialists), could be done automatically, and does not require a large number of trained personnel on site. Future work such as comparison of discriminative performance between RNFL map and the 3D DL system, and testing the ability of the 3D DL system to detect GON damage in people with suspected glaucoma are warranted [104].

DL Algorithms for Glaucoma Using Anterior-Segment OCT

Anterior-segment OCT (AS-OCT) has been used increasingly to assess the anterior chamber angle for differentiating open-angle glaucoma, closed-angle glaucoma, and angle closure diseases. Imaging with AS-OCT has several advantages over conventional gonioscopic examination, such as noncontact approach and better reproducibility [105, 106]. Xu et al. developed a DL model with multiclass CNNs to classify the anterior chamber angle into open- or closed-angle using 4036 AS-OCT images collected from the Chinese-American Eye Study. They found that using the ResNet-18 architecture, the DL algorithm can achieve an AUC of 0.933 on the cross-validation dataset and 0.928 on the testing dataset for detecting gonioscopic angle closure. Although inclusion of more anterior-segment OCT images for the classification and external validation are needed, the results of this study indicate that the detection of eyes with gonioscopic angle closure may be automated using DL framework with favorable performance compared to the manual and semi-automated methods [107]. In addition, the authors also suggested that DL algorithm may be further applied to identify patients with early angle closure diseases who are at high risk of

GON and may require laser peripheral iridotomy [107, 108].

Visual Fields

VF is a pivotal test in the diagnosis and monitoring of glaucoma patients. Compared to optic disc photographs or OCT images, VF data points usually have low dimensionality and high noise. Due to the lack of consensus in the definition of glaucoma, DL systems may help play a role in defining the minimal thresholds to diagnose glaucoma. Using the pattern deviation (PD) probability plots, Li et al. developed a CNN to discriminate glaucomatous from normal eyes, with 93.2% sensitivity and 82.6% specificity [109]. For identification of glaucoma progression, various ML and DL techniques have been attempted. First, Yousefi et al. used an alternative Gaussian mixture and expectation maximization method to decompose VFs along different axes to detect VF progression [110]. This approach was as good or superior to current algorithms, including glaucoma progression analysis, visual field index, and mean deviation slope, in detecting VF progression. Second, Garcia et al. reported that Kalman filtering (KF), a ML technique, is effective in forecasting disease trajectory in a total of 263 normal-tension glaucoma patients in prediction of 2-year mean deviation (MD) forecast than linear regression of MD [111]. Third, using approximately 32,000 Humphrey VFs with more than 1.7 million perimetry points, Wen et al. trained a CNN that is able to use a single Humphrey VF to generate predictions of future Humphrey VFs for up to 5.5 years, [112] with an excellent correlation of the MD between the predicted and actual Humphrey VF (average difference of 0.441 dB).

Several AI algorithms have been developed for relating structural changes of glaucoma on OCT to functional loss on VF [113–115]. Using over 25,000 pairs of standard automated perimetry (SAP) and SD-OCT measurements from patients with glaucoma or glaucoma suspect, Mariottini et al. built a CNN that is capable of predicting SAP sensitivity thresholds based on RNFL defects seen in SD-OCT, evidenced by a mean absolute error of 4.25 dB and an average correlation

coefficient of 0.60 ($P < 0.001$) with the measured values from SAP [113]. With a smaller training dataset, the DL model developed by Park et al. could predict the VF results from OCT images with a root mean square error of 4.79 ± 2.56 dB [115]. Application of these AI-based structure-function maps may assist the interpretation of OCT and VF results in clinical practice, especially for patients who may not be able to conduct VF assessment. Nevertheless, glaucoma is a disease affected by many clinical factors; future research is needed to combine the patients' demographic profile, intraocular pressure, and structural and functional tests in a multimodal approach to develop more accurate algorithms.

Infantile Facial Video Recording

In China, Long et al. reported a DL system that could discriminate the infantile behavioral dynamics of visual impairment (Fig. 4) [116]. In this study, a 5-minute video was recorded for 4196 infants, and analyzed for four main categories (13 subtypes) of behaviors labeled using a consensus definition: 1) eyeball movement (strabismus, nystagmus, and incongruous binocular movement); 2) hand-related behaviors (eye rubbing, pressing, and poking); 3) fixation-related behaviors (compulsive light gazing, compensatory head position, motionless fixation, and poor fixation); and 4) eyelid reaction (frequent blinking, squinting, and frowning), diagnosed independently by five experienced researchers and ophthalmologists, with the disagreement cases arbitrated by three senior professors. Based on the facial behaviors, the DL system was able to discriminate mild visual impairment vs healthy, severe vs mild visual impairment, and various ophthalmic diseases from healthy vision, with AUC of 0.852, 0.819, and 0.816–0.930, respectively. Given the convenience of a 5-minute video recording, this approach may be a useful alternative to identify and monitor infant with visual problems. Nevertheless, the generalizability of the algorithm may need to be further evaluated in the non-Chinese settings considering the differences in facial features. How to integrate the video recording in the busy clinical workflow is another

issue to be dealt with for the clinical application of the video-based AI algorithm.

Electronic Health Records

Electronic health records (EHR) have been adopted by the healthcare users since over a decade ago [117]. In 2018, DL using EHR has been shown to be effective in predicting the in-hospital mortality, 30-day unplanned readmission, and prolonged length of stay in two US academic centers [118]. In ophthalmology, Baxter et al. described using the structured EHR data and ML to predict the need for surgical intervention in 385 patients with primary open angle glaucoma [119]. Using the various statistical and ML models (e.g., multi-variable logistic regression, random forests, and artificial neural networks), the authors reported an AUC of 0.67 in discriminating patients with progressive disease requiring glaucoma surgeries. In this study, they also found that the use of certain ophthalmic and systemic medications (e.g., lipid lowering agents, non-opioid analgesics, macrolide antibiotics, and calcium blockers) were associated with decreased needs for glaucoma surgeries, suggesting the usefulness of some systemic data, in addition to eye-specific data, in the predictive modeling.

Although big data is always considered as a great resource to build data-based algorithms, the real-world data, unfortunately, are always sparse, lack organization and reference standards. In addition, the algorithm developed using a specific population data may not be generalizable to others, given the differences in patients' demographics, as well as epidemiological and geographical risk factors. Thus, it is important to ensure robust external independent testing, or the need for the specific algorithm to be fine-tuned further based on the specific population needs.

Image Quality Assessment

Image quality is of paramount importance for the training and performance of a DL algorithm. In the laboratory setting, preprocessing of images by

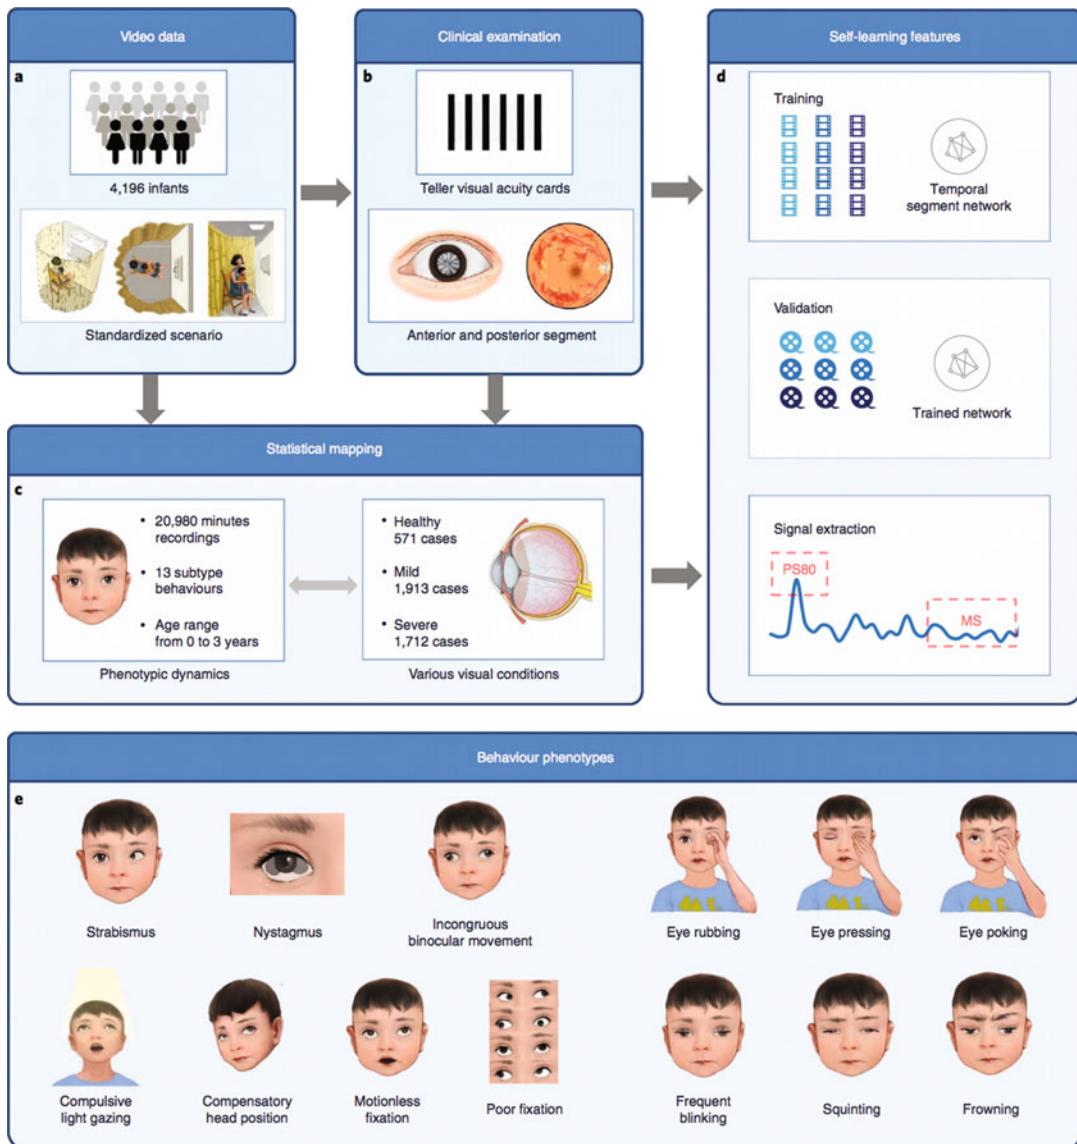

Fig. 4 Overall study pipeline. A. A total of 4196 infants' panoramic dynamics of behavioral phenotypes with various visual conditions were collected under a designed standardized scenario. B. Each infant underwent Teller visual acuity cards and structural examinations using a slit lamp and fundoscope. C. On the basis of the records, the statistical associations between behaviors and severities of visual impairment were calculated. D. A temporal segment

network was trained to self-learn features from the behavioral phenotypes in the training set (video symbols in the upper box). After testing the deep learning system performance using an independent validation dataset (film-reel symbols in the middle box), the trained network was used to extract two indices (MS and PS 80) to discriminate behaviors. E, Static representations of 13 behaviors [116]

filtering out those with poor quality is usually conducted during the development of DL algorithm, given that a suboptimal image may have impact on the diagnostic performance. In the real-world clinical setting, however, image quality could be compromised by several factors, such

as small pupil size, cataract, and patient's cooperation. It is therefore essential for a DL model to automatically assess the image quality with the gradability algorithm. Using 6139 retinal fundus images from preterm infants during routine ROP screenings, Coyner et al. developed a DL

framework for automated assessment of fundus images quality in ROP, where quality was defined as the ability to confidently assess an image for the presence of ROP. This DL model achieved comparable performance to that of human experts, with AUC of 0.965 for differentiating acceptable quality and not acceptable quality [120]. With use of over 40,000 ultra-widefield fundus images, the DL model built by Li et al. could filter out sub-optimal images with high sensitivity and specificity (>95%). Besides, the application of this image filtering system was shown to improve the diagnostic performance of established AI systems [121]. Automated assessment of images has also been explored in filtering OCT scans. The traditional index for assessing the quality of OCT scan is signal strength, which is limited in evaluating other factors such as off-centration, missing data, and artifacts. Ran et al. developed a 3D DL system for filtering out ungradable OCT volumes, with AUC of 0.954, sensitivity of 86.2%, and specificity of 92.6% using squeeze-and-excitation ResNeXt strategy [122]. Although DL algorithms for automated analysis of image quality are essential, cautions are warranted in setting the appropriate threshold, as images that are marked as ungradable by the DL system may result in unnecessary referral to the tertiary eye care centers.

Future Research and Challenges

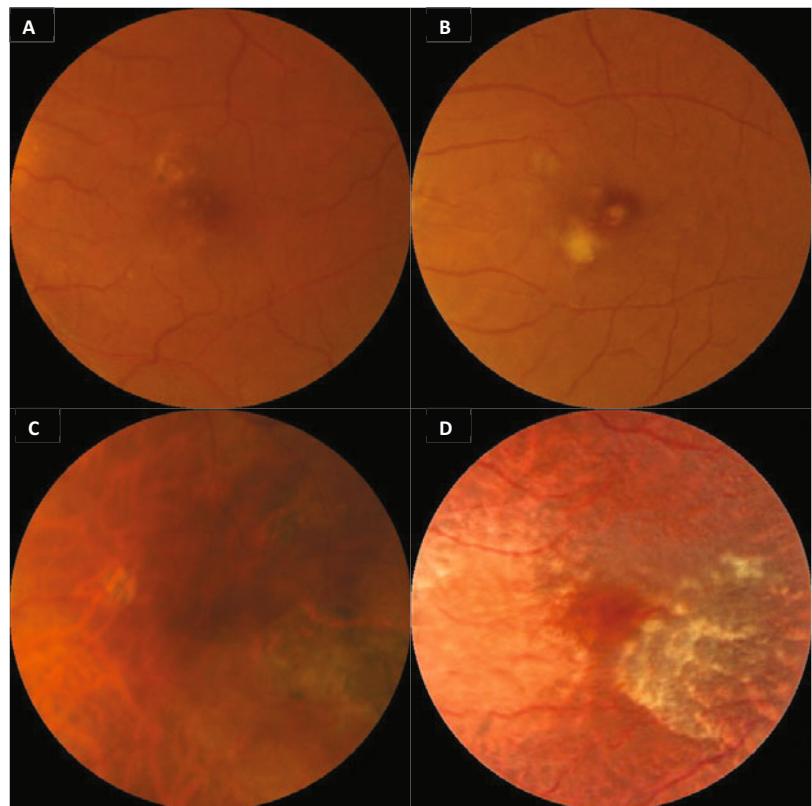

Novel Technical Approaches

At present, the majority of DL studies focus on segmentation and classification task. In terms of predictive DL algorithms, limited studies were conducted using the long-term clinical data to train the baseline images (fundus or OCTs) [123]. Although it may be ideal to develop more predictive algorithms to deliver preventive or personalized medicine, some diseases may simply do not have early signs that could be detected by the DL algorithms from the images. Even if they do, the limited longitudinal progression data is another contributory factor to suboptimal performance in many predictive algorithms. Another challenge related to

datasets is the availability of large training datasets, especially for rare diseases. To address this limitation, Burlina et al. applied low-shot DL methods to train the algorithm with relatively low number of images. Using 160 images, the DL model trained using low-shot methods and self-supervision outperformed the traditional DL system (AUC 0.747 vs 0.659) in differentiation of referable DR from non-referable DR. The superior performance remained when the training data was reduced further down to ten images. In addition, the low-shot methods might be beneficial to address AI bias due to imbalance of data or infeasibility of data partition [124].

Another innovative area in AI research is the application of generative adversarial network (GAN) to artificially synthesize ophthalmic images. GAN is an unsupervised DL machine based on two models: a generator and a discriminator, introduced by Goodfellow et al. [125]. The generative model learns to capture the data distribution, take random samples of noise, and generate plausible images from that distribution. The discriminative model estimates the probability that a sample comes from the data distribution rather than generator distribution, and therefore is tasked to discriminate between real and fake images. The performance of both networks simultaneously improves each other over time during the training process. GAN-synthesized images may be an alternative to address the limitations commonly encountered when developing a robust DL system, such as availability of large datasets, the privacy of patients, and personal data protection. Burlina et al. showed that the retinal specialists could not distinguish GAN-synthesized retinal images with AMD lesions from the real AMD images. Besides, the DL classifier trained on synthetic data achieved noninferior performance in detecting referable AMD (AUC 0.924) comparing to the one trained on real images (AUC 0.971) [126]. Figure 5 shows an example of GAN-synthesized normal fundus images and real images with AMD. Future research will be of great value to evaluate whether the similar algorithm could be generalized to other retinal conditions.

Fig. 5 Generative adversarial network (GAN) created images of AMD (B, D) compared to real images of AMD (A, C), with macular segmentation

Research Ethics and Artificial Images

Given the noninterventional and retrospective nature of AI research, institutional review boards in most countries do not require individual consent for such studies, particularly when the data being studied have been anonymized. For example, the NHS Constitution states that the physicians should harness the anonymized clinical information to support research and improve care for others [127]. The development of AI for clinical applications requires large amounts of training data, often an order of magnitude more than that collected even in large clinical trials. The application of AI in this context presents a number of considerations and challenges: 1) the datasets are often orders of magnitude larger than in previous retrospective case series, with attendant information security risks; 2) the datasets must often be shared outside the hospital in which they have been collected, either with academic or industry collaborators; and 3) whether or not ophthalmic images are considered truly

de-identified or the regulations around this may potentially change in the future.

Data Ownership and Sharing

In addition, the ownership and value of the data always raise a question regarding how the patients, institutions, and the public get the appropriate benefits from the use of their data to train AI systems? Although the relative value of clinical data is widely appreciated, it is far less clear how to determine its absolute value. For example, if an algorithm is trained on multiple datasets from different institutions or different countries, how can the relative contribution of each dataset be valued? In the coming years, the ophthalmic research community will learn more about the nuances of this – is a dataset of one million poor-quality retinal scans more valuable than a dataset of 100,000 scans of high quality? And what feature or disease distributions are optimal? A large dataset of healthy eyes is less likely to be

of value than a smaller one with a disease distribution more similar to that of the intended clinical application. These questions of value will become increasingly important as the use of innovative approaches such as federated learning become more widely adopted. Even when these factors have been elucidated, there are additional complexities, particularly when sharing data outside an academic setting. The governance around such decisions may be best undertaken by so-called “data trusts,” which allow the voices of multiple stakeholders to be considered and which can balance principles of reciprocity and proportionality [128, 129]. It appears increasingly likely that tiered access to data may be most appropriate, with larger companies being charged a license fee while smaller companies might prefer to offer a revenue share; conversely, academic researchers should ideally have free access to data for noncommercial applications.

Although the above considerations may be viewed negatively, as an additional burden on clinical researchers, in fact, there may be a step forward. If done correctly, the storage of data in cloud-based infrastructure may provide considerable additional safeguards against data loss, much better security, and greatly improved audit capabilities. With the introduction of European Union (EU) General Data Protection Regulations (GDPR), it will now be incumbent on clinical researchers to complete data protection impact assessments (DPIAs) before embarking on the use of innovative technologies, such as AI, in healthcare. This will provide an opportunity for researchers to incorporate good practice at an early stage in their studies and hopefully to avoid significant missteps at a much later stage. Taken together, extra care in these departments, combined with thoughtful engagement with patients will provide an opportunity to greatly improve patients trust and thus aid translation “from algorithm to application.”

Patients and Physicians Acceptance

To date, limited studies were available to assess the patients’ acceptance of the AI technologies in

medicine. In Tran et al., [130] merely half of the patients felt that the development of AI is an important opportunity, and 10% felt it could potentially dangerous. On the other hand, Keel et al. reported that 96% of participants reported that they were satisfied with the AI DR screening, with 78% preferred to have AI to manual screening [27]. One potential barrier to physicians’ acceptance to AI systems in ophthalmology is the “black box” functioning of these systems [131]. A number of technical methods (e.g., occlusion testing and integrated gradients) have been described to visualize where the DL “thinks” is abnormal. However, none of which has shown superiority to another [132, 133]. Regulatory bodies in the USA and Europe have also written about the potential importance of developing “explainable” AI systems [134–136]. Thus, to increase the adoption of AI within the clinical practice, the AI algorithms will need to be seamless, user-friendly, and unbiased to help making clinical decisions faster and more effectively [137, 138].

Education

The “tsunami” of the AI and digital health algorithms may warrant the educational department of medical schools and residency programs to revisit the teaching syllabus. To better equip the next generation of ophthalmologists with AI and digital health, it may be useful to include the ML and DL courses as part of the training, similar to how the statistics course is taught. Likewise, for the computer science or engineering department, it is worthwhile to explore the possibilities of having medical students or residents attachment to allow them to learn the basic courses on programming, coding, and statistics.

Guidelines

In April 2019, the US FDA adopted the definition by the International Medical Device Regulators Forum (IMDRF) to consider AI-based software as a medical device (SaMD) [139]. Applications of AI in ophthalmology described previously, for

example, were intended to be used for performing one or more ophthalmic purposes single-handedly without being part of a hardware medical device. The FDA also adopts quality systems and good ML practices for AI-based SaMD which include clinical evaluation guidance in three domains: valid clinical association between AI output and targeted condition, analytical validation (correct processing input data to generate accurate, reliable, and precise output data), and clinical validation (the accurate, reliable, and precise output data achieve the intended purposes in the targeted populations in clinical care).

In 2019, the World Health Organization (WHO) released a guideline to critically appraise digital health interventions such as AI, aiming to evaluate the benefits, harms, acceptability, feasibility, resource use, and equity considerations [140]. This not only helps prevent a proliferation of short-lived implementations of digital tools in the healthcare system, but also helps the health policymakers and relevant stakeholders to make informed investments into these large pools of AI algorithms in the market. The guideline also states that to promote digital health implementations, it is important to have the combination of health content, digital health interventions, and digital applications that can be supported by a robust information technology design and architecture.

To standardize the reporting of AI studies, an international effort has been made to develop AI extensions to the Consolidated Standards of Reporting Trials (CONSORT) and the Standard Protocol Items: Recommendations for Interventional Trials (SPIRIT) guidelines, which were described by Liu et al. and Rivera et al. with 14 and 15 additional AI-specific items, respectively [141, 142]. The CONSORT-AI and SPIRIT-AI extensions provide recommendations for reporting AI clinical trials, such as specifying the device used and indication for use, the applicable patient group, the type of data, and the limitation of the study.

In ophthalmology, AAO has also established an AI taskforce to gather the major AI key opinion leaders in ophthalmology, aiming to educate the current and next generation of

ophthalmologists on the AI-related research and clinical applications; [143] gather the experts' opinion to generate consensus guidelines on reporting metrics and regulations for different AI technologies; [17, 144–146] and explore the relatively uncertain safety and ethical considerations [147]. The establishment of guidelines, white papers, and recommendations will help streamline and increase quality of AI research and applications within the ophthalmology settings.

Conclusion

AI is an exciting, disruptive technology that will likely have a significant impact on medicine and healthcare. There has been remarkable progress in the use of AI in ophthalmology, and AI has been applied to many of the major eye diseases. However, there remains significant challenges for AI to show actual clinical translation in “real-world” settings to improve healthcare.

Abstract

Ophthalmology presents as an exciting field in medicine for artificial intelligence (AI) systems, with its numerous digital imaging techniques – only surpassed, perhaps, by radiology – and the increasing prevalence of eye diseases that cause preventable vision loss that accompanies the global increase in life expectancy. Machine learning and deep learning can be applied for screening, detection, identification of progression, and assessment of the response to treatment of the main eye diseases. Recent studies demonstrated that these systems show good

performance in the detection of diabetic retinopathy, glaucoma, age-related macular degeneration, retinopathy of prematurity, refractive errors, and in the identification of risk factors for systemic diseases using eye fundus photos. This chapter describes the technical and clinical uses of AI in ophthalmology and discusses the challenges for its incorporation into clinical practice.

Keywords

Artificial intelligence · Machine learning · Deep learning · Big data

Introduction

To date, the application of data science to ophthalmology has been less apparent than in other areas. However, large clinical databases obtained from electronic medical records and digital

images have provided opportunities for the detection of several ocular diseases through artificial intelligence (AI).

Diabetic retinopathy (DR), age-macular degeneration (AMD), glaucoma, and cataract represent the main causes of blindness worldwide, with alarming projections of increased prevalence with aging [1]. Over the past decade, AI has become a popular topic, since substantial burden of visual impairment and blindness from major eye diseases have not been adequately tackled using traditional models of eye care [2, 3].

New algorithms, systems, and software have been developed to perform diagnostic and grading tasks from imaging with operations analogous to human's learning and decision-making. In addition, accurate algorithms for pattern recognition may help clinicians by reducing diagnostic and therapeutic errors with the interpretation of large quantity of complex data in time-consuming tasks.

AI has three main applications in imaging: (1) Classification, where an image will be classified into different categories, for example, presence or absence of disease, or stage of the disease. This function can be used for automated diagnosis, screening, or staging. (2) Segmentation, to detect and outline anatomical structures or injuries, in order to measure shape or volume. This can be used for automated quantification of biomarkers in an image. (3) Prediction, to predict future results or predict the value of another measure. For example, predicting visual acuity, age, or blood pressure from an image. This function can also be used to estimate the prognosis of diseases or to promote correlation between structure and function.

The practical utility of an algorithm is to aid clinicians on decision-making and to educate or advise patients. There are two main modalities of AI's clinical utility: (1) computer-aided diagnosis allows clinicians to use the computer's output data as a "second opinion," which will help on decision-making; and (2) automated computer diagnosis, which suggests a diagnostic classification by the algorithm output, without the input of a physician.

Clinical Application of AI in Ophthalmology

The outpatient nature of the practice and the use of various imaging modalities makes ophthalmology a promising field to the implementation of AI for screening, diagnostic staging, and therapeutic guidance.

In 2050, the world population over 60 is estimated to reach 2 billion. The increase in longevity will lead to an increase in the number of people with visual impairment and blindness caused by diabetic retinopathy, glaucoma, and AMD [4]. Other eye diseases that require early detection and are important causes of childhood blindness include retinopathy of prematurity, refractive errors, and amblyopia [5]. AI algorithms can be used as alternative screening tools for all the abovementioned eye diseases.

The most common application of AI methods to the retina includes the detection of disease-related features from color fundus photographs. Fundus photography is an important screening tool for eye diseases, due to the low cost, portability, and wide availability of fundus cameras, allowing *in vivo* evaluation of the microvasculature and neural tissue. An important first step in evaluating fundus photographs is to identify whether the image orientation is adequate so that the automated system can analyze the condition of the retina. The landmarks of the retina commonly used for this task are the large retinal vessels, the optic disc, and the fovea, which can be easily recognized (Fig. 1) [6]. Using fundus photographs, AI has shown good accuracy in predicting age, gender, blood pressure, and smoking habit in an individual. The same algorithm was also able to indicate whether an individual had a higher risk for unstable angina, heart attack, stroke, or death due to cardiovascular causes [7].

With the increasing success of neural networks, there is a need to explain its decision base. The interpretability of the neural network generally is given by the identification of which part of an image is responsible for the activation of the network. This is typically represented in the form of a heat map, which indicates the location of

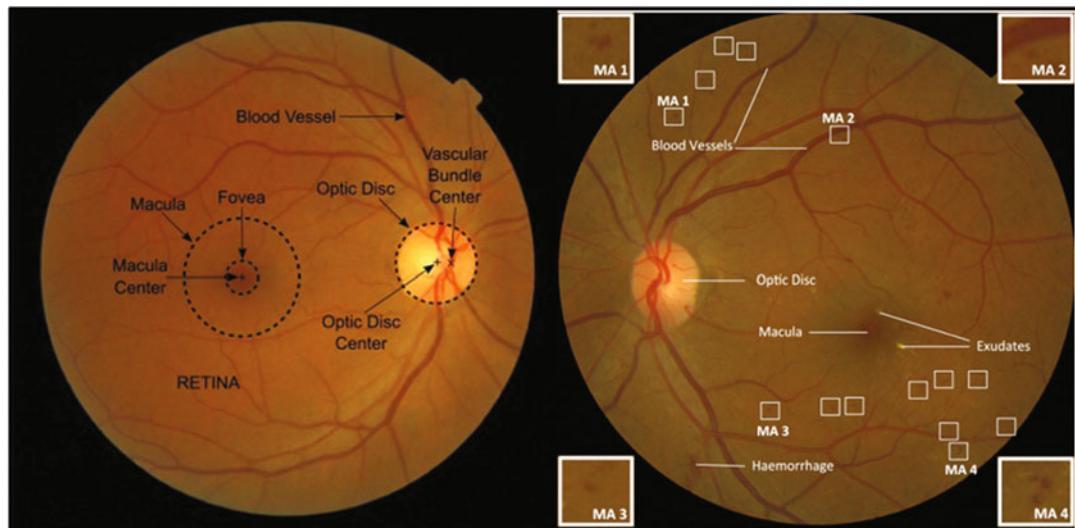

Fig. 1 Left: Anatomical landmarks used for orientation in a fundus photograph: fovea, macula, blood vessels, optic nerve head, and optic nerve head center. Right: Detection

the image where the features modify the network's predictions. The most common and simplest approach is to perform the so-called occlusion test (Fig. 2) [8]. To identify the areas of the image that contribute most to the decision of the neural network, a "white box" is placed in all areas of the image and the respective probability of output class is recorded. The biggest drop in the likelihood of categorization will represent the region of greatest importance.

The following sections will discuss the use of AI for the screening, diagnosis, and prognosis of diabetic retinopathy, glaucoma, and age-related macular degeneration.

Diabetic Retinopathy (DR)

Diabetic retinopathy is a specific microvascular complication of diabetes and remains one of the leading causes of preventable blindness in the world. It is identified in one-third of people with diabetes and it is associated with increased risk of life-threatening systemic vascular events, such as stroke, coronary heart disease, and heart failure [9]. Although diabetes affects the eye in many ways (e.g., increased risk of cataract), diabetic

of abnormal structures such as microaneurysms and hemorrhages; the white squares show examples of microaneurysms detected by the algorithm [6]

retinopathy is the most common and serious ocular complication [10].

Ophthalmologists typically diagnose and stage DR by the direct assessment of the retina during a fundus examination or by color fundus photographs. Given the large number of diabetes patients globally and to address the shortfalls of current diagnostic workflows, automated solutions could ease the burden of expensive and time-consuming screening by specialized doctors. A clinical trial demonstrated a sensitivity of 87.2% and a specificity of 90.7% in the detection of DR by AI, with a classification accuracy of 96.1%, using an external reading center as a reference standard. It is interesting to note that this reading center used wide-angle retinal examination and optical coherence tomography (OCT) to detect the presence of macular edema, whereas the algorithms were developed with the use of inexpensive posterior pole retinography. Due to differences in reference standards, it is difficult to compare the performance of AI algorithms reported in several studies [11]. To solve this challenge, an algorithm was tested on 11 independent datasets with a single reference standard. This algorithm showed a sensitivity of 90.5% and a specificity of 91.6% in the primary dataset

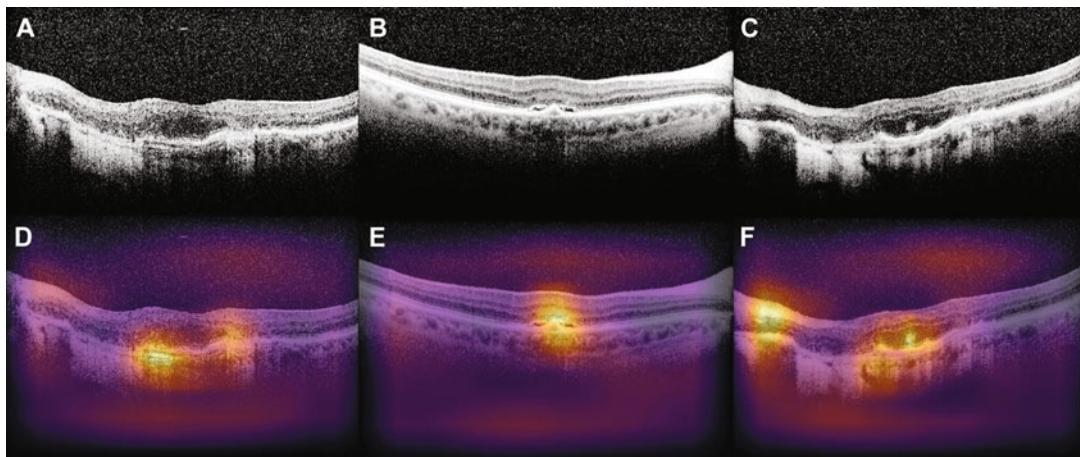

Fig. 2 Examples of identification of age-related macular degeneration (AMD) by deep learning (DL). Optical coherence tomography images in which A, B, and C are used as input images, and heat maps D, E, and F are

identified using the DL algorithm occlusion test. The intensity of the color is determined by the drop in the likelihood of the image being categorized as AMD when this area is occluded [8]

and an area under the ROC curve (AUC) >0.90 , and sensitivities $>90\%$ and specificities $>70\%$ in the ten remaining datasets [12].

The AI models for DR screening in clinical practice may be implemented through a cloud-based configuration, in the office, or built in the retinography cameras. The cloud-based model can integrate AI information into information technology platforms to assist in the analysis of routine images. On the other hand, office-based model implements an application programming interface on computers that integrate the algorithm with retinographies, promoting the image capture followed by an instant diagnosis. In April 2018, the Food and Drug Administration (FDA) approved the first medical device to utilize AI to detect DR, the iDx-DR, which uses a cloud-based algorithm with an almost autonomous retinography camera (Fig. 3). Sufficiently good-quality images can automatically detect vision-threatening and referable diabetic retinopathy [13]. Several studies have been published with the use of AI and detection of DR with retinography images. In one of these studies, [12] 494,661 retinographies were used to develop and validate a DL system for detecting DR and concomitant diseases, such as glaucoma and AMD. The sensitivity and specificity for detecting DR were 91% and 92%, 100% and

91% for high-risk DR, 96% and 87% for glaucoma, and 93% and 89% for AMD, respectively. In this same study, external and multiethnic datasets were tested for DR detection and revealed sensitivities that varied between 92% and 100% and specificities that varied between 73% and 92% [14]. Another study reported a DL algorithm developed to classify the presence of any stage of DR in 75,137 color fundus images from public databases. Their model achieved a 0.97 AUC with a 94% and 98% sensitivity and specificity, respectively. Testing against independent databases achieved AUCs of 0.94 and 0.95, respectively [15].

Glaucoma

Glaucoma is a group of optic neuropathies characterized by progressive degeneration of retinal ganglion cells that have their cell bodies in the inner retina and axons in the optic nerve. Degeneration of these axons results in cupping, a characteristic appearance of the optic disc, and visual field loss [16]. Glaucoma is the main cause of irreversible blindness in the world, with more than 2.9 million blind people in the world [4]. The number of individuals with glaucoma is expected to increase to 111.8 million in 2040 [17].

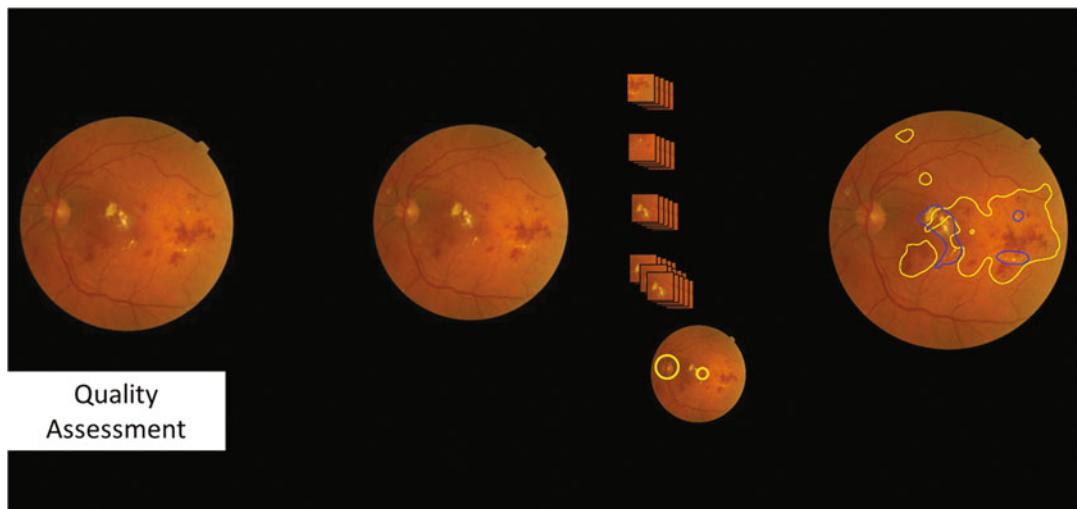

Fig. 3 Working diagram of the iDx-DR algorithm for DR screening. First, a quality assessment indicates whether the image can be used for analysis or whether there are any acquisition artifacts. Then, a DL algorithm using convolutional neural networks evaluates the image for

clinical biomarkers (microaneurysms, hemorrhages, exudates, etc.). As a last step, the evaluation of clinical biomarkers and their location allows for decision-making and classification into no DR, moderate, or high-risk DR [13]

Therefore, early diagnosis of glaucoma is essential, and the use of AI may play a key role in screening, diagnosing, and following the disease.

Major challenges in the development of AI systems for screening or clinical utility in glaucoma include the structural and functional definition of the disease and the heterogeneity of optic nerve findings in glaucoma patients. Training a model capable of diagnosing or detecting early glaucoma is difficult due to three main factors [18]. The first is the presence of borderline parameters between suspicion and normality, such as pre-perimetric glaucoma with little structural change in the peripapillary retinal nerve fiber layer (RNFL) or with a slight thinning of the neuroretinal rim. The second is the lack of standardization of diagnostic criteria for glaucoma, as many studies are based on perimetric criteria. Finally, adequate longitudinal data are needed to identify the suspect cases that will develop glaucoma.

Structural evaluation is essential for the early detection of glaucoma and fundus photographs allow proper documentation and identification of optic disc characteristics at low cost. Ting et al. [12] proposed that a DL algorithm could be

developed to screen for glaucoma with existing teleretinal imaging. Using a large database of 494,661 teleretinal photographs acquired in diabetics, 125,189 of which had been labeled by human graders in the training set, the authors developed an algorithm capable of detecting images that were considered “referable” for glaucoma. In the test dataset, the algorithm detected “referable” glaucoma on photographs with an AUC of 0.942, with a sensitivity of 96.4%, and a specificity of 87.2%. In order to create an approach that would not depend on the low reproducibility of the subjective evaluation of optic disc photographs, Medeiros et al. proposed a DL algorithm that used retinal photographs to estimate RNFL thickness measured with spectral-domain OCT. OCT is a noninvasive imaging test that uses light waves to make cross-section images of the retina, allowing the evaluation and measurement of distinctive layers in a micrometer scale. For glaucoma, the thickness of the RNFL is used as an important metric of damage, widely used to diagnose and detect progression. The dataset included 32,820 pairs of optical disc photographs and OCT scans of the RNFL. There was a strong correlation between the predicted RNFL

value from the DL algorithm's interpretation of the fundus image and the actual RNFL thickness value from the corresponding OCT ($r = 0.832$, $P < 0.001$), with a mean absolute error of approximately 7 μm . The AUC for discriminating healthy from glaucomatous eyes was 0.944. This algorithm would allow the use of a low-cost system to diagnose and stage glaucoma from fundus photographs, which is especially useful where there is no OCT available (Fig. 4a) [19]. Thompson et al. published a follow-up study using a similar approach, in which the OCT Bruch's membrane opening-minimum rim width (BMO-MRW) parameter served as a reference standard for labeling optic disc photographs. BMO-MRW may be particularly useful in images where the optic disc is difficult to grade, such as in eyes with high myopia [20]. The DL predictions were again highly correlated with the actual BMO-MRW values (Pearson's $r = 0.88$, $P < 0.001$), and the AUC for discriminating between glaucomatous and healthy eyes was 0.945 for the DL predictions. Class activation maps confirmed that the neuroretinal rim was

critical to the algorithm's classification (Fig. 4b). A study by Maetschke et al. [21] developed a DL algorithm that could discriminate glaucomatous from healthy eyes using raw, unsegmented OCT volumes of the optic nerve head. The algorithm also performed better than conventional OCT parameters, with AUC of 0.94 compared to 0.89 for a logistic regression model combining OCT parameters. As illustrated in Fig. 4c, the class activation maps appeared to highlight regions in the OCT that have been clinically identified as important to glaucoma diagnosis, particularly the neuroretinal rim, optic disc cupping, and the lamina cribrosa and its surrounding area.

In a subsequent study, Jammal et al. demonstrated that the OCT RNFL predictions from the DL algorithm using fundus photos performed at least as well as and often better than human graders for detecting eyes with reproducible glaucomatous visual field loss. A total of 490 fundus photos of 490 eyes were graded by two glaucoma specialists for the probability of glaucomatous optical neuropathy. Correlations with standard automated perimetry global indices

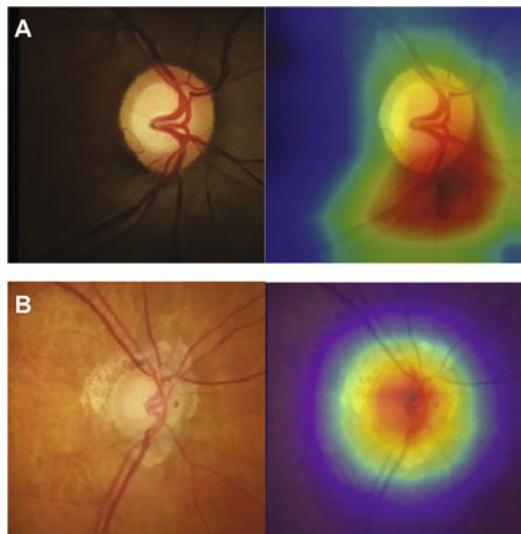

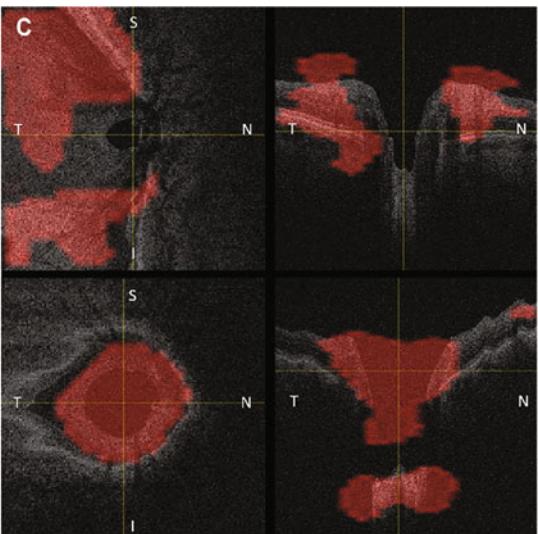

Fig. 4 Class activation maps (CAM) for several examples of deep learning (DL) models. (a) Gradient-weighted CAM from the DL model to predict RNFL thickness from fundus photographs. It can be seen that the heatmap correctly highlights the area of the optic nerve and adjacent RNFL as most relevant for the predictions [19]. (b) Gradient-weighted CAM from the DL model used to

predict rim width in an eye with glaucoma. Note that the heatmap strongly highlights the cup and rim regions [20]. (c) CAM showing the regions in a spectral-domain OCT identified as the most important for the classification of the scan into healthy versus glaucoma eyes. For glaucoma eyes the map highlighted the optic disc cup and neuroretinal rim [21]

were compared between the human gradings and DL RNFL thickness predictions. The DL RNFL thickness predictions had a significantly stronger correlation with mean deviation ($\rho = 0.54$) than the probability of glaucoma given by human graders ($\rho = 0.48$; $P < 0.001$). The partial AUC for the DL algorithm was also significantly higher than that for the probability of glaucoma by human graders (partial AUC = 0.529 vs 0.411, respectively; $P = 0.016$) [22].

Another DL algorithm was developed with training and testing of 1364 glaucoma-compatible fundus photos and 1768 normal fundus photos for the detection of typical glaucomatous signs, such as notching, diffuse thinning of the neural rim, increased disc cupping, RNFL atrophy, disc hemorrhage, and peripapillary atrophy. This algorithm showed an AUC of 0.96 [23]. Another group developed an algorithm using 1758 macular OCT images, incorporating the thickness measurements of the RNFL and ganglion cell complex for the early diagnosis of glaucoma with an AUC of 0.94 [24].

In addition to the analysis of posterior segment OCT, DL models have also been applied to anterior segment OCT images for the diagnosis of angle closure, a sight-threatening event in glaucoma. Fu et al. reported an AUC of 0.96 for a DL system trained to detect angle closure from Visante OCT images, with a sensitivity of 90% and a specificity of 92%, compared to clinician gradings of the same images as the reference standard [25]. In another work, Xu et al. tested three different multiclass CNNs in Chinese-American eyes, and the best-performing classifier detected gonioscopic angle closure with an AUC of 0.93. Given the difficulties associated with the subjective interpretation of gonioscopy and anterior segment OCT images, such models offer great promise in automating the detection of narrow angles [26].

Functional assessment includes the detection of changes in the visual field, which is also fundamental for the diagnosis and management of glaucoma patients. The glaucoma hemifield test (GHT) represents a supervised algorithm that is commonly used in the definition of glaucoma [27]. However, AI techniques can also identify glaucomatous

patterns or detect progression in the visual field, with a capacity equal to or greater than current algorithms. Elze et al. [28] proposed a technique of “archetypal analysis” to classify patterns of visual field loss in glaucoma. The authors showed that the patterns detected by their technique, such as arcuate, partial arcuate, etc., corresponded well to the classification made by human graders. An ML approach called Kalman filtering, which filters out noise from a series of parameter measurements and allows for a trend forecast over time, has been used in longitudinal studies to assess perimeter progression and has shown ability to detect progression up to 2 years before mean deviation linear regression. In this same study, a DL algorithm showed good ability to discriminate between pre-perimetric glaucomatous visual fields and normal visual fields, with an AUC of 0.93. Interestingly, this detection occurred before the appearance of visual field defects defined by Anderson’s criteria [29] (Fig. 5).

The combination of anatomical and functional data has been shown to be superior in relation to these data in isolation in the diagnosis of glaucoma. The ML classifiers allow you to combine these data and assist in the diagnosis of glaucoma. A study has been published to compare the diagnostic ability between ML classifiers and ophthalmologists exposed only to OCT and standard automated perimetry data [30]. The results demonstrated that the diagnostic accuracy of the best ML classifier (the radial base function network, with an AUC of 0.93) was similar to that of glaucoma specialists (AUC = 0.92) and significantly better than general ophthalmologists (AUC = 0.88, $p < 0.05$). These results suggest that the use of ML classifiers can be useful in clinical practice, especially when there is no glaucoma specialist available. Mariottini et al. [31] proposed a combination of global and localized parameters with the requirement for topographic correspondence between structural and functional damage that could be combined in an objective way to be used as a robust reference standard for the development of AI models for glaucoma diagnosis. The criteria assume that the diagnosis of glaucomatous optic neuropathy should involve corresponding structural and functional damage,

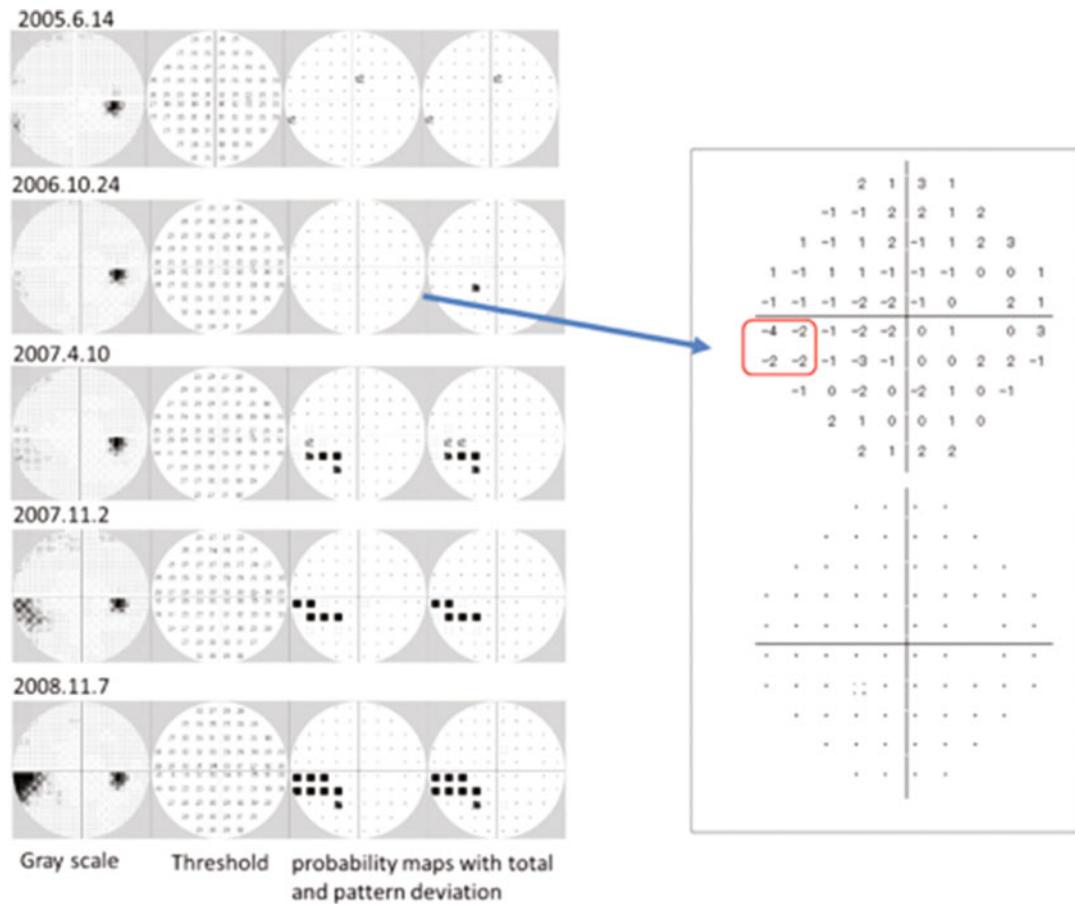

Fig. 5 A case in which the visual field of 10/24/2006 did not show changes that satisfied Anderson's criteria; however, there was a progression that was evident in

subsequent field examinations. With the DL algorithm, the visual field of 10/24/2006 had already been diagnosed as abnormal [29]

based on RNFL assessment by OCT and visual field assessment by standard automated perimetry. The authors then developed a DL model that used fundus photographs to discriminate glaucoma from normal eyes, which had been classified based on the objective reference standard. The model achieved an AUC of 0.92. Of note, an objective reference standard combining OCT and standard automated perimetry data may obviate the need for laborious and time-consuming expert gradings, and may increase the comparability of diagnostic studies across devices and populations.

As for DL applications in detecting progression, there have been only very few studies.

Berchuck et al. [32] proposed a DL variational autoencoder model to learn a low-dimensional representation of standard automated perimetry visual fields using 29,161 fields from 3832 patients. The model was then applied to predict rates of change and future visual field observations. The authors found that at 4 years of follow-up, the model identified 35% of the eyes as progressing versus only 15% for mean deviation. In another study, Park et al. [33] used a recurrent neural network and showed that it achieved better prediction of future visual field observations compared to ordinary least squares linear regression.

Age-Related Macular Degeneration (AMD)

Age-related macular degeneration is a progressive chronic disease of the central retina. Most visual loss occurs in the late stages of the disease due to one of two processes: neovascular (“wet”) age-related macular degeneration and geographic atrophy (“late dry”). In neovascular age-related macular degeneration, choroidal neovascularization breaks through to the neural retina, leaking fluid, lipids, and blood, and leading to fibrous scarring. In geographic atrophy, progressive atrophy of the retinal pigment epithelium, choriocapillaris, and photoreceptors occurs [34].

AMD is a major cause of visual impairment. It is estimated that the number of people with AMD in 2020 will be 196 million and will increase to 288 million in 2040. The treatment of exudative AMD has proved to be effective with the advent of endothelial vascular growth factors inhibitors (anti-VEGF), with a reduction in the incidence of blindness of more than 50% [35]. Patients at higher risk for developing AMD require clinical investigation with imaging tests such as OCT or angiography. AI algorithms can be used as an alternative tool for screening, diagnosis, prognosis, and disease monitoring.

DL-based classification systems have been successfully used to detect and segment AMD lesions (Figs. 6 and 7), and to estimate the risk of progression to advanced stages, or conversion from dry AMD to wet AMD (Fig. 8) [36–38]. A model was created that targets the posterior hyaloid and the epiretinal membrane, which allows an improved assessment of disorders of the vitreomacular interface and retinal pigment epithelium and quantifies the extent of AMD and its atrophic areas. In segmentation, the algorithm outlines the margins of the abnormal areas in OCT scans, allowing the measurement of the area or volume of the abnormal region [38]. Some groups have developed models that allow segmentation of the detachment of the pigment epithelium, delimiting the space between the retinal pigment epithelium and Bruch’s membrane [39].

Since anti-VEGF treatment for AMD involves repeated, invasive, and high-cost application of intravitreal injections over an extended period of time, some authors have applied AI algorithms to predict treatment outcomes and reduce treatment burden. Prahls et al. used a total of 183,402 OCT B-scans from patients with wet AMD to train a DL algorithm to predict whether an injection of anti-VEGF would have to be administered within the next 21 days [40]. Another study used data from the HARBOR clinical trial to develop models to predict the visual acuity of patients who received intravitreal injection of ranibizumab for neovascular AMD and to predict the risk of converting dry AMD to the exudative form [36]. Other AI systems have used the dataset from the age-related eye disease study (AREDS) [41, 42] or their own databases to assess the prognosis of eyes with AMD [37, 38, 40].

Future research is important to assess the generalizability and cost-effectiveness of these AI systems in international multiethnic cohorts. In addition to screening, it will be of great value to generate new algorithms to predict the functional, structural, and treatment results for patients with AMD, with the appropriate stratification of risk profiles.

Conclusions

Given the aging of the population and the increasing financial burden of blindness on health care, there is an urge to innovate in order to improve the detection of eye diseases. AI algorithms are likely to result in a significant shift in ophthalmology in the coming decades, although several challenges need to be resolved to encourage the adoption of AI in health care. First, validation of new diagnostic tests should be based on rigorous methodology. Therefore, the requirements for diagnostic performance may vary considerably depending on whether the algorithm is being considered for community-based or opportunistic screening versus detection or monitoring of disease in a tertiary care center. Secondly, AI approaches require a

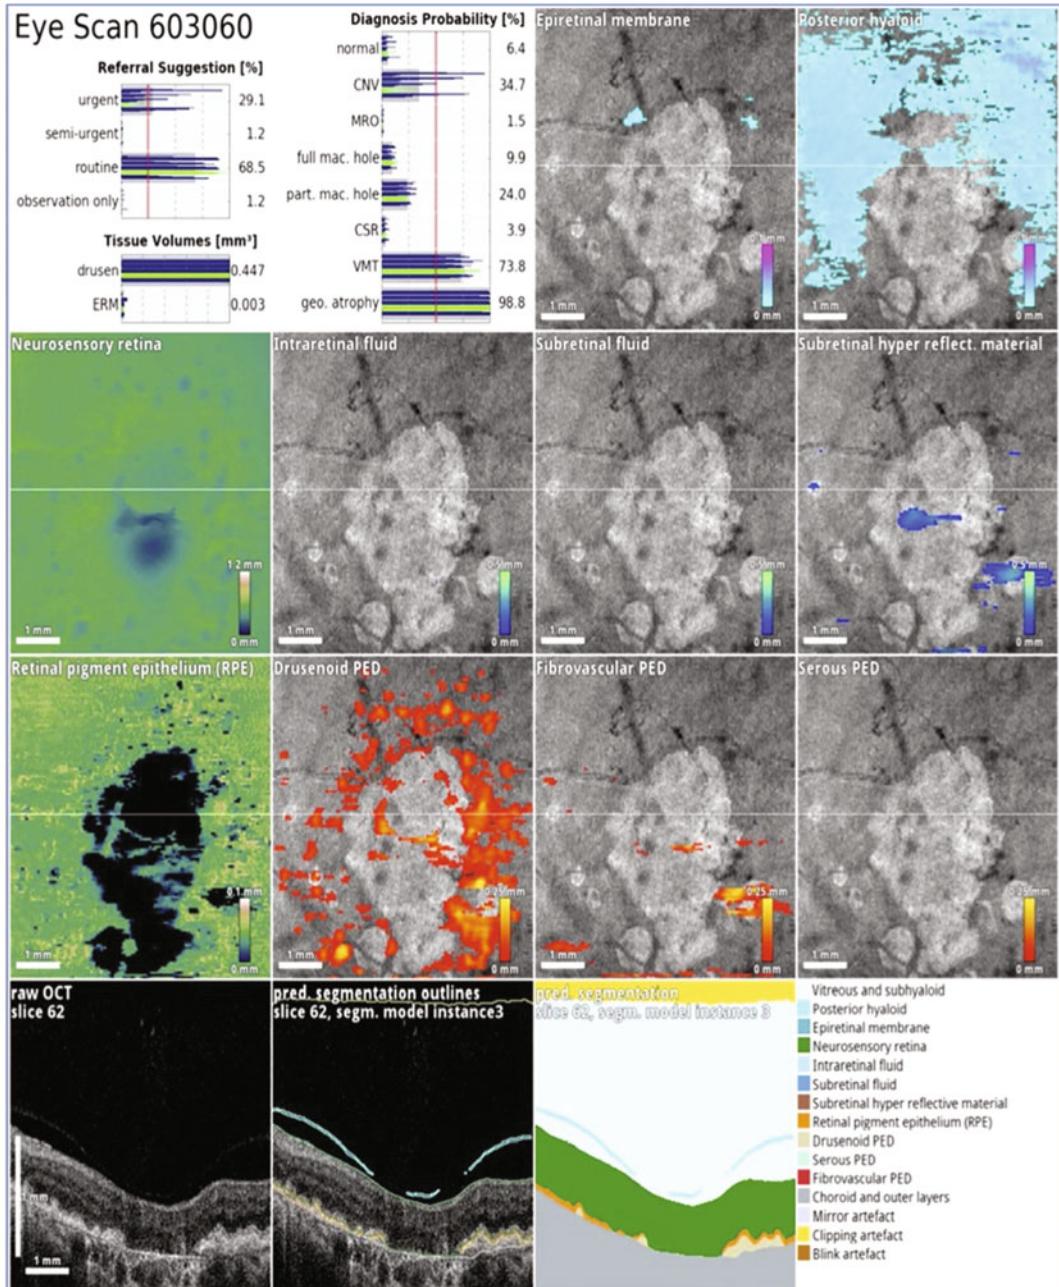

Fig. 6 DL application in the segmentation of OCT images – prototype of the Moorfields DL system (DeepMind). In this case, the system correctly segments the loss of the retinal pigment epithelium (RPE),

highlighting an area of geographic atrophy (red dots in the third line). Geographic atrophy is surrounded by foci of pigmented drusenoid detachment. The partial detachment of the posterior hyaloid is also outlined in the last row [37]

large number of images. However, increasing data does not necessarily improve the performance of a network, which will depend on the

quality of the images, the reference standard, and the representativeness of the data. A possible solution includes the sharing of data between

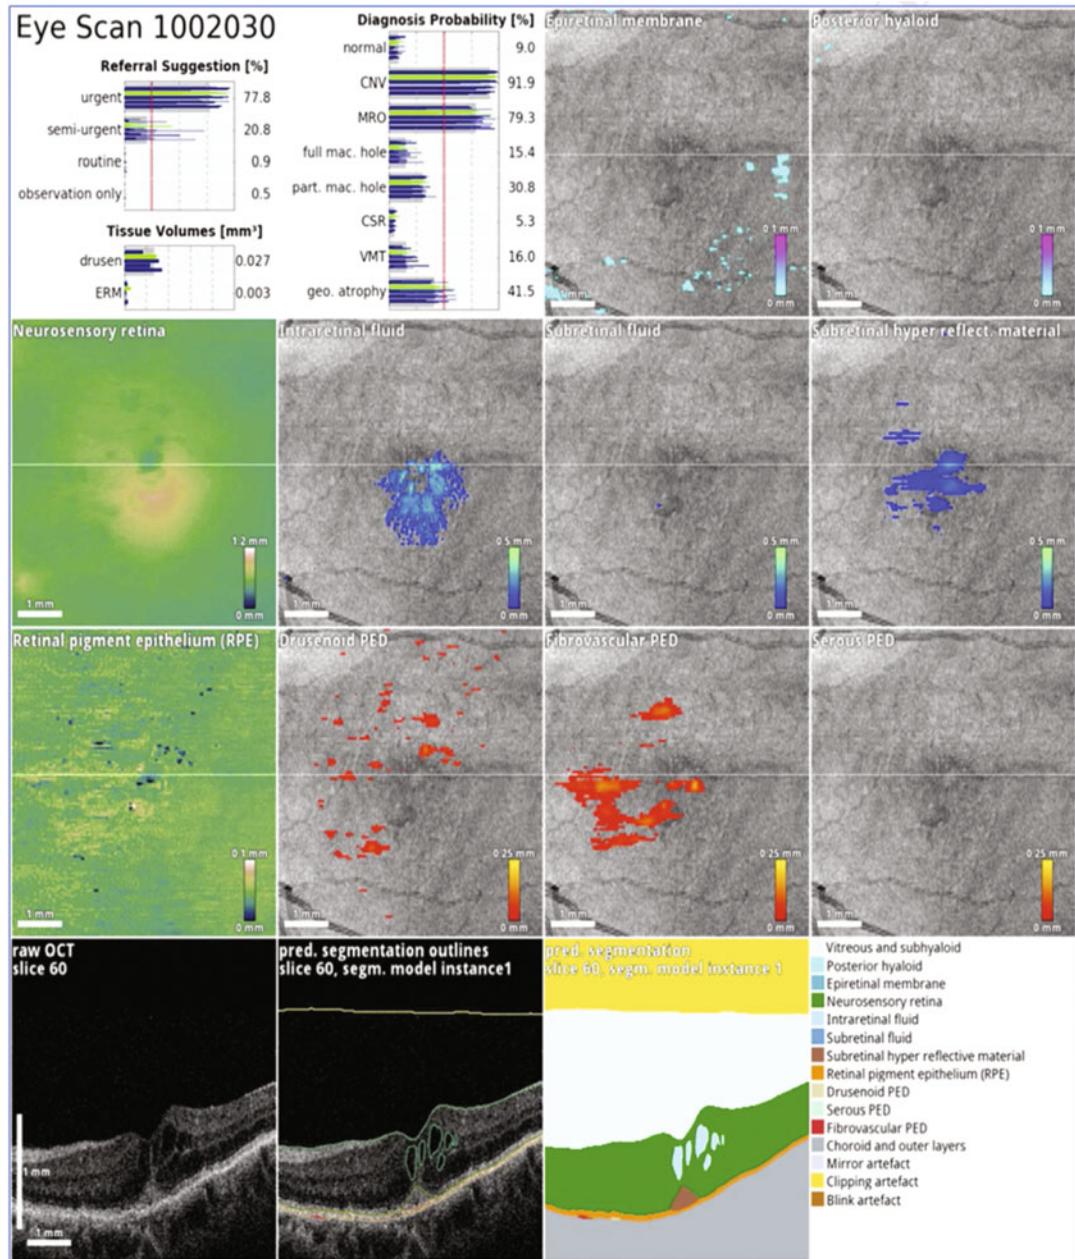

Fig. 7 DL application in the segmentation of OCT images with DeepMind. In the case of angiomatic proliferation of the retina, the system correctly segments an area of intraretinal fluid superimposed on an area of subretinal hyper-reflective material. The presence of macular edema

and choroidal neovascularization was detected and a referral to the specialist was suggested. Through the creation of a tissue representation on a 2D map (seen below and on the right), the system facilitates interpretation by the ophthalmologist [37]

different research centers, always privileging ethical and privacy standards. Data sharing also requires technical solutions, including data

storage, management, and analysis, which implies high investments in hardware and software, and specialized labor.

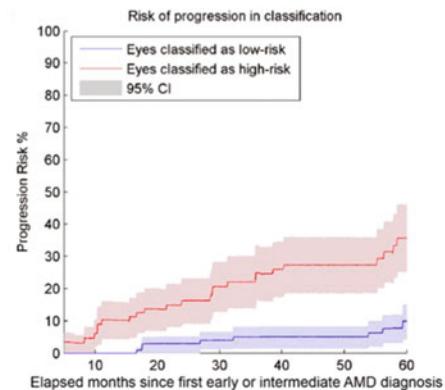

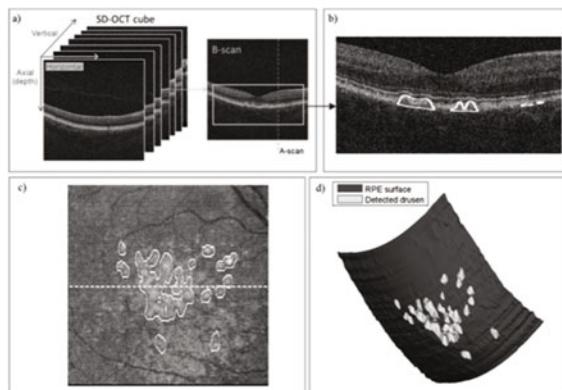

Fig. 8 Artificial intelligence to predict risk of progression of AMD from a set of quantitative parameters extracted from drusen. The system assigns each patient a risk rate and

In conclusion, AI models have consistently shown robust performance in detecting and staging a number of eye diseases using standard imaging tests in ophthalmology. Although many of these algorithms are not yet available for commercial use, it is expected that AI will soon be able to aid ophthalmologists to provide the best and effective clinical care. If eye care professionals intend to maintain control of their occupational future, they will need to understand and incorporate intelligent algorithms into practice.

is highly accurate, as shown in the Kaplan-Meier curve on the right [36]

Abstract

Depression and anxiety disorders are common and associated with considerable impairment. Although effective treatments are available, many patients do not respond sufficiently. By matching treatments to individual patient characteristics, precision medicine bears great potential for improving detection and treatment of these disorders, and AI and machine learning may be the most important tools for realizing this potential. By learning from data

with already known outcomes, predictive models can be trained which, after careful evaluation, may be used to predict unknown outcomes for individual patients in clinical practice, such as disorder onset or treatment success. For depression and anxiety disorders, a variety of potential applications have been investigated, including risk and onset prediction, (differential) diagnosis, treatment outcome prediction and treatment selection, prediction of suicidality, and relapse prediction. Many of these studies reported very promising findings, but so far, few replications or predictions in independent samples are available. Additionally, prediction performance has to be further optimized before clinical application. Rigorous research is needed in

Introduction

Depression and anxiety disorders are among the most common mental disorders [1]. Recent epidemiologic estimates suggest that 30% of all individuals will have a diagnosis of depression (i.e., a unipolar depressive disorder such as major depression or dysthymia) at some point in their life and about 40% will have one of an anxiety disorder [2]. Patients with these disorders are also frequent treatment utilizers, placing both diagnostic groups among the most common disorders seen in outpatient and (for depression) inpatient settings for mental disorders. Both clinical depression and anxiety are associated with considerable individual [3] and societal burden [4]. This includes a considerable reduction in life expectancy, in the range of 7–11 years and thus comparable to moderate-to-heavy smoking, and an about 20-fold risk for suicide, both for depression [5]. For anxiety disorders, the increase in mortality is less pronounced, but still these disorders are associated with an odds ratio >3 for suicide compared to the general population [5].

For depression and anxiety disorders, a number of effective treatment options are available. The main options for depression are pharmacological treatment, including selective serotonin reuptake inhibitors (SSRIs), serotonin–norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs), and tricyclic antidepressants as the most often used medications, and psychotherapy, including cognitive behavioral therapy (CBT), interpersonal therapy (IPT), and psychodynamic therapy as most common therapies. Further treatments are available such as electroconvulsive therapy, transcranial magnetic stimulation, and others, and are particularly applied in the case of

treatment-resistant depression. For anxiety disorders, psychotherapies are regarded as first-line treatment. The best evidence is available for CBT, but other therapies such as mindfulness-based therapies and psychodynamic therapy are used as well. Pharmacological treatment is also common, again including SSRIs, SNRIs, and others, but also benzodiazepines as acute treatment.

Although effective treatments for depression and anxiety are available, there is still a substantial portion of patients who do not respond sufficiently [6–8]. As such, patients with these disorders may have much to gain from precision medicine, which aims to match treatments to individual patient characteristics [9]. Artificial intelligence is among the most promising tools in order to realize this potential. This chapter aims to summarize the main research questions that have so far been investigated using artificial intelligence in the field, describe selected studies and outcomes, and present an outlook for the future.

AI and Machine Learning for Precision Medicine in Depression and Anxiety Disorders

The application of AI for depression and anxiety disorders is realized by the use of a specific type of machine learning, supervised learning. Basically, these methods extract the relationship between a set of given variables, called features, and a set of outcomes (labels) from known data. Importantly, this relationship is not explicitly given or defined by the researcher, but identified from the data by the algorithm, hence “machine learning.” After the relationship has been established, the algorithm can be applied to make predictions for new data, for which the outcomes are not yet known. However, before doing so, it is crucial that the algorithm is applied on independent data in order to evaluate its performance. This is necessary as the established association may not generalize well beyond the initial dataset for a number of potential reasons, such as the algorithm overly depending on noise in the initial dataset, or the initial dataset being not representative of the underlying population. The process of

establishing the association between input data and outcomes is commonly referred to as training and the process of evaluating the algorithm performance as testing. Figure 1 provides a schematic overview on the generation, evaluation, and use of predictive models via machine learning. The outlined concepts may be easily illustrated by one example from the field: imagine a patient with treatment-resistant depression. Before admission to another inpatient treatment program, the patient and clinicians would like to know whether this new program is promising. Here, a machine learning algorithm could be trained to predict response or nonresponse based on the patient's characteristics before initializing treatment. Pretreatment characteristics and treatment outcomes from previous patients in the clinic would constitute the training data. If an algorithm can be developed and shown to predict treatment outcome with sufficient accuracy, it could then be used on the patient in question, for whom the treatment outcome is not yet known. However, testing the algorithm before application in real clinical decision-making is critical in order to evaluate its generalizability to new data. This could for instance be limited if the treatment program changed between earlier patients comprising the training data and the patient in question, or if by chance only women have been included in the training data, but the patient is male.

This simple example demonstrates that the use of AI and machine learning for depression and anxiety is a complex endeavor, but it also points towards its great potential: if successful, it may be

a valuable tool supporting clinical decision-making by providing evidence-based predictions for individual patients. Additionally, machine learning models particularly excel if the outcome depends on complex interactions between a variety of variables, which is commonly the case for all kinds of clinical outcomes in the field of mental health. Finally, the machine learning algorithm builds the predictive model from the data itself with no need for the researcher or clinician to specify a certain theoretical model, which is beneficial if the theoretical connections are not yet fully understood. Outcomes can either be categorial (e.g., therapy response or nonresponse, presence or absence of a specific diagnosis), in which case the performance of the model is often evaluated in the field by examining sensitivity, specificity, overall accuracy, or area under the curve (AUC) of a receiver operating characteristic curve, or dimensional (e.g., symptom severity), in which case the model performance is often measured by quantifying the difference between true and predicted scores. Typical indices are the mean absolute error (MAE) or the root mean square error (RMSE). For optimizing the performance, a plethora of machine learning algorithms with differing advantages can be used, the hyperparameters controlling how these algorithms work can be tuned, features can be engineered, tuned, or selected to find the best predictors, and the sample size available for training and testing can be increased – models based upon larger samples usually work better until a plateau of maximum performance has been reached.

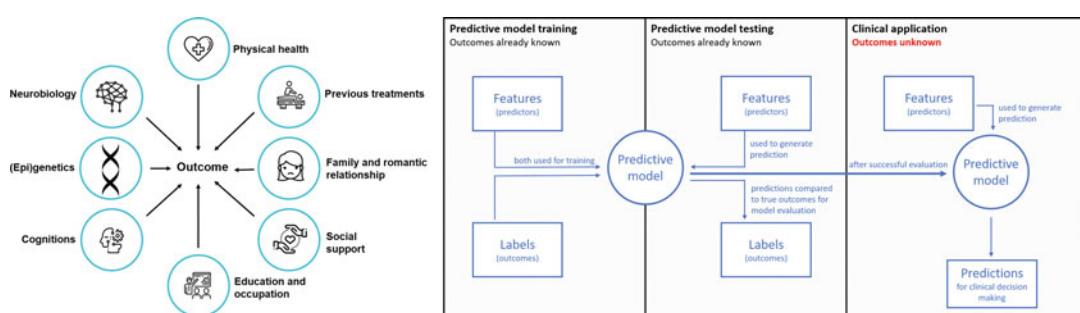

Fig. 1 A non-exhaustive selection of potential data sources for outcome prediction in depression and anxiety disorders (left side) and a schematic overview on the

process of training, testing and application of predictive models via machine learning (right side)

While the remainder of this chapter exclusively reports on findings made by supervised learning, i.e., where the outcome categories have been given by the researcher, it should be noted that there is a second type of machine learning called unsupervised learning which has also been applied to depression and anxiety disorders. In unsupervised learning, labels are not given, but the machine learning algorithm aims to find patterns in the data on its own. Common examples for unsupervised machine learning are clustering methods. In recent years, some studies employed sophisticated unsupervised learning on clinical [10] and neuroimaging data [11] in depression. The approach is interesting as it may be possible to detect subtypes associated with different disorder-courses or coming from separate etiological pathways, but as this research is still very scarce, it will not be presented in more detail here.

Aims for Using AI in Depression and Anxiety

When utilizing machine learning for depression and anxiety disorders, precision medicine can be understood more broadly, including not only treatment selection in the strict sense but various kinds of clinical decision-making based on

evidence-based predictions for individual patients. This may even include decision-making for individuals who are not yet affected by a disorder, for instance when deciding on access for indicated prevention programs based on individual risk scores. On the other end of the spectrum, it may also include decisions after treatment termination, for instance based on relapse predictions. Figure 2 uses a simplified sketch of depression symptoms before and over the course of an episode in order to illustrate stages of the disorder and associated clinical decisions which may be supported by AI in the future. Of course, the same stages and clinical decisions apply to anxiety disorders. In the following sections, exemplary studies for each field of application are presented, particular challenges or approaches are noted, and the case for AI and machine learning is illustrated. Notably, only a selection of studies can be discussed, as this is a fast-evolving field of study.

Risk

Substantial research suggests that individuals affected by mental disorders experience substantial delay before treatment is initiated, which is potentially related to individual and care-system barriers and considerable stigma still associated

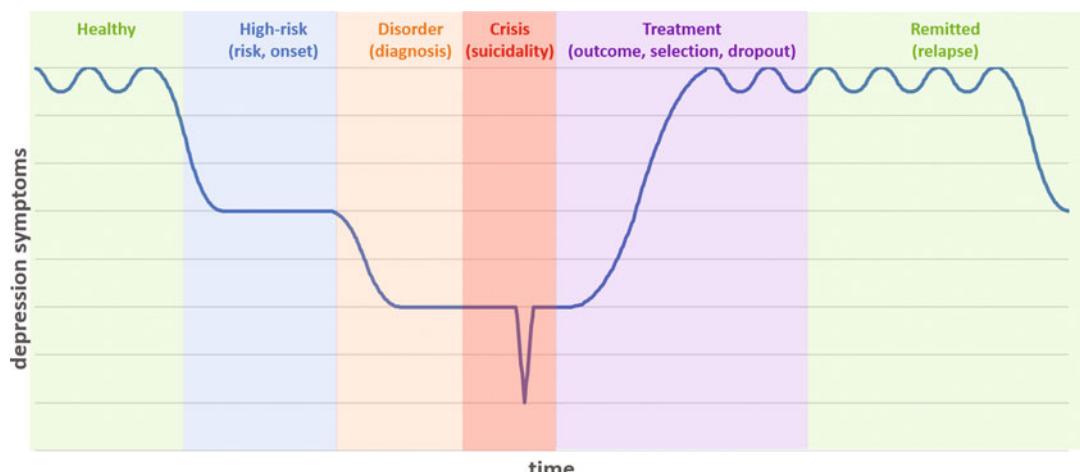

Fig. 2 The figure depicts change in depression symptoms over time, starting with day-to-day mood changes before the onset of the disorder. AI may support clinical decision

making at many different stages, illustrated by coloured boxes. Within parentheses, exemplary targets for classification and prediction via machine learning are given

with mental disorders [12]. Treatment delay is also common for depression and anxiety disorders. Against this background, individual risk prediction may be highly advantageous for identifying and monitoring high-risk individuals in order to shorten time to intervention. Additionally, prevention programs might be easier distributed to the relevant target groups. For depression and anxiety disorders specifically, a number of interesting studies have been published, but particularly for anxiety disorders there is considerably fewer data available compared to the prediction of psychosis onset or PTSD onset after trauma.

Of particular interest are two papers that built predictive models based on data from large nationwide prospective surveys, in the USA and the Republic of Korea, respectively [13, 14]. The first paper examined prediction for a range of disorders, including depression, social anxiety disorder, panic disorder, and generalized anxiety disorder, while the second study only investigated the onset of depression. Additionally, one notable difference between the studies is that the depression diagnosis was based on structured clinical interviews in one study [13], while based on cut-off scores in the other [14]. Both studies reported very encouraging prediction performances: AUCs in the first study ranged between 0.75 and 0.80, depending on the specific anxiety or depressive disorder [13], while an AUC = 0.87 was given in the second study [14]. Interestingly, the most relevant predictors differed, with clinical and biographic data such as previous PTSD comorbidity, trauma, and childhood adversities scoring high for study one [13] and satisfaction within a number of areas such as health and significant social relationships being the most important predictors in study two [14].

Given that depression and anxiety disorders often begin before adulthood, onset prediction in corresponding samples is particularly interesting. A paper by Cohen and colleagues used data from two prospective studies in youth to predict depression onset [15]. Here, a particular merit was that the predictive model was trained on one of the samples but tested on the other, i.e., the predictors had to generalize on a completely independent

sample. When using a cumulative risk score based on rumination, impairment, and negative affect in a regression approach the authors found AUCs for depression onset of 0.73 for the training sample and 0.68 for the independent test sample [15]. First studies in further high-risk cohorts such as elderly individuals or postpartum women are also emerging [16, 17].

Diagnosis

Under this umbrella section a number of studies can be sorted that investigated the use of AI and machine learning for diagnostic purposes in a broader sense, i.e., for classifying individuals with depression or anxiety disorders versus healthy comparison subjects or for classifying individuals with depression or anxiety versus other disorders. Generally, the classification of individuals with these disorders versus healthy individuals seems comparably simple, as many studies reported very high classification accuracies for this task, often exceeding 80–90% [18]. However, it should be noted that these studies often operated on small sample sizes, which may lead to overly optimistic estimates of classification performance [19]. Consequently, some reviews reported that classification accuracy decreases with increasing sample size [18, 19]. In a similar vein, a large-scale study that aimed to predict trait anxiety composite scores in a second sample unrelated to the sample where the model was trained found that the predictive model based on structural and functional neuroimaging data failed to exceed chance level [20]. Notably, trait anxiety is different although related to an anxiety disorder diagnosis, but still this methodologically well-conducted study suggests that generalization to truly independent test samples may be difficult despite promising model performance during cross-validation in the original sample.

As distinguishing individuals affected by depression and anxiety disorders from healthy individuals can usually be achieved reliably with the clinical instruments already available, supporting differential diagnosis (i.e., classifying

between several potential diagnoses) may be the more interesting case for AI and machine learning. Here, two example cases are considered: first, a current depressive episode presented by a patient is likely part of a unipolar depressive disorder, but it may also be part of bipolar disorder. Rapidly identifying those patients with bipolar disorder would be highly helpful for treatment selection, thus an AI solution might yield high clinical benefit. Second, some disorders within the internalizing spectrum such as major depression and generalized anxiety disorder (GAD) share not only a variety of symptoms and diagnostic criteria, but also risk factors or descriptive features. Again, this may hamper diagnosis and treatment selection and thus make an interesting use case for AI and machine learning. For the classification of unipolar depressive versus bipolar patients, early studies in comparably small samples found high classification accuracies of 90% and 81% for functional [21] and structural [22] MRI data. Also using neuroimaging data acquired with near-infrared spectroscopy, Takizawa and colleagues classified more than 400 matched patients with current depressive symptoms but an underlying diagnosis of major depression, bipolar disorder, or schizophrenia that were collected at seven different sites [23]. Optimal thresholds for binary classifications were determined on data from one site and then tested on data from the remaining six sites, achieving AUCs of 0.74 for depression versus bipolar disorder and 0.86 for depression versus schizophrenia. While these accuracies are somewhat below those from initial studies, they were achieved in considerably larger and more heterogeneous multisite data. These promising results are complemented by a very recent work using routinely acquired outpatient data in order to predict transition to bipolar disorder within 3 months after initializing depression treatment with antidepressants [24]. Several models were trained in the largest part of a first cohort comprising more than 40,000 patients in total, and then tested on a heldout set from this first cohort as well as on a completely independent second cohort of more than 25,000 patients. The best performing models achieved AUCs of 0.76 in the heldout data from

the first cohort and of 0.70 in the independent second cohort [24]. With its very large sample and independent out-of-site testing, its reliance on routinely acquired outpatient data and its naturalistic setting with very imbalanced groups (i.e., very few patients transitioning to bipolar disorder), this final study shows outstanding internal and external validity. For the classification of unipolar depressive versus other internalizing patients, an example study used clinical questionnaire, structural MRI, and cortisol data to separate individuals with GAD and major depression from healthy individuals and then to separate the individuals with major depression but without GAD from those with both disorders or GAD only [25]. In this study, clinical questionnaire data alone was sufficient and suitable to separate healthy individuals from individuals with a disorder, but only MRI and cortisol data was suitable to separate the diagnostic groups. When combining all multimodal data types, significant classification models for both tasks could be constructed [25]. Despite its limited sample size, this study demonstrates that some data types may be more suitable for some tasks than others, and provides an interesting case for the combination of multimodal data using machine learning.

As the selection of studies presented here demonstrates, a substantial proportion of studies in the literature used neuroimaging data for these classification tasks. However, also other modalities are increasingly investigated, with some of the most intriguing approaches using data that can be collected with no additional effort in real life, such as passive smartphone data, wearables, or social media postings. In the long term, this may enable identifying affected individuals that have not yet established contact to the health system very quickly and thus may lead to shortened delay until treatment is initiated.

Treatment Outcome

The prediction of treatment outcomes based on individual patient information is at the core of precision medicine. For depression and anxiety disorders, an increasing number of studies

becomes available, with many investigations reporting promising and encouraging results. Still, findings for the prediction of treatment outcomes are often based on very distinct predictive models, with few conceptual replications or comparable approaches across studies. In order to provide a concise overview, this section will point out three recurring themes in the literature, starting with the emergence of comparably large-scale studies for binary outcome prediction across a number of settings and samples, then outlining the use of the personalized advantage index (PAI; [26]) for predicting superiority of one treatment over another for an individual patient, and finally describing the repeated finding of anterior cingulate cortex-based neuroimaging predictors that achieve good prediction performances in depression and anxiety disorders.

There are a number of binary outcome studies (e.g., remitter or responder vs. nonremitter or nonresponder) in samples of considerable size available. A first study trained a model to predict remission after SSRI treatment in a sample of approx. 2000 patients and reported prediction performance in several treatment groups of an independent sample [27]. Interestingly, the predictive model's capacity to generalize was dependent on the antidepressant type: accuracies of 59.6% and 59.7% were achieved when predicting outcomes in groups treated with SSRI alone or in combination in the independent sample, while only a non-significant accuracy of 51% was achieved for a group treated with antidepressants different from SSRIs. Comparable prediction performances were reported in a study predicting treatment dropout across two large treatment centers totaling more than 20,000 patients for model training and more than 15,000 patients for testing [28]. Here, prediction resulted in a mean AUC of 0.68 in the independent test sample for the best performing approach. Again, roughly similar prediction performances were achieved in a third study across several psychiatric hospitals comprising more than 40,000 inpatient episodes [29]. When training the model on all but one of the included institutions and predicting on the heldout hospital, the mean AUC for nonresponse was 0.65. Finally, a fourth study predicted remission in a sample of

approx. 2000 CBT outpatients who on the majority had a diagnosis of depression or anxiety and reported a balanced accuracy of 59% for the heldout set [30]. All of these studies used substantial samples sizes and powerful approaches for validation and additionally, all of these studies used sociodemographic and clinical data for building the predictive models, although the exact information included varied. Given these similarities, it is an interesting finding that prediction performances were in a comparable range. It remains to be seen whether such binary predictions can be made considerably more accurate without including new data sources.

A second trend is using the PAI [26] to predict which one of two available treatments will result in superior outcomes for a given patient. By identifying predictor variables that do and do not interact with the treatment, outcome predictions for the treatment a patient actually received and the treatment a patient did not receive can be made [26]. The difference between the predicted outcomes for the optimal (i.e., superior) and non-optimal (i.e., inferior) treatments is the PAI [26]. A PAI closely around zero indicates that both available treatments are predicted to perform comparably for a given patient, while PAIs with increasing absolute values indicate an increasing predicted benefit of one treatment over another [32]. The PAI can then be evaluated by comparing the outcome scores of patients who received their optimal treatment to those who did not; if the model is useful, patients who received their optimal treatment should have significantly better outcomes scores such as lower severity measures [26]. This approach has been used in a variety of studies to predict optimal treatment for depression, for example, for CBT versus antidepressants [26], CBT versus psychodynamic therapy [31], CBT versus IPT [32], or for comparing different CBT variants [33]. The PAI may be superior to binary (e.g., response versus non-response) outcome prediction as it uses a dimensional perspective and thus may also predict treatment superiority if outcomes for both treatments fall into the same overall outcome category. Additionally, while the specific statistical approach varied between some of the studies, the

overall PAI framework provides some similarity in the general approach. Intriguingly, statistical treatment outcome prediction using the PAI also outperformed predictions by clinicians in one study examining cognitive therapy versus IPT for depression [34]. Still, also for the PAI, specific predictive models from the individual studies have to be thoroughly evaluated in new, independent samples.

A third recurring theme is the predictive performance of anterior cingulate cortex (ACC) structure, function, and connectivity for treatment outcomes, particularly for depression and social anxiety disorder. For depression, a differential pattern of subcallosal ACC resting-state connectivity predicted remission after antidepressant and CBT treatment, respectively [35], and subgenual ACC activation predicted response to cognitive therapy in two independent samples [36]. In patients with social anxiety disorder, functional activation in the dorsal ACC during fMRI tasks predicted treatment response to Internet-delivered CBT with antidepressant or placebo [37] and, together with amygdala activation, to Internet-delivered CBT alone [38], while functional activation in the rostral ACC during emotion regulation predicted treatment response to face-to-face CBT [39]. Further results are reviewed elsewhere [40]. Despite these promising findings, it is important to note that a considerable variety of tasks, fMRI analytic methods, and machine learning approaches have been used in these studies. Furthermore, while prediction accuracies mostly ranged between 70% and 92%, sample sizes overwhelmingly were limited, risking overly optimistic estimates. Nevertheless, these studies provide a convincing foundation for future work examining the potential of the ACC for treatment outcome predictions.

Suicidality

Clearly, suicidality is one of the most severe symptoms associated with depression and, to a lesser degree, with anxiety disorders. Suicidality can be broken down in different stages with increasing proximity to actual suicide, from suicidal thoughts and ideation, to plans, and to suicide attempts. Particularly in moderate to severe

depression, suicidal thoughts are comparably prevalent, while plans and attempts are still less common. It is immediately clear that accurate prediction of emerging suicidality and particularly of suicide attempts would have tremendous clinical benefit and would provide a valuable tool to prevent actual suicides. Thus, it is a promising development that in recent years, a considerable number of studies aimed to use machine learning for individual prediction of suicidality.

In one exemplary study, suicide attempts were predicted for varying time intervals within the range of the next 7 days to the next 2 years from electronic health data using random forests [41]. The predictors from the electronic health data included for instance sociodemographics, diagnoses, medication data, past health care utilization, and past suicide attempts. One particular feature of this study is noteworthy: those without a future suicide attempt were selected from two groups: in one analysis, these individuals were hospital cases without a record of suicide attempts, while in the other analysis, these individuals also showed self-injury, but without suicidal intent. As expected, predicting future suicide attempts versus nonsuicidal self-injury was harder than predicting future suicide attempts versus general hospital cases, but both predictions showed very promising results, with AUCs of 0.84 and 0.92, respectively, for suicide attempts within the next 7 days. Also, prediction performance was only slightly decreasing for larger time intervals. Besides focusing on actual suicide attempts as a clinically relevant outcome, the study excels through its large sample size of approx. 5,000–15,000 patients for these analyses. An important point to keep in mind however is that the presented study requires that a suicidal individual has already established some sort of contact to the health system. As this cannot be taken for granted, there is increasing interest in using publicly available data for the prediction of suicidality (e.g., [42]).

Relapse

In contrast to other potential applications, the prediction of relapse, readmission, or rehospitalization versus lasting treatment success

has not received much attention so far, and only few studies are available. However, this might change, as a substantial proportion of patients experience reoccurrence of symptoms. Predictive models could be valuable to identify patients for receiving additional treatment doses such as booster sessions in psychotherapy or for intensified monitoring after treatment termination. Among the few studies available, one predicted relapse within 12 months after terminating CBT for depression and anxiety problems [43]. Four separate models were investigated, which used information gathered up to and including different time points (baseline only, treatment termination, 1-month follow-up, and 3-months follow-up). Relapse was predicted with an AUC of 0.72 based on baseline data and did only somewhat increase to a final AUC of 0.84 with more data becoming available, although prediction sensitivity and specificity varied considerably across the models. A second study is available that predicted rehospitalization within 2 years after treatment with most patients receiving medication [44]. Here, the best prediction achieved an AUC of 0.68. Although both studies are roughly comparable in their sample sizes of between 300 and 400 patients, a notable difference is that the first study only used sociodemographic and clinical predictors, while the second study also included structural MRI, blood serum, and sleep information. The benefit of this additional information was only moderate, however.

Outlook

Within the field of mental health, and particularly for depression and anxiety disorders, there is considerable interest in applying AI and machine learning methods under the broad framework of precision medicine. This approach bears great potential for improving the detection and treatment of mental disorders, but at the same time, there seems still a long way to go before clinical application. While sample sizes in some studies are becoming substantial and methods get more and more refined, most work is still on a “proof-of-concept” level. That means, initial results appear promising and worthy of further

investigation, but prediction accuracy may be far from clinical utility, or results are accompanied by considerable limitations. Moreover, predictive models are usually trained from zero for every study, but rarely applied across studies, which would be paramount to evaluate replicability and generalizability. Additionally, there may be considerable publication bias, with many prediction studies in small samples that do not provide significant results remaining unpublished. In order to move forward, more systematic research is needed that replicates and validates promising predictive models. In their excellent paper, Woo and colleagues give a formal characterization of the needed research program, where the most promising candidate models are examined further, from initial studies in single, small datasets to replication and generalization in other samples, sites, and settings until, eventually, the population level may be reached [45]. Across these stages, the predictive models also get more and more characterized regarding their performance overall and for specific groups and settings. Although originally aimed at neuroimaging models, this framework can be applied independently of data modality.

Considering such a research program emphasizes the need for datasets of substantial sample size. Ultimately, even representative samples for certain populations may be needed. Acquiring large datasets in the field of mental health and particularly for patient data is very challenging due to a number of reasons, including data privacy and confidentiality. The need for large sample sizes is furthermore related to the open question which kind of data is needed for good predictive models: it is probably not by chance that the studies with substantial sample sizes presented in the section on treatment outcome all used sociodemographic and clinical data for prediction, which is often either routinely collected in naturalistic settings or represents the backbone of data collection in large clinical trials. However, it is unclear whether predictive models suitable for clinical use can be constructed based on this data alone. It may be that more specific clinical assessments, for instance including etiologic or maintenance factors, or additional data modalities such as EMA,

MRI, or others are needed. In a very promising development, the last years have seen increasing efforts across many fields to acquire new large-scale datasets or to share and pool already collected data. Some examples in the neurosciences and in mental health may be the UK Biobank sample, the ENIGMA consortium, or the German KODAP initiative. These and similar initiatives may play a crucial role in the development and validation of AI and machine-learning-driven predictive models for depression and anxiety in the future.

Beyond the more and more extensive evaluation of prediction performance, the framework by Woo and colleagues also specifies that the performance of predictive models needs to be characterized more in depth with subsequent stages of testing [45]. At the moment, prediction performance is often given only by one or few metrics for the complete test sample. However, this may not be enough, given that it appears that statistical models may either discriminate against or produce incorrect results for certain groups, depending on the representation of these groups during the training stage of the model [46]. This may affect predictive models for depression and anxiety disorders as well. In the future, it will become more and more important to evaluate prediction performances in relationship to relevant sociodemographic and clinical characteristics (see recommendation in [47]). Again, this may speak in favor of collecting and using representative samples at some point. Finally, beyond the construction, optimization, and evaluation of the predictive models, there are a number of further ethical, legal, and societal aspects that may influence the development, application, and acceptance of predictive models in the field [48].

In conclusion, precision medicine bears great potential for improving the detection and treatment of depression and anxiety disorders, and AI and machine learning may be the most important tools for realizing this potential. However, while research interest increased considerably in recent years, the field is just starting to develop. Rigorous research with replication and evaluation of promising predictive models is needed in order to move toward clinical application.

Abstract

Autism spectrum disorder (ASD) is a chronic and extremely heterogeneous neurodevelopmental disorder, difficult to diagnose and with a still unclear multifactorial etiology. Given the scarce knowledge on this condition the research cannot be hypothesis-driven and must range across various sub-fields of biology and medicine, analyzing the big data produced by last generation healthcare and smart technologies. Artificial intelligence (AI) can

represent a valuable tool in this context, thanks to its ability to automatically discover complex patterns in high-dimensional data. This work represents a guide to the use of AI for research on ASD, describing various possible applications, which can differ for their objective (improving diagnosis, ranking severity, defining subtypes of ASD, drug discovery, etc.) and field (genetics, structural and functional neuro-imaging, etc.). For each application, the nature of the data and the most appropriate AI techniques to analyze them are described, along with illustrative examples of successful studies. The guide also includes a discussion on the major challenges currently affecting AI-based research on ASD: the lack of data and the subsequent problems of overfitting and confounding effects. Finally promising future research avenues, such as the adoption of explainable AI and ensemble learning are outlined.

Introduction

Autism spectrum disorder (ASD) is a chronic and extremely heterogeneous neurodevelopmental disorder characterized by deficits in communication and social interaction, in addition to restricted and repetitive patterns of behavior [1]. According to the Autism and Developmental Disabilities Monitoring Network, the latest estimate of ASD prevalence in the USA is 1 in 59 [2], with a male to female ratio of approximately 3:1. Symptoms may be visible already at 6 months of age, becoming explicit around the second or third year, and may vary widely along lifespan.

Several evidences suggest a genetic liability for ASD. For instance, the individual risk of ASD is much higher in families with one member already diagnosed with it: approximately 10 times greater in subjects with a sibling with ASD [3]. Furthermore, in these families even undiagnosed members can show autism-related traits, termed broader autism phenotype. Despite substantial progress has been made in understanding ASD genetic underpinnings, most ASD-associated DNA variations account for no more than 1% of ASD cases and very few of them lead to ASD in every carrier [4]. All these considerations suggest a *complex or multi-factorial* nature of ASD [5]. According to various researchers in fact the ASD etiology may be explained in terms of a multifactorial threshold model, meaning that ASD is caused by the accumulation of both genetic and environmental risk factors over a certain threshold that determines a diagnosable phenotype. In such a model, the broader phenotype can be explained by the presence of a lower, but still high, number of risk factors (see Fig. 1).

The scarce knowledge on the causes of ASD limits the progress in the research and development of targeted therapies; however, many psychological treatments exist, that can improve the quality of life of the subjects with ASD. Such treatments proved to be more effective when started at an early age and thus an early diagnosis is of fundamental importance [6]. However, diagnosing ASD is a difficult task requiring psychiatrist assessment, since no quantitative biomarkers exist and the heterogeneous behavioral symptoms can be easily misunderstood or ignored during infancy.

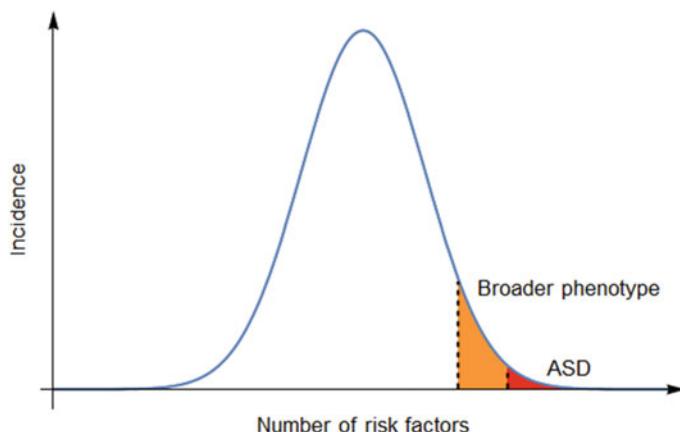

Because of the multifactorial nature of ASD and the lack of knowledge about it, the research on this disorder cannot be hypothesis-driven and must range across various sub-fields of biology and medicine, analyzing high-dimensional data such as DNA sequence, gene expression, and neuroimaging data. In this kind of open ended research, Artificial Intelligence (AI) can be very promising, because of its ability to autonomously discover complex patterns in large datasets, requiring minimal preprocessing and data domain expertise.

AI Applications for ASD: Objectives, Data, and Challenges

As detailed in the introduction, the scarce knowledge on ASD and its heterogeneous etiology and phenotype allow a wide variety of approaches to study this condition. In this section some of the most important and promising AI applications to study ASD are presented and categorized according to two criteria: the objective of the analysis and the research field. Challenges in the application of AI methods are also discussed at the end of this section. A brief presentation of all these contents is also provided in (Video 1).

Throughout the text, several AI methods are simply mentioned while for some a brief and qualitative description is reported. In any case an in-depth discussion of the algorithms is out of the scope of this chapter. More details about clustering, conventional machine learning (ML) (such as logistic regression, support vector machine,

Fig. 1 Multifactorial threshold model applied to ASD. According to this model, ASD is caused by the accumulation of certain amount of risk factors, which are naturally present in the population, but are more numerous in ASD subjects. The broader phenotype can be explained by the presence of a lower but still high number of risk factors

random forest, etc.) and multivariate regression-based methods can be found in this book [7], while a comprehensive reference for deep learning (DL) method is provided in [8].

Objective-Based Categorization

In this section, different approaches to study ASD are outlined, subdivided by their objective. Although several different aims are described, by far the most common one is *automatic/early diagnosis*. In fact, as previously said, ASD diagnosis is currently very complex and somewhat subjective, and thus may greatly benefit from the discovery of an objective classifier based on a quantitative biomarker.

Automatic/Early Diagnosis

Automatic diagnosis is the typical application for which a categorical classifier based on ML or DL techniques is employed. Basically, a classification algorithm is trained to distinguish between two classes of subjects, the ASDs and Healthy Controls (HCs), which are represented by a set of data, that can range from medical images and records to domestic videos of the subject behavior. The objective is to obtain an accurate and sensitive predictor able to provide a diagnosis on new subjects with acceptable performance. If a reliable classifier is found, it can be used for computer-aided diagnosis or for a screening program to identify subjects at risk. If this algorithm also

performs well on subjects of pre-verbal age, it can be used for *early diagnosis*. This application may have a large social impact, given that treatments started before the first year of life can significantly improve the quality of life of ASD subjects.

A wide range of studies encompassing several fields of research can be categorized under this label and many examples will be provided in section “[Field-Based Categorization](#).” Particularly encouraging results have been obtained on electroencephalography (EEG) data with standard ML methods, and in video analysis with more complex DL approaches. However, these fields are less explored, compared for example to magnetic resonance imaging (MRI), and the few studies available have been conducted on small datasets, making the assessment of their reliability more difficult.

Severity Recognition

Severity recognition is mainly performed using a multivariate regression approach. Usually a ML algorithm is trained to reproduce a score measuring symptom severity or disability degree of input subjects. Typical scores reconstructed can be ASD-specific such as ADOS and ADI [9], but also more generic indicators such as Intelligence Quotient (IQ) or Verbal Intelligence Quotient. As for *automatic/early diagnosis* applications, the input data representing each subject can be very heterogeneous, but the most common approach consists in trying to infer an ASD-related score from brain MRI data. The objective of this kind of

studies is to understand if the severity perceived at the behavioral level and measured with such scores can be extracted from biomedical data, meaning that there is a measurable biological feature that correlates with such scores. An example of a *severity recognition* study is described in [10]. The authors used a multivariate regression method on structural MRI (sMRI) data to predict the ADOS score (ranging from 0 to 10) achieving an average absolute error of 1.36. Similar results have been obtained also using task-based functional MRI (fMRI) data [11].

Subtypes Definition

Considering the heterogeneous nature of ASD, another interesting approach consists in finding more homogeneous subgroups of ASD using clustering algorithms. Decomposing the heterogeneity might help in the definition of ASD subtypes that individually may be easier to distinguish from HCs. Furthermore, given that ASD heterogeneity ranges across multiple sectors (i.e., genetics, neural systems, cognition, behavior, development, and clinical topics), a possible approach consists in comparing data-driven subtypes defined in different fields. An example of this technique is given by [12], in which severity-based subtypes of ASD obtained with clustering methods applied to ADI and ADOS information have been genetically analyzed. An increased genotype similarity within subjects belonging to the same subtype was observed, suggesting that subjects with similar symptom severity may have similar genetic etiology.

Longitudinal Studies

Given that ASD symptoms can naturally change during lifespan or in response to treatments and stressful/traumatic events, longitudinal studies can be very important to understand the disease. However, collecting data of the same subjects along time can be very resource-intensive and this limits the number of works of this kind. Despite these studies are mainly designed with the same aim and methodology of the previous applications, they deserve a distinct category because the data collection process and the conclusions drawn are substantially different.

For instance, a *longitudinal study* for *early diagnosis* may use data collected multiple times during early childhood to train an ML to distinguish ASDs from HCs analyzing the temporal evolution of the subject records. This approach has been adopted using multiple behavioral and developmental measures acquired between 8 and 36 months of age, showing that already at 14 months ASD and broader atypical development can be classified with an area under the receiver operating characteristic curve (AUC) of 71% [13]. Another possible approach, tailored for *severity recognition*, consists in using past records to predict disease evolution after a certain temporal interval. With this aim, using a multivariate regression on features extracted from resting-state fMRI (rs-fMRI) data, it has been shown that it is possible to predict improvements in adaptive behavior scores after more than 1 year with 100% sensitivity and 71% precision [14].

Explorative Analysis

The approaches belonging to the first three categories described above can be evaluated with quantitative measures, such as accuracy, sensitivity, and AUC for categorical classifications, mean squared error for regressions, overlap, and centroid distance for clusterings. However, as it will be better explained in section “[Challenges of the AI-Based Research on ASD](#),” in ASD research it is very difficult to achieve good and reproducible results. For this reason, a valuable study must not be restricted to the sole production of a satisfactory result as measured by the aforementioned metrics, but must also include an analysis of the data that mostly drove such result. For example, an ML/DL-based analysis should include an explanation of the decisional process learned from the data; a regression-based one should provide a measure of the variance explained by each independent variable; a clustering-based one should report the features that characterize each cluster.

Thus, in this objective oriented categorization, the distinct label of *explorative analysis* is dedicated to studies that include the mentioned explanations. Providing an intelligible interpretation of the results also facilitates the comparison with other studies, which would be otherwise

impracticable using only performance-based metrics, and can provide new insights about the disease even without achieving state-of-the-art performance.

For instance, in one recent *explorative analysis* [15] for *automatic diagnosis* based on sMRI derived features and reaching an AUC of 79%, the authors performed a wide permutation test to isolate the most reliable part of the entire decisional pattern found by the classifier. Surprisingly, they showed that this reduced pattern is still able to capture mean differences between ASD and HC classes, using substantially different data, that is, acquired with different modalities and recruitment criteria. This study proves the importance of explainability in ML/DL applications in order to collect reliable results.

Drug Discovery

Given that the exact causes and a common biomarker of ASD are still unknown, it is very difficult to conduct drug discovery studies and the few ones currently ongoing are not based on AI, but on more conservative approaches. However, as already said AI is perfectly suited for this kind of open ended analysis involving large number of data. For instance, it has been shown that a DL model trained with experimental data of drug effects on singular cells can predict pharmacological effects (such as toxicity, efficacy, therapeutic use) on the entire human organism [16]. In the specific case of ASD, after the discovery of some protein-coding genes directly involved in syndromic forms of the disorder, the use of AI has been suggested for *target druggability* applications, that is, identification of the genes, out of the ones involved in the disease, that are likely to be successfully targeted by existing drugs [17].

Teaching and Interaction

Children with ASD have from moderate to severe difficulties in socialization, verbal and non-verbal communication, and understanding other perspectives: abilities that significantly affect the learning process. For this reason, computer-aided learning has been extensively analyzed proving that ASD children show a preference for electronic screen media, computer-generated speech, and

game-like elements. In this context, AI can really make the difference, allowing targeted learning and personalized interaction. For instance, a smartglasses-based augmented reality system based on AI has been developed to teach ASD children life skills that may facilitate or enhance self-sufficiency. The device implements a DL algorithm that recognizes facial expressions viewed by the user and teaches to him/her how to interpret them [18]. Another interesting application is the development of robots able to interact with humans and the environment, thanks to the continuous AI-based analysis of audio and video data collected in real-time. This application seems very promising, in fact, it appears that ASD subjects pay more attention and reduce the repetitive behaviors when interacting with the robots rather than with people [19].

Field-Based Categorization

This section provides a summary of the main fields of research on ASD where AI can make the difference. Each field description focuses on the peculiarities of its data and on which AI techniques are most suited to them. To show the potential impact of each field, some illustrative studies are reported. Since, as explained in the previous section, ASD research is commonly oriented toward *automatic/early diagnosis*, most of the studies reported are based on the use of ML/DL techniques to classify ASDs from HCs; however, all the other approaches detailed in the objective-based categorization are also possible in the fields mentioned here.

Brain Structural Imaging

Brain structural imaging can be done essentially with computed tomography (CT) and sMRI. However, the last one is usually preferred for research purposes because it allows a better diversification of the brain soft tissues and it does not use ionizing radiations, thus it is totally safe also for children.

SMRIs are 3D images, depending on the spatial resolution adopted, they can be composed by up to tens of millions of voxels (i.e., 3D pixels),

and, when decompressed, they usually occupy tens of MBs.

Due to their large volume, typically these images are processed using dedicated algorithms to extract meaningful properties and features, such as volume, surface area, thickness of various brain regions, or structural connectivity via diffusion tensor imaging techniques. Then conventional ML methods are usually applied to these features for *automatic/early diagnosis* applications. Alternatively, raw or minimally pre-processed sMRIs can be analyzed using DL algorithms which accomplish the feature extraction process and classification integrally. The most commonly used DL algorithms are convolutional neural networks (CNNs) or their derivatives, which proved to be highly performant in extracting relevant features while taking into consideration spatial dependencies important in images [8] (see Fig. 2).

Thanks to its non-invasivity and high spatial resolution, MRI (both functional and structural) is the most used technique to study ASD and to date there is a high number of papers on the application of AI to MRIs, mainly for *early/automatic diagnosis* and for the discovery of a quantitative biomarker of the disorder. Studies have been conducted both on small cohorts of homogeneously scanned subjects and on large, multicenter datasets of images acquired using different modalities, scanners, and recruitment criteria. Despite this large body of literature, a consensual anatomical biomarker for ASD based on sMRI is still missing. In fact, the results obtained are very

heterogeneous and often not significant, since they allow to distinguish ASDs from HCs with an accuracy often lower than 60% [20] on the largest datasets, while the few higher-performing results are rarely replicated in subsequent studies or with bigger samples [21]. However, particularly worth mentioning is a prospective study [22] conducted on a large sMRI dataset of infants between 6 and 12 months with both high and low risk for developing the disorder, aimed at understanding a long debated observation: early increased brain volume in ASD development. The authors showed that hyperexpansion of the cortical surface area precedes brain overgrowth observed in 15 high-risk infants who were subsequently diagnosed with ASD. Relying on this assumption, they trained a DL algorithm with structural features extracted from MRIs encoding the growth of brain regions, achieving a true positive rate of 81% and a sensitivity of 88% in predicting ASD in high-risk children [22].

Brain Functional Imaging

Brain functional imaging can be done with different techniques, each capturing different properties of brain activity. The most employed ones are: positron emission tomography (PET), EEG, and fMRI.

PET provides brain metabolic information. During a PET exam, a radioactive tracer bound to a molecule of metabolic interest is injected into the patient and, thanks to its emissions, the scanner can reconstruct the spatial distribution of the molecule, revealing in which tissues it is

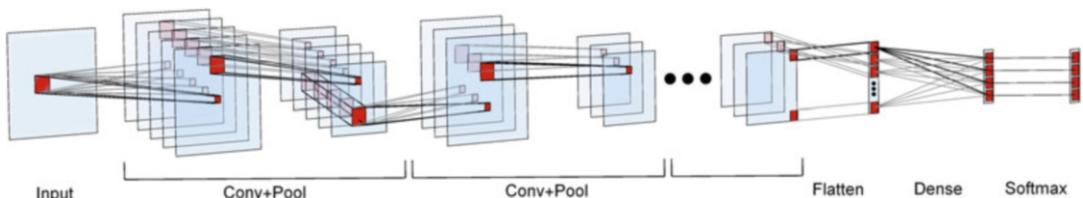

Fig. 2 Structure of a CNN. A series of convolutional and pooling layers is followed by a flattening operation and a sequence of dense layers, ending in the classification layer (Softmax), which contains the probability of the input of belonging to each possible class. A convolutional layer extracts spatial (or temporal) features through stackable receptive fields (called kernels) with tunable size. The

size of the kernel determines the resolution with which the layer sees the input, while the depth of the layer determines the level of abstraction of the feature extracted. More shallow layers will therefore recognize lines, points, and basic shapes, while deeper layers will extract more complex and complete features, up to the characteristics that allow the final classification

accumulated. With PET it is possible to acquire a single image, that recapitulates the distribution of the molecule after a certain period of assessment, or a video recorded while the subject is performing a certain task, to analyze the metabolic changes during that task. Usually PET images are composed by between 500,000 and 5,000,000 voxels, depending on the spatial resolution adopted and videos usually acquire 1–10 frames per minute. The dimension of a PET scan can be roughly estimated in the range of tens of MBs per frame, as an sMRI.

Given that PET requires exposition to ionizing radiation and an intravenous line for radioactive tracer injection, it is not suited for research purposes on young subjects. However, for its ability to investigate complex metabolic process in the brain, not otherwise analyzable, PET-based research has been carried on involving small groups of adults. The scarcity of participants currently limits the possibility to apply AI approaches, but the important perspectives of this field and the need to analyze high-dimensional and complex data suggest that PET-based studies will be a promising application for AI.

For ASD research, the study of cerebral blood flow (CBF) and glucose metabolism (GM) along with the most peculiar PET application, that is, pharmacokinetics, are particularly promising. Traditional data analysis studies on CBF consensually show the presence of hypo-perfusion of temporal lobes and in speech related areas in ASD subjects, while with GM an atypical metabolism in cingulate, parietal, and occipital cortex during memory tasks is observable in ASD subjects. A rare example of the application of AI on PET data consists in the use of standard ML algorithms for *automatic diagnosis* to discover multivariate combination of hypo- and hyper-perfusion characterizing ASD brain. The classifier trained reached an accuracy of 88% and an in-depth analysis of the decisional pattern shows that ASDs present a hypo-perfusion in right superior temporal sulcus and hyper-perfusion in the contralateral postcentral area of the brain [23].

Electroencephalography (EEG) records the electrical activity of the brain, by detecting the

electrical pulses that propagate along neuron sequences aligned with pairs of electrodes placed on the head. The main limitation of EEG is the difficulty to place the electrodes in the same exact position for each patient, due to the high variability of head dimensions. This clearly represents an important obstacle to data comparison across a cohort of subjects and to studies aggregating data from multiple sites.

EEG data consist in a set of time series, called channels, that depending on the protocol adopted can vary between 3 and 130. Single raw channels are acquired with a sampling frequency between 100 and 500 Hz. Thus, for task-based studies, with acquisition duration in the order of the tens of minutes, the data size can easily exceed 50 MB. EEG data are very difficult to interpret in a medical perspective, thus usually they are analyzed extracting statistical features typically employed to describe time series, such as average, standard deviation, signal power (i.e., the average of the squares of its values), and their corresponding measures in the Fourier space. All these features (and possibly others) are calculated on different frequency bands, known to contain electrical signals from brain activity and conventionally named with Greek letters.

According to a recent review on this matter, many studies have been conducted using EEG-based features to train ML algorithms for ASD diagnosis, reaching very high accuracy values [24]. In fact, the reference reports 10 recent studies obtaining between 90% and 100% of accuracy. To date, this application is one of the most promising for finding an ASD quantitative biomarker, but it should be considered that available studies are usually conducted on small cohorts (usually less than 40 subjects). Furthermore as it has been extensively described for MRI applications, it is likely that also for EEG the equipment and the infrastructure used to record data (i.e., electrode locations, number of channels, sampling rate) may strongly influence the trained classification algorithm, making classifying EEG data acquired with a different setup almost impossible. Another issue is the difficulty in giving a physiological interpretation of a possible EEG-based biomarker for ASD, which would

corroborate the findings. However, in the specific case of a syndromic form of ASD caused by the duplication of a portion of the 15th chromosome (and thus called Dup15q), an EEG biomarker with a reasonable physiological interpretation has been found [25]. In fact, it has been observed that subject with Dup15q presents higher signals in the beta frequencies band with respect to both non-syndromic ASDs and HCs. This signature similarly appears in subjects treated with drugs that enhance the effect of the GABA neurotransmitter, which is also regulated by genes that are duplicated in the subjects with Dup15q.

Functional MRI (fMRI) allows to detect the changes in the magnetic properties of the brain due to the transport of oxygenated blood in correspondence of neuronal activity, providing thus an indirect measure of spatial and temporal brain activity. FMRI exams can be done while the subject is performing a certain task, to analyze which brain areas are involved in the task, or at rest to study spontaneous brain activity (resting state fMRI, rs-fMRI). This last exam is much simpler to perform on ASD subjects which, depending on the severity of the disease, may not be very collaborative in task execution.

FMRIs are 4D images (three spatial dimensions and a temporal one); depending on the resolutions adopted and on the duration of the task for fMRI or on the protocol followed for rs-fMRI, an acquisition can contain between 10 and 100 millions of data points, corresponding to 20–200 MB.

Similarly to sMRIs, fMRIs are usually pre-processed using dedicated toolboxes and pipelines which collect multiple important steps, such as skull removal, temporal filtering, head motion correction, and slice timing correction, that is, the temporal alignment of signals coming from different slices of the brain which have been acquired asynchronously. Another common step consists in reducing the number of temporal signals, which can be done condensing the signals of the voxels belonging to the same brain regions, or with a completely data-driven approach performing an independent component analysis. These reduced signals are then fed into a standard ML or transformed in correlation matrices (known

as functional connectivity matrices) and analyzed as images with DL. Alternatively, the raw data, minimally preprocessed, are used to train a 4D CNN, which treats the temporal dimension exactly as the spatial ones, or a recurrent neural network (RNN), specifically designed for temporal analysis [8]. The characteristic of the RNNs that makes them particularly suited for temporal analysis is that they process the temporal signals as streams of data and they contain memory retaining layers that simultaneously process the current input and the previous ones (see Fig. 3).

The previous discussion on the scarce reproducibility of sMRI research also applies to fMRI and rs-fMRI analyses. One of the best results in classification obtained to date in a large multi-site dataset reaches only an AUC of 70% [26]. The approach used was quite standard: the rs-fMRI data were reduced to functional correlation matrices and then fed into a DL algorithm trained to distinguish ASDs and HCs. Until now, the adoption of more sophisticated approaches such as the use of an RNN directly on time series has not improved this result, reaching an AUC of 68% [27].

Genetics

Genetic data comprise various kinds of data (i.e., genome, transcriptome, proteome, and metabolome), which can be analyzed in different ways.

The genome sequence is the complete list of the three billion nucleotide pairs composing the DNA, but usually only two types of genetic variations are stored and analyzed: the single nucleotide polymorphisms (SNPs, genetic variations relative to a reference genome involving a single nucleotide), which are roughly four to five million in a person's genome, and the copy number variations (CNVs, gain or loss of segments of genomic DNA relative to a reference) which are above 70 per genome with a mean size of 10^5 nucleotides.

In literature, some SNPs and CNVs that individually may be implicated in ASD etiology have been found. For instance, strong evidences are related to the SNP rs2217262 in the DOCK4 gene, which increases risk of ASD between two to four times, and the CNV known as Dup15q

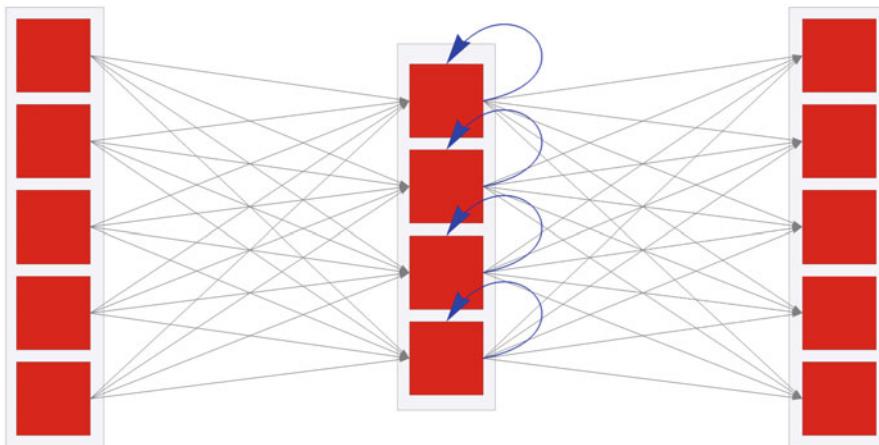

Fig. 3 Structure of an RNN. An RNN is based on the concept of memory. Each layer retains memory of what has previously passed through it, thanks to connections to itself (the blue arrows in the picture). These connections allow

the analysis and extraction of features from data that are not simultaneously available to the layer (such as for example in a video stream, or in any variable-length input)

which causes the homonym syndromic form of ASD. However, being ASD a complex disease, the multivariate approach typical of AI tools can help to unravel the articulated interactions of combinations of genetic variations, understanding how genetic risk factors confer susceptibility to ASD. A study shows that using SNP data it is possible to develop a regression based classifier correctly predicting ASD diagnosis in up to 80% of the cases in two datasets composed mainly by European subjects, however losing accuracy in a genetically dissimilar cohort of Asiatic people [28]. Similarly, another work [29] shows that a Random Forest-based classifier trained with CNV data can explain 7.9% of ASD while misclassifying only 3% of HCs, which is an important result considering that to date only 10% of ASD are expected to be caused by CNVs.

Another genome-level type of data, rarely analyzed but very promising for *early diagnosis* applications, is DNA methylation, an epigenetic modification by which methyl groups can be added to cytosine or adenine bases (about 4% of the cytosines are methylated in the human genome) changing in this way the activity of a DNA segment without changing its sequence. In a recent study it has been shown that a simple logistic regression using DNA methylation data can predict ASD with an AUC of 95% in newborns [30].

Transcriptome, proteome, and metabolome describe respectively which and how many gene transcripts, proteins, and metabolites are present in a cell or in a group of cells of a specific tissue. Thus, all these data can be represented as a vector of weights, of a size up to roughly 240,000 different transcripts, 80,000 proteins, and 120,000 metabolites; however, these numbers can significantly vary depending on the reference library used and to which extent these elements are grouped in similar functional sets. Being tissue-specific measures, transcriptome, proteome, and metabolome of brain tissues would be of particular interest in the study of ASD. Unfortunately, this kind of analysis is possible only on post-mortem samples, which limits the number of available data and as a consequence the possibility to analyze them with AI techniques. However, research on data from other tissues still yielded good results: in a classification study based on blood transcriptome, an AUC of 70% has been reached [31], while on plasma metabolome an accuracy of 81% has been obtained [32].

Besides the typical ML approaches for *automatic/early diagnosis* that have been mentioned so far, all the genetic data are particularly apt to be analyzed with clustering techniques, especially with hierarchical clustering algorithms, in order to explore the genetic heterogeneity of the disease

and to define genetically-grounded subtypes of ASD. For instance, a typical analysis pipeline of transcriptome includes the construction of a gene co-expression network, that is, a network showing closer connections between the highly correlated genes, and then the application of hierarchical clustering algorithms to define gene modules with coordinated biological functions. With this approach, one of the largest studies on brain post-mortem transcriptomic data showed that synaptic and glial functions along with inflammatory pathways are important brain downstream mechanisms characterizing ASD [33].

Finally, another important and promising field for exploring the genetic bases of ASD is risk gene discovery with ML or DL methods. Basically, the idea consists in moving from the traditional analyses to discover new genes implicated in the disease based on the comparison of HCs and ASDs genetic data, to a machine learning approach using genome-scale data (such as prior scores of genetic association, brain gene expression, and topological information from large gene interaction networks) as predictors to identify new genes with similar properties to already established ASD risk genes [34].

Video and Sensor Analysis

Neuroimaging and genetic data can be obtained only in medical structures, thus, when the subject has been already diagnosed or has a familial risk to develop ASD. Promising applications for *early detection*, likely life-impacting in the near future, are based on the study of data that can be acquired at home and analyzed remotely via telemedicine, such as home-made videos and sensor data that can be obtained with mobile or wearable devices. A high number of studies tried to automatically detect ASD through the analysis of children video, reaching high classification performances using either 3D CNNs (two spatial directions and one temporal), RNNs, or other more advanced network architectures derived from the previous ones. However, most of the classifiers developed expect input videos to portray the subject while performing specific actions. One recent study instead shows that it is possible to build a classifier able to recognize ASD typical repetitive behaviors

from arbitrary-length home-made videos of the children, without requiring them to do specific activities [35]. The classifier built reached an accuracy of 95%. From a methodological point of view, this work built a DL model made of four components, a 3D CNN used to extract spatiotemporal features followed by a temporal pyramid network (TPN), which progressively identifies longer and more abstract types of actions. In the third component the intermediate representations of this TPN are used to identify single actions typical of ASD children. Finally, the fourth component uses the TPN top-layer to predict the presence of repetitive behaviors. Interestingly, the presence of the third component forces the entire network to focus exclusively on ASD behaviors, such as hand flapping, head banging, spinning, toe walking, and moving fingers.

This example shows that in applications for which a large body of prior knowledge is available, such as the visual recognition of ASD typical behaviors, it is possible to fruitfully adopt more complex AI architectures exploiting highly annotated datasets, thanks to an implicit knowledge transfer from humans to machines. On physiological data, such as EEG and MRI, it is instead more difficult to guide the AI, which is in fact used to gain new insights on the disease adopting often simpler and more interpretable models.

Besides video analysis, there are a lot of other applications that study established behavioral characteristics of ASD, such as the sensor-based analyses of gait patterns, eye-movement, and repetitive gestures. In fact, using DL methods based on CNNs, accuracies up to 96% have been reported on this kind of data [36]. It must be noted that a long-standing and consensual result observed in this kind of studies is that ASD subjects present an eye-attention map focused toward objects rather than people, as it happens instead in HCs [37].

Despite all the applications described in this section reach very high performance in detecting ASD and are promising for remote and early diagnosis, due to the nature of the data, they cannot provide new insights neither on the causes nor on the possible treatments of the disorder.

Miscellaneous

The heterogeneity of ASD manifestations and the still very uncertain causes of the disorder keep the way open for an unlimited number of studies, which for the sake of synthesis cannot be fully reported in this chapter. For instance, given that retinal changes have been found in ASD, an AI-based classifier for retinal images was developed showing a promising AUC of 97%, although being tested on a small cohort of subjects [38]. Similarly, the higher incidence and severity of gastrointestinal problems in ASDs with respect to HCs and the plurireported alterations of the gut microbiome in the disorder, suggested the development of a machine learning diagnosing tool based on intestinal microbiome, which achieved an AUC of 83% [39]. These few examples show how many fields and types of data can be involved in the research on ASD. In this context, AI is a versatile and promising tool, not only because it allows to examine complex data structures such as the ones described in this chapter but also because it can be used to combine multi-modal data without making any prior assumption on them. This has already been done for data that are somehow related, such as sMRI and fMRI [40], but considering the heterogeneity of ASD, it might be interesting to combine even very different modalities, possibly using ensemble methods, that is, machine learning techniques that combine several classifiers in order to produce a single optimal predictive model.

Challenges of the AI-Based Research on ASD

One of the most appetible and legendary feature of AI is its ability to automatically discover patterns from raw data, that is, without any preprocessing step. This power has a price: the access to a high number of examples, which is a long-standing issue in medical applications in general and for research on ASD in particular. The following problems obstruct the data collection process:

- The heterogeneity of ASD, which can be represented only collecting data from a large

and diversified sample, possibly including healthy relatives and subjects belonging to the broader phenotype

- The necessity to collect data during early infancy, with all the issues related: privacy, family consensus, and collaboration from the children during data collection/acquisition
- The difficulty in the diagnosis, which may delay the acquisition of data

The scarcity of data, affecting all the fields of research on ASD, is exacerbated by their high dimensionality, which causes problems of overfitting and leads to wrong results driven by spurious correlations. This phenomenon may explain why in MRI research a significant drop in classification performance has been reported going from the initial studies based on small cohort of patients to larger ones. Whether the good results obtained in less investigated fields with limited access to data may suffer from the same overfitting problem is still not fully understood and deserves further investigations.

In addition, another important factor that may mislead an AI-based study is the presence of the so called confounders, that is, variables affecting the data that do not represent clinically relevant aspects, but might nevertheless bias the analysis if they are unequally represented in the dataset. In fact, biomedical data, but also video and sensor data, depend on a high number of variables: demographics information, acquisition/recording modalities and instruction given to the patient, personal physiological characteristics, medications, and feature assessment criteria (such as qualitatively defined scores or indices); thus it is common that one or more of such variables are biased in the dataset under examination. Confounder effects are well known in various medical applications, but in a recent work it has been shown that their effect is particularly severe in MRI-based ASD research using ML/DL algorithms [15]. The authors used the Confounding Index (CI) [41], an index measuring how much a confounder variable can affect a classification problem, to quantify and compare the effects of commonly cited sources of heterogeneity in sMRI-based research. The results (Fig. 4) show

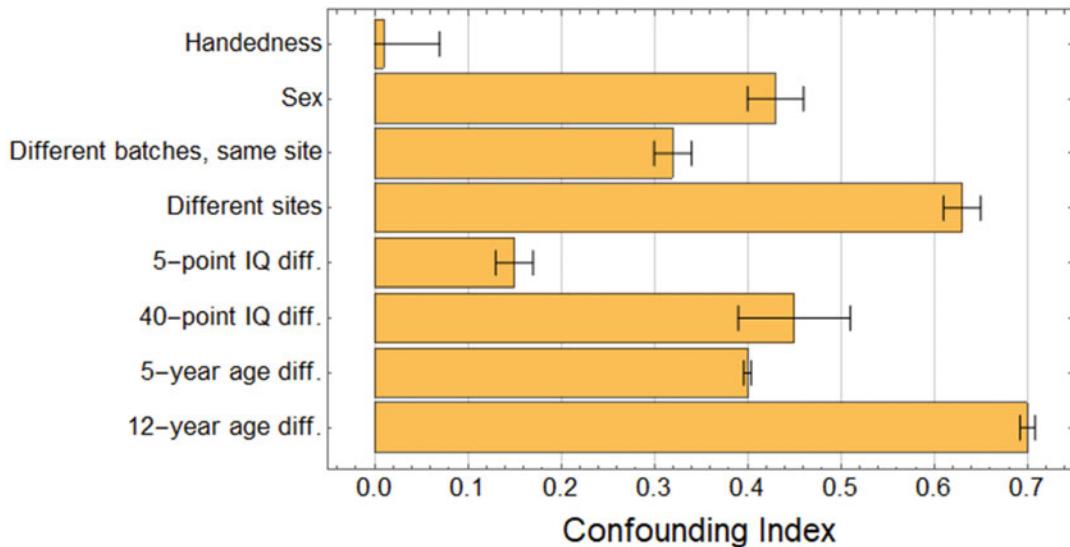

Fig. 4 CI value of several possible confounders for ASD. The CI is an index that ranks from 0 to 1 the effect of a confounder variable on a certain binary classification task.

For ASD, sex, acquisition modalities, acquisition site, large IQ differences, and even small age differences are all strongly confounding. (Data from Ref. [15])

that there are a large number of factors that have a strong confounding effect on the ASD/HC classification task, including nonbiological ones such as acquisition site. Given that the analysis was conducted on highly processed data, the unexpected strength of the site effect is supposedly enhanced by two phenomena: the complexity of the classification task caused by the heterogeneity of the disorder and the ability of AI to find unrealistically complex multivariate patterns. As a proof for this hypothesis, the authors trained the same algorithm several times to classify subjects scanned in different sites, using a variable number of randomly selected highly processed features. As it can be noted from Fig. 5, the algorithm needs at least 20 features (regardless of which ones) to understand the site provenience, proving that individually the features are substantially independent from the acquisition site, but ML can discover subtle and highly multivariate dependencies which are difficult to pinpoint (and thus correct). This ability that might be considered a strength of AI methods turns out to potentially drive misleading effects. Considering that the difficulty of the ASD classification task and that the use of ML/DL approaches is common to several important

research works on ASD, this problem may not be circumscribed solely to MRI data.

Summarizing, besides the collection of larger datasets, which might prevent overfitting, another important challenge for AI-based research is the adoption of confounding-resilient methods, which are currently object of study in applied computer science.

Conclusions

Despite a high number of studies ranging different domains have been conducted, current understanding of ASD is still incomplete and research has a long way to go. AI is a powerful and versatile methodology to address open-ended research involving high-dimensional data, when prior knowledge necessary for hypothesis-driven analyses is missing. Currently, the most common application is the adoption of ML/DL approaches to discover quantitative biomarkers to improve the diagnosis process and allow early treatment intervention. Across the various fields that can be explored in this way, MRI is the most studied one, because it represents a safe technology that can

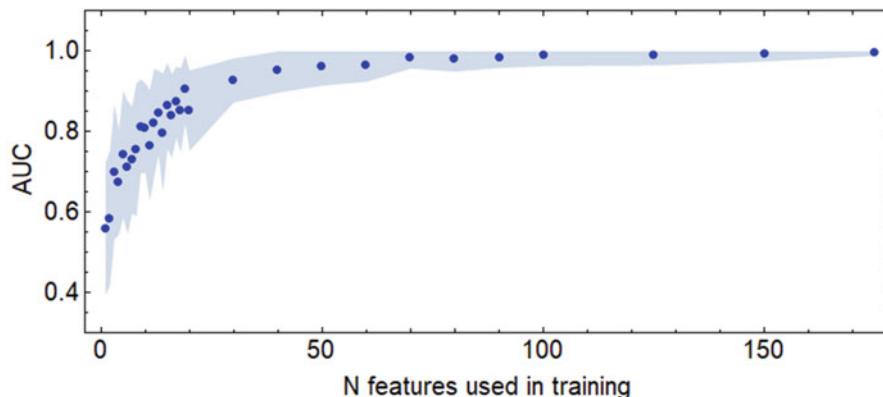

Fig. 5 AUC obtained vs number of features used in the training process of a classifier distinguishing MRIs of subjects scanned in two different sites. The classifier needs at least about 20 features to reach good performance. The

relatively tight error band in light blue, representing different instances of training with a different set of features, shows that the results do not significantly depend on the specific features chosen. (Data from Ref. [15])

investigate ASD brain structural and functional abnormalities with high spatial resolution, and thus is potentially useful both to find a biomarker and to understand the neurological causes of the disorder. However, the large body of literature produced contains highly heterogeneous results, often difficult to reproduce and sometimes even contradictory. The lack of a consensual result has been imputed mainly to the diffuse presence of overfitting and confounding effects, which can be highly misleading in data-driven approaches.

The next major challenges for AI-based research on ASD are thus the collection and release of large datasets and the development of new AI techniques to deal with confounding effects. Furthermore, the adoption of explainability approaches, which allow a better understanding of the decisional process made by the algorithm, might help to spot and correct for the mentioned problems and at the same time ease the discovery of new insights on the disorder.

In conclusion, given the heterogeneity of ASD, research should move forward on multiple fields, possibly integrating multimodal data, encouraging the adoption of explainable AI and ensemble methods (which may capture the multi-faceted nature of ASD) and keeping up with the development of new AI-based tools to deal with overfitting and confounding effects.

Abstract

Principles and methods in artificial intelligence applied to the research, diagnosis, and treatment of schizophrenia and related disorders are reviewed from the 1980s to 2020. Support vector machines (SVMs), neural networks,

expert systems, deep learning neural networks, autoencoders, deep belief networks, random forests, ensemble methods, and cognitive architectures are some of the AI techniques reviewed as applied to schizophrenia and related disorders. Connectionist models are used to better explain the development of schizophrenia. SVMs and deep learning neural networks are used to help interpret neuroimaging data in patients with schizophrenia. Deep learning networks are used to predict various outcomes for patients with schizophrenia. Deep learning neural networks and SVMs are used in the schizophrenia drug discovery process. AI-powered avatar therapy and socially

interactive robots are used in the therapy of patients with schizophrenia. At the time of this writing, use of AI techniques is starting to switch from the research setting to the clinical setting to help diagnose and treat patients with schizophrenia or schizophrenia-related disorders. For example, a multimodal machine model combined with human evaluations can fairly accurately predict the transition to psychosis for high-risk young individuals.

Introduction

Artificial intelligence (AI) is defined by Russell and Norvig [1] in terms of inclusion as a member in one of four broad categories – thinking rationally, acting rationally, thinking humanly, or acting humanly. In the “thinking rationally” class, an AI system applies logical reasoning to facts in order to solve a problem. In the “acting rationally” class, the AI system acts somewhat autonomously to obtain the best possible outcome of some goal given the existing constraints. In the “thinking humanly” class, the AI system should think like a human, thus there must essentially be cognitive modeling on the part of the AI system in this category of the definition. In the “acting humanly” class, an AI system successfully approaching the popular Turing Test (i.e., the AI system functions so well that a human asking written questions in a different room, could not tell whether the responses are from another human or from an AI system) is required. Here the AI system needs to have the following abilities – natural language processing (to communicate with the questioner), knowledge representation, automated reasoning, and machine learning (to improve knowledge representation as well as to recognize patterns). Applications of artificial intelligence to areas of

schizophrenia fall in all these areas, as well as in areas that are more statistical in nature and less in keeping with the categories above (Video 1).

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), classifies schizophrenia within the chapter on “Schizophrenia Spectrum and Other Psychotic Disorders” [2]. Schizophrenia diagnostic criteria require that there must be, for much of the time, at least one month of delusions, hallucinations, or incoherent or derailed speech, resulting in a reduced level of functioning. As well there must be at least two of the following: delusions, hallucinations, disorganized speech, catatonic or very disorganized behavior, and/or negative symptoms such as reduced emotions. While as noted above the active symptoms must be present for at least a month, there must also be active or residual symptoms for 6 months. The diagnosis requires exclusion of affective disorders with psychotic features, autism spectrum disorder (although comorbid diagnoses are possible), and physiological or medical causes of symptoms.

In the chapter of the DSM-5 on “Schizophrenia Spectrum and Other Psychotic Disorders,” in addition to schizophrenia, there are other related disorders listed [2]. These disorders include delusional disorder, brief psychotic disorder, schizophreniform disorder, schizoaffective disorder, substance/medication-induced psychotic disorder, psychotic disorder due to another medical condition, catatonia associated with another mental disorder, and schizotypal personality disorder, although in the latter details are found in the DSM-5 chapter on “Personality Disorders.” While below the focus is principally on applications of AI in the etiology, diagnosis, and treatments in schizophrenia, there will be consideration, where relevant, of AI applications toward any of these DSM-5 schizophrenia-related disorders.

In the International Statistical Classification of Diseases and Related Health Problems, Tenth Revision (ICD-10), in the chapter on “Mental and Behavioural Disorders” there is a block on “Schizophrenia, Schizotypal and Delusional Disorders” [3]. This group includes: schizophrenia, schizophreniform disorder/psychosis,

schizophrenia unspecified, schizotypal disorder, persistent delusional disorders, acute and transient psychotic disorders, induced delusional disorder, schizoaffective disorders, other nonorganic psychotic disorders, and unspecified nonorganic psychosis. Although the focus below is mainly on the application of AI for schizophrenia, applications of AI for the study, diagnosis, or treatment of any of these ICD-10-described schizophrenia-related disorders will be included where relevant.

The field of artificial intelligence is often arbitrarily divided into what are termed “Symbolic AI” and “Subsymbolic AI” approaches. Symbolic AI uses symbolic formulations of problems and symbolic logical solutions, i.e., there is manipulation of discrete symbols. Symbolic AI is sometimes referred to as “good old-fashioned AI (GOFAI)” due to the more current predominance of subsymbolic AI approaches. In subsymbolic AI there is not a formulation of the problem or its solution with a particularly human-obvious symbolic-like representation. For example, in artificial neural networks (ANNs), typically referred to as “neural networks,” there is not an obvious symbolic representation of a problem, but instead there is a massive collection of nodes (or “artificial neurons”) with connections (or “synapses”) to each other in a variety of wiring arrangements. Below both symbolic and subsymbolic approaches to AI applied to schizophrenia and related disorders will be included.

Artificial Intelligence Applied to the Research, Diagnosis, and Treatment of Schizophrenia and Related Disorders: Pre-2000

Artificial intelligence techniques started to become more consistently applied to the field of schizophrenia in the mid-1980s. Work by Hoffman used specialized Hopfield neural networks to simulate models of psychosis induction [4]. However, during this era, in general in the field of AI, expert systems were the most predominantly used paradigm for AI systems, and started to find applications in psychiatry. An expert system is a

symbolic approach to AI, utilizing a large collection of if-then rules obtained from a human expert, and software that applies these if-then rules to the properties of a problem that is to be solved. Work by Maurer and colleagues in the late 1980s compared an expert system that diagnosed schizophrenia from patient data with diagnoses obtained via the more traditional classification systems, with the expert system giving similar results [5].

By the 1990s expert systems in many different areas of AI had not performed as well as had been hoped for, and the entire AI field received less funding and attention, often referred to as the “AI Winter.” Artificial neural networks (or “neural networks”), essentially related to the modern deep learning artificial neural networks that would later be developed, were at this time unfortunately not thought to hold much promise. However, work did slowly continue on artificial neural networks. Cohen and Schreiber in 1992 described a neural network model which explored attention and language deficits in schizophrenia [6], and Hoffman and McGlashan in 1993 used artificial neural networks to model a breakdown in corticocortical communication [7].

Symbolic reasoning algorithms had long been part of the AI field, and during this time, indeed continued to be used in applications related to schizophrenia. For example, work by Garfield and Rapp in 1994 applied semantic networks with node and pathway-based reasoning rules to psychotic speech [8]. A semantic network is essentially a diagram representing knowledge, with lines between the nodes representing concepts, i.e., a symbolic approach to AI. In Garfield and Rapp’s work, reasoning rules operated on the nodes of and the lines in the semantic network diagram, and could recognize what they termed “crazy talk” from the violations of the reasoning rules.

As noted by Seeman, work on artificial neural network models of schizophrenia started to increase modestly by the mid-1990s, with the hope that these models could provide better explanations for the pathophysiology in schizophrenia [9]. Work by Lowell and Davis used artificial neural networks (ANNs) for the more practical

purpose of predicting the length of hospital stay based on schizophrenic and other psychiatric patient data the ANNs were trained on [10]. Work by Hoffman and McGlashan in 1998 used ANNs to show that decreased cortical connectivity modeled the development of auditory hallucinations [11]. Work by Corson and colleagues in 1999 used an ANN to identify and measure the caudate nucleus in neuroimages of first-episode psychosis patients and control subjects [12].

Artificial Intelligence Applied to the Research, Diagnosis, and Treatment of Schizophrenia and Related Disorders: 2000–2012

During this era there was work on both symbolic and subsymbolic artificial intelligence approaches to schizophrenia and related disorders. For example, Razzouk and colleagues in 2006 described using decision support systems, which are essentially expert systems, to help the practicing physician in the clinical diagnosis of schizophrenia [13].

As neural network theory and technology slowly improved over this decade, there was the obvious application of using machine learning to extract indicators of schizophrenia and related disorders from neuroimaging. For example, Jafri and Calhoun used ANNs to attempt to detect the presence of schizophrenia from brain fMRIs [14]. Bose and colleagues in 2008 describe using an ANN model to distinguish schizophrenic patients from controls in PET imaging with an 89% sensitivity and 94% specificity [15].

Support vector machines (SVMs) started to be more widely used during this time period to classify features in a variety of datasets obtained from research on patients with schizophrenia. Support vector machines are not actually machines but a type of supervised machine learning model, useful for classifying data into a particular category as well as finding relationships between variables. As shown below in Fig. 1, the SVM model attempts to find the best hyperplane between different classes of datapoints. Similar to a neural network, there is a training phase where annotated

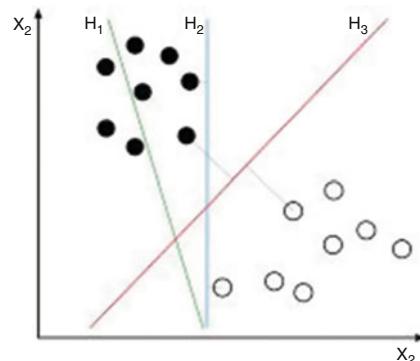

Fig. 1 SVM model creates a “hyperplane” that allows classification of data points. In this simple low-dimension example note that H₃ separates the classes with a better margin than H₁ or H₂. (Creative Commons License BY-SA. Credit to Zack Weinberg)

training examples (i.e., annotated with the correct category an example belongs to) allows the SVM to build a model of the data. The SVM can then be used to classify data it has not seen before. Modifications of the SVM algorithm allow it to also function in an unsupervised fashion and find clustering of similar items in a large collection of data. Struyf and colleagues in 2008 used a variety of classification algorithms including SVMs, nearest shrunken centroids, decision trees, naïve Bayes, and nearest neighbor classification to classify patient genomics, demographics, and clinical data as bipolar disorder versus schizophrenia [16]. SVMs classified significantly better than the other algorithms used. Ozyurt and Brown in 2009 described a variety of AI techniques including SVMs and probabilistic reasoning, for retrieving knowledge from the scientific literature including schizophrenia abstracts [17].

The nodes or “neurons” in an ANN, while originally inspired by biological neurons, are artificial constructs quite different and much simplified compared to a natural neuron, as is their organization or wiring. There is an interest in the computational neuroscience community for more biologically realistic neural networks. Unlike in ANNs, biological neurons are much more sparsely and recurrently connected to each other [18]. Given that a variety of hippocampal abnormalities are found in schizophrenia, more realistic hippocampal computer simulations, for example,

were thought to help better understand its etiology [19]. ANNs continued to be used to model aspects of the pathology of schizophrenia. For example, Karolidis and colleagues in 2010 used ANNs to model a number of cloned molecules which could bind to human dopamine D1 and D2 receptors [20].

Artificial Intelligence Applied to the Research, Diagnosis, and Treatment of Schizophrenia and Related Disorders: 2012–2018

The theory and technology behind various machine learning approaches, including ANNs with multiple hidden layers and termed “deep learning,” had started to greatly improve in the mid-2000s. In 2012 work by Krizhevsky, Sutskever, and Hinton using deep learning won a computer vision competition by a large margin over older methods [21]. This achievement is regarded as an approximate start of what is called the “deep learning revolution” and propelled the utilization of deep learning into many domains, including the research and clinical aspects of the field of schizophrenia. In the ImageNet contest a computer-based system needed to classify as accurately as possible large numbers of different images into some thousand different classes. Krizhevsky and colleagues used a deep convolutional neural network. In such a neural network there are multiple layers of nodes (or “neurons”) connected with layers where the nodes act as convolutional layers where such layers extract features from the previous layers preserving the spatial relationships but essentially mapping into a small-size receptive field and extracting features as such. Krizhevsky and colleagues used 650,000 neurons arranged in a number of layers including five convolutional layers. Within a few years deep learning neural networks improved (and grew in size and processing power) to the point where they could classify the ImageNet images more accurately than human competitors.

A review by Veronese and colleagues in 2013 gives an overview of machine learning approaches

in schizophrenia but describes little of deep learning [22]. However, within a few years deep learning was being used in the field. In 2016 Kim and colleagues note that deep neural networks (DNNs) with multiple hidden layers were performing much better in classification tasks compared to SVMs and earlier AI models. They used a DNN to obtain functional connectivity patterns from resting-state functional magnetic resonance imaging [23]. A review by Arbabshirani and colleagues in 2017 considers the application of machine learning techniques including the emergence of deep learning to the prediction of brain disorders from patient neuroimaging data [24].

From 2016 onwards there was increasing application in the research and clinical aspects of schizophrenia of not only deep learning but also a variety of artificial intelligence techniques. For example, innovative work by Miotto and colleagues used a deep learning network incorporating autoencoders on a hospital-wide patient database to extract in an unsupervised fashion actionable features on individual patients such as personalized prescription, disease prediction, and clinical trial recruitment with better predictions for patients with schizophrenia than many other disorders [25]. Miotto and colleagues used a stack of particular denoising autoencoder layers. An autoencoder is a neural network that has an encoder layer of neurons that as its name suggests encodes an input signal. The encoded signal, usually reduced in dimensionality, i.e., there is a reduction in size of the input via nonlinear modifications, is then reconstructed by the decoder layer of neurons to give an output that maps in some way to the input signal. Thus, the output is not an exact copy of the input but a transformation of the input signal and, depending on how the autoencoder is constructed as well as combined with multiple layers of other autoencoders, can allow unsupervised learning to produce an efficient coding of the input signal which can extract or classify features of the input data (Fig. 2).

An interesting area of robotics in the 2010s was the development of “socially interactive robots” which are engineered to improve human-robot interactions by displaying nonverbal cues including facial emotions. Since nonverbal social

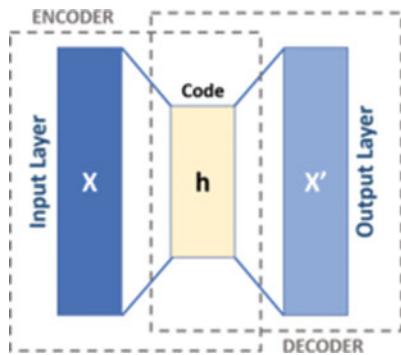

Fig. 2 Overview of an autoencoder. (Creative Commons License BY-SA. Credit to Michaela Massi)

interactions are known to be poorer in patients with schizophrenia, Raffard and colleagues in 2016 considered the use of a humanoid iCub robot, shown in Fig. 3 albeit without emotions activated in this photograph, in patients with schizophrenia [26]. It was found that both patients and controls recognized better the emotional facial expressions of humans than robots. Thus, the authors conclude that while humanoid robots have a theoretical potential in the role of increasing social functioning in patients, this study should only be considered exploratory.

Work by Arnon and colleagues in 2016 approached the theoretical realm of what is possible using modern electronics and AI technologies. Arnon and colleagues described the potential use of thought-controlled nanoscale robots which are activated by a magnetic field which is produced when an external sensor detected a particular EEG pattern, and can do a particular function such as make available bioactive molecules that could treat schizophrenia [27].

Use of SVM methods continued in the 2010s. For example, work by Mikolas and colleagues in 2016 used SVM analysis on the resting-state fMRI images of patients with a first-episode schizophrenia spectrum disorder and healthy controls, and was able to distinguish the anterior insula connectivity of patients from controls with an accuracy of 73.0% [28]. Work by Zarogianni and colleagues used SVM analysis in predicting schizophrenia based on a self-completed measure

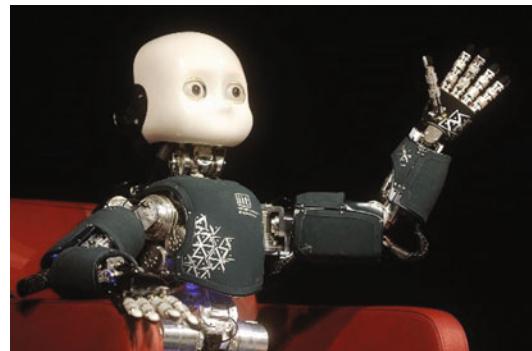

Fig. 3 iCub socially interactive robot, neutral emotions. (Creative Commons License BY-SA. Credit to Niccolò Caranti)

of schizotypy, a declarative memory test and a structural MRI brain scan [29].

A deep belief network is a type of deep neural network with a stack of layers of simpler often unsupervised learning neural models. Each layer in the deep belief network extracts a higher level of features of the input signal. Deep belief networks had been used for extracting information from and recognizing images, for example. Work by Pinaya and colleagues trained a deep belief network on features from MRI brain morphometry to distinguish between patients with schizophrenia and healthy controls with an accuracy of 73.6% [30].

A technique known as random forest creates many different decision trees during training and later will use the class decided by, for example, the most decision trees. Work by Pergola and colleagues in 2017 used random forests methodology to classify grey matter volume in the thalamus of MRIs from patients with schizophrenia, non-affected siblings, and controls, and found a familial relation associated with reduced thalamic grey matter volume in patients with schizophrenia [31].

Just as older AI techniques in the 1980s were used to model possible mechanisms in the development of psychosis, this continued in the 2010s with the now popular deep learning neural networks. For example, Keshavan and Sudarshan discuss how deep learning algorithms can possibly overemphasize objects

the network believes are recognized leading to outputs that are detached from reality, and thus may possibly model some mechanisms involved in psychosis [32].

As in other fields of medicine, mobile apps incorporating AI features began to emerge with increasing frequency, especially from 2016 onwards. Work by Bain and colleagues in 2017 describe a mobile app to assess medication adherence by visual confirmation for patients with schizophrenia [33]. Work by Birnbaum and colleagues in 2017 used machine learning of Twitter (American blogging service) feeds from users self-diagnosed with schizophrenia in an attempt to classify users of this blogging service with schizophrenia from users who were considered healthy controls [34].

Machine learning started to become commonplace in imaging. For example, Dluhoš and colleagues describe creating a meta-model by combining SVM classifiers trained on local datasets and combining data from multiple centers [35]. Honnorat and colleagues used a clustering machine learning method that indicated a distinction between schizophrenia patients and controls in the temporal-thalamic-peri-Sylvian regions, frontal regions, and thalamus [36].

Work by Winterburn and colleagues compared logistic regression, SVMs, and linear discriminant analysis on cortical thickness and tissue density estimates, in patients with schizophrenia and healthy controls, with most accuracies between 55% and 70% [37]. Zeng and colleagues in 2018 used a deep discriminant autoencoder network to learn and distinguish fMRI functional connectivity features from patients with schizophrenia from healthy controls [38]. Bae and colleagues used SVM analysis to show from a public fMRI dataset that there were significant differences in patients with schizophrenia from healthy controls, especially in the anterior right cingulate cortex, the superior right temporal region, and the inferior left parietal region [39]. Work by Mikolas and colleagues used SVM to distinguish diffusion tensor MRI data from patients with first-episode

schizophrenia spectrum disorder and healthy controls with an accuracy of 62.3% [40].

Artificial Intelligence Applied to the Research, Diagnosis, and Treatment of Schizophrenia and Related Disorders: 2019–Present

Toward the end of the 2010s a variety of AI techniques, including DNNs and SVMs, started to be applied to more relevant challenges in schizophrenia research, diagnosis, and treatment. AI methods allowed better interpretation of neuroimaging of patients with schizophrenia. Machine learning was being used in schizophrenia drug discovery research. AI techniques were being used in clinical schizophrenia diagnosis and care.

Zhao and So used DNNs and SVMs to predict the repositioning of schizophrenia drugs based on their drug expression profiles as candidates for other diseases [41]. Work by Lin and colleagues used three different machine learning algorithms (logistic regression, naïve Bayes classifier, and C4.5 decision tree) to examine two G72 SNP genotypes and G72 (D-amino-acid oxidase activator, DAOA) protein levels (previously associated with schizophrenia patients) to try to classify schizophrenia patients from healthy controls. The G72 protein levels alone gave most of the effect, with the naïve Bayes giving the best specificity of 0.95 and the logistic regression technique yielding the most sensitivity of 0.88 [42].

Fond and colleagues used machine learning via decision trees of data from patients with controlled schizophrenia to predict relapse at two years. High anger, high physical aggressiveness, high lifetime psychiatric hospitalizations, low education level, and high positive symptoms at baseline were the strongest predictors of relapse [43].

Work by Kalmady and colleagues examined resting-state fMRI data from patients with schizophrenia who had not been treated with antipsychotic medications and healthy controls. They

used an ensemble machine learning classifier that was able to classify a resting fMRI into the correct schizophrenia/healthy control class with an accuracy of 87% versus 53% accuracy expected by chance alone [44]. An ensemble method uses multiple machine learning algorithms to obtain better accuracy than any one of the individual machine learning algorithms that it is based on. Kalnady and colleagues called their ensemble model “EMPaSchiz” which stood for “Ensemble algorithm with Multiple Parcellations for Schizophrenia prediction.”

Work by Brodley and colleagues in 2019 trained SVMs from the responses of patients to the Early Psychosis Screener for Internet (EPSI) and predicted if the patient would be diagnosed with a psychotic disorder in 12 months [45]. Barrera and colleagues used digitally assisted nursing observations (i.e., obtained via computer vision and signal processing) in an acute mental health input ward with patients with schizophrenia, and found that patients’ safety was not compromised [46]. Wu and colleagues trained an ensemble machine learning method on the records of 70% patients with first-episode schizophrenia to predict a successful antipsychotic medication selection. Success was defined as not switching medications and not being hospitalized in the next 12 months. The remaining 30% patients’ data was not used for training, but kept for testing the machine learning model. If the individualized treatment which the machine learning method suggested was used, then the treatment success was 51.7% versus the actually observed 44.5% success [47].

Parola and colleagues used Bayesian classifier networks and found that pragmatic linguistic (language as well as other expressive means) impairment was the most important factor in classifying patients with schizophrenia versus healthy controls [48]. Using electroencephalographic patient data, Tikka and colleagues used SVM to classify patients with schizophrenia from healthy controls, and to classify patients with schizophrenia with positive symptoms from patients with schizophrenia with negative symptoms [49]. Particular eye movements are associated with schizophrenia and other disorders. However, it can be difficult to

experimentally obtain eye movement features and associate the movement pattern with a disease. Mao and colleagues in an exploratory study classified eye movements with a random forest of decision trees [50].

Work by Kim and colleagues published in 2020 trained a convolutional neural network to analyze social media users’ posts in a particular social media channel associated with a particular mental illness including schizophrenia, and thus create a deep learning model with natural language processing that could identify social media posts as belonging to various mental disorders including schizophrenia [51]. Work by Adler and colleagues published in 2020 used an app which collected schizophrenia patients’ passive cellphone data which included location, acceleration, app use, screen activity, text messages, and as well prompted users every 2–3 days to self-report positive and negative symptoms. A fully connected neural network autoencoder and recurrent unit sequence-to-sequence model learned input time series data from the patients, and was able to predict certain behavioral changes which occurred before there was a clinical relapse [52].

Yang and colleagues reviewed concepts in artificial intelligence that could help with the drug discovery process, although there is little discussion of potential medications which could be used with schizophrenia-related disorders [53]. Zilocchi and colleagues showed an interesting association of 245 mitochondrial proteins to bipolar disorder, schizophrenia, and mood disorders. The authors looked at mitochondrial proteins listed in a number of public databases and then deduced the proteins associated with bipolar disorder, schizophrenia, and mood disorders by comparisons with gene disease listings in the DisGeNET database which already compiles data from many repositories. The authors then examined pharmaceutical repositories for mood stabilizers and obtained a small number of active ingredients, which they then examined in a drug-gene interactions database, and found that seven of the active ingredients actually targeted a number of these 245 mitochondrial proteins. The authors suggested that future use of machine learning methods could allow a virtual synthesis process

that explored more of the chemical reactivity space and gave more possible potential drugs [54].

Work by Schneider took biological concepts from schizophrenia and applied them as constraints *back* to the field of artificial intelligence [55]. While neural networks, e.g., deep learning, have emerged as a very important technology in the field of artificial intelligence over the last decade, and while they can recognize patterns beyond human abilities, compared to a young child they are poor in logically and causally making sense of a problem they are solving. Deep learning networks have been getting better at performing their tasks by using ever faster computing hardware and training on ever larger sets of data, in a fashion that is not sustainable. As well, their amazing pattern recognition abilities do not give them many abilities we take for granted from human intelligence, e.g., the ability to usually explain why we made this or that decision.

Mammalian brains are characterized by cortex organized in repeating minicolumns. Schneider's Causal Cognitive Architecture 1 (CCA1) [56] pre-processes input sensory vectors through a hierarchy of Hopfield-like neural networks, but then feeds them to a navigation module. Unlike a deep neural network or unlike a symbolic artificial intelligence system, everything is processed and stored as navigation maps, which are inspired by the biological cortical minicolumns. Maps are stored, and retrieval can be triggered by other maps as well as operations on the maps. The architecture is not a tabula rasa but starts off with basic procedures termed "Instinctive Primitives" and learns procedures during its lifetime termed "Learned Primitives." The primitives are triggered by input sensory vectors and by maps in the navigation module. As well there are a number of other modules such as a "Goal/Emotion Module." This architecture is capable of performing pattern recognition much like artificial neural networks, but emerging almost automatically from the CCA1 architecture is a map-based precausal behavior to simple problems.

Just as feedback pathways abound in the human brain, they similarly exist in the CCA1 and downstream circuits can affect what inputs upstream circuits are to expect. The topic of

whether any animal, other than humans and possibly some primates, possesses true causal behavior is controversial, but no nonhuman possesses robust causal behavior, chimpanzees included. Of interest, psychosis seems to readily emerge in humans, e.g., even though only small percentage of the population will suffer from schizophrenia, more than 10% of the population will actually experience psychotic-like symptoms [57]. In Schneider's CCA1 architecture if the navigation module feeds back intermediate results to the input circuits, then they can be processed again, and over and over again, with each of the input-processing output cycles the architecture follows. Full causality readily emerges from the architecture when this occurs, as opposed to precausal behavior otherwise [56]. As well, the navigation maps do not need to be used for physical navigation but automatically allow navigation of complex concepts. As well, explainability emerges (which really is just sequential retrieval of maps executed), and the ability to use and create analogies almost automatically emerges from the architecture. However, in this fuller architecture, any small flaw of many possible such small flaws causes a cognitive dysfunction as well as misinterpretation of intermediate results as sensory input signals (i.e., delusion-like and hallucination-like).

Rezaii and colleagues used neural networks to show that during the prodromal phase, low semantic density, i.e., essentially what is clinically referred to as poverty of content, increased the likelihood of conversion to psychosis [58]. McFarlane and Illes discuss the work of Rezaii and other researchers who have developed techniques of identifying psychosis by machine learning methods of analyzing speech and use of social media, and write of the ethical concerns in making such early predictions of psychosis, some of which will be flawed [59].

Craig and colleagues, including Julian Leff, the inventor of the therapy, discuss patients with persecutory auditory hallucinations interacting with a digital avatar representing the hallucinated persecutor, such that the avatar becomes less hostile and the patient feels more in control. In a 12-week study of 75 patients receiving AVATAR therapy

versus controls receiving supportive therapy, there was a significant reduction in the severity of the auditory hallucinations in the AVATAR therapy group compared to the control group [60].

Work by Oh and colleagues, published in 2020, took ordinary structural MRI (1.5 and 3 T) brain images and trained a deep learning convolutional neural network to infer whether or not an image had cortical features of a patient with schizophrenia compared to normal subjects [61]. In the training data the neural network was able to correctly classify 840 out of 866 images, i.e., an accuracy of 97%. When the network was then tested on new images from different patients, the accuracy dropped, as is to be expected when a neural network starts classifying images it has not seen before in its training data, but it still was able to classify images reasonably well. It should be noted that human clinical specialists (five psychiatrists and two radiologists) had difficulty in discerning schizophrenia patients from the normal subjects in a random selection of the structural MRI images above.

Current and Future Clinical Use of AI Techniques in the Diagnosis and Treatment of Schizophrenia and Related Disorders

Fernandes and colleagues in 2017 write about what they consider the “new field of precision psychiatry” [62]. Just as “precision medicine” takes the individual features, i.e., the differences of each patient into account in crafting a prevention and treatment strategy [63], so does precision psychiatry. Bzdok and Meyer-Lindenberg write about the need for machine learning in precision psychiatry [64]. However, at the time of this writing, December 2020, the direct utilization of artificial intelligence techniques is not considered a standard of care (i.e., a legal term describing the expectations that health-care providers are to deliver in the care of their patients) in the diagnosis and treatment of patients with schizophrenia and schizophrenia-related disorders, in Canada where this chapter is being written, and it would seem worldwide as well. As well, in research

studies related to schizophrenia it could be argued that many studies incorporating artificial intelligence techniques could be rewritten to instead incorporate advanced conventional statistical techniques, including some of the references described above. However, all this is starting to change.

For example, consider the work by Koutsouleris and colleagues, with preliminary publication online in December 2020 [65]. In young people who meet the clinical high-risk (CHR) criteria for psychosis development, only about a fifth will have a transition to psychosis over a three-year timespan. As well, psychotic disorders do develop in individuals who would not have been classified in the CHR group. Koutsouleris and colleagues fed patient information including MRI imaging, clinical data, and neurocognitive data into a multimodal machine learning model, to predict the transition to a psychotic disorder in 167 patients meeting the criteria for CHR, 167 patients with a recent-onset depression, and 334 healthy matched controls. The mean age was 25.1 years old. The machine learning model was combined with clinicians’ risk estimates (where clinicians’ predictions had relatively high specificity but lower sensitivity versus the model’s relatively high sensitivity but lower specificity) and was able to predict the transition to psychosis with an accuracy of 85.9% (sensitivity 84.6%, specificity 87.3%). As a result, the authors recommend that this work be clinically implemented: “.... augmentation of human prognostic abilities with algorithmic pattern recognition improves prognostic accuracy to margins that likely justify the clinical implementation of cybernetic decision-support tools.”

At the time of this writing, there is much controversy about the need for functional neuroimaging in clinical as opposed to research psychiatry. However, in 2020 Henderson and colleagues [66] write about the field clinically using functional neuroimaging to “guide the ordering diagnostician to a better and more efficient evaluation and treatment of the neurobiological processes that underlie a particular patient’s symptoms.” As noted in many of the references above with regard to neuroimaging of

patients with possible schizophrenia, incorporation of AI techniques was a part of obtaining higher accuracies in the functional, as well as structural, imaging. For example, as noted above, Kalmady and colleagues [44] using AI techniques were able to differentiate healthy control subjects from patients with schizophrenia on fMRI with an accuracy of 87%. For example, as noted above, Oh and colleagues [61] using AI techniques were able to distinguish cortical features on ordinary structural MRIs between patients with schizophrenia and healthy controls. Indeed, Topol writes about the convergence of human decision-making with artificial intelligence in treating patients, particularly in the interpretation of imaging [67].

Starke and colleagues, writing in 2020, note that while machine learning is not routine in the clinical practice of psychiatry, in particular in schizophrenia, this is starting to occur, and thus there is a need to consider the ethical issues [68]. For example, machine learning algorithms, which could potentially be used in the future to diagnose and treat patients with schizophrenia, often do not explain well how they came up with their decisions.

The use of artificial intelligence in the clinical diagnosis and care of patients with schizophrenia is at the time of this writing in its infancy but starting to accelerate quickly. It is expected that in the 2020s not only will the capabilities of AI in the care of patients with schizophrenia keep improving, but the details of clinical implementations will start to become better managed.

Abstract

The most evident use of artificial intelligence within the mental health field are within chatbots. The adoption of mental health chatbots is a nascent field with the potential to fill mental health treatment gaps and alter perceptions of support to help reduce depression and anxiety in patients. This chapter will define mental health chatbots and explore

their measurable benefits through applications in case studies and an analysis of technological opportunities within the health care industry.

Introduction

The most evident use of artificial intelligence within the mental health field are within chatbots. The adoption of mental health chatbots is a nascent field with the potential to fill mental health treatment gaps and alter perceptions of support to help reduce depression and anxiety in patients. This chapter will define mental health chatbots and explore their measurable benefits through applications in case studies with an analysis of the* technological opportunities within the health care industry.

Mental Health Support using Chatbots

Chapter Summary

The most evident use of artificial intelligence within the mental health field are within chatbots. The adoption of mental health chatbots is a nascent field with the potential to fill mental health treatment gaps and alter perceptions of support to help reduce depression and anxiety in patients. This chapter will define mental health chatbots and explore their measurable benefits through applications in case studies and an analysis of technological opportunities within the health care industry.

Mental Health Chatbots

The first AI chatbot, ELIZA, was developed at MIT and used natural language processing to conduct mock psychotherapy chats with people. Due to the limited availability of personal computers and cell phones, ELIZA was never turned into a commercial product. Where ELIZA was limited, the capabilities of modern chatbots have expanded rapidly thanks to technological advancements in AI memory and emotion identification.

Modern-day artificial intelligence chatbots are computer programs designed to simulate how a human would behave as a conversational partner and encourages* authentic exchanges with patients. Chatbots are a low-cost, user-friendly, and highly customizable solution that enable emotional support to be scaled to hundreds of

thousands of people at a time. Accessing support from a chatbot is convenient through existing and familiar communication channels, including text messaging (iMessage or SMS), Facebook Messenger, and integrations with Amazon Alexa/Google Home voice-enabled services [1].

The Value of Mental Health Chatbots

Mental illness impacts many facets of life. Within the workforce, 6.8% of people are directly impacted by depression and as a result \$11,936 is lost annually on average per affected employee due to absenteeism, disability, and lack of productivity. For many people, access to mental health support is hampered by long wait times, high treatment costs, as well as the social stigma in seeking mental health support. Nearly 60% of people with a mental health problem encounter barriers to receiving care.

Chatbots can lower these barriers to access by providing flexible and scalable support to the user. Designed to have conversations with thousands of people a day, chatbots can support underserved groups through on-demand 24/7 availability and eliminate travel costs or the need to schedule appointments. Individuals may find it challenging to talk about mental health, and may be more likely to share and disclose information using chatbots than through traditional in-person therapy, enhancing a sense of privacy and quelling stigmatic concerns.

In 2011, it was estimated that 37% of individuals on Medicare had a serious mental health disorder [2]. Mood disorders are associated with relatively high treatment center readmission rates, further taxing the already limited availability within the inpatient mental health system. Within 30 days, 15% of patients with mood disorders are readmitted nationally and across the USA; the average cost for the repeated hospital stay is approximately \$7200 [3].

A key factor in influencing the rate of readmission includes poor outpatient follow-up [4, 5]. Follow-up calls often follow a structured script which a call center nurse follows, but through a chatbot these call scripts can be converted to chatbot scripts. Through the

electronic health record (EHR), a digital version of a patient's paper chart, patients can opt in to allow a chatbot follow-up by sending them a text message. When a predetermined script is not sufficient for the needs of the conversation, it is escalated to call center staff to take over the conversation from the chatbot. The majority of these conversations can be handled by the chatbot which provides increased access to care and a reduction in the* total cost of care.

How Chatbots Work

To explain how chatbots work we focus on one case study analyzing Tess, a chatbot developed by X2AI Inc. used by health care systems, employers, and employee assistance programs (EAP's) to deliver emotional wellness support. Tess is designed using a combination of technologies, emotional algorithms, and artificial intelligence techniques to learn about the needs of the user and offer personalized support. In collaboration with mental health professionals, Tess repeats conversations that specialists have crafted, in order to engage with users in an empathetic way that is appropriate to the inputted emotion or scenario. All recommendations from Tess require sign-off from a counselor to ensure safety and consistent quality support.

Specific interventions are employed based on the patient's reported concern. If the patient tells Tess that they feel anxious, Tess may offer a strategy to help them achieve a more relaxed state. When starting a conversation, Tess states "It's important for you to know that if you are in a crisis you should contact emergency services. You can type SOS for resources after our first chat is over. OK?" Anytime a user types or says "SOS" or reports suicidal ideation during the conversation, Tess offers resources. Tess also provides basic risk assessment and sends crisis alerts to a counselor or crisis center, instructing humans to take over the conversation in order to de-escalate the situation. Similarly, to how a caseworker would make recommendations on patient care, chatbots can also leverage existing resources and refer patients to other digital health tools.

There are different ways to build mental health chatbots. Companies like X2AI can provide a customized version of an existing chatbot, and platform that allows clients to build chatbots from the ground up. There are general purpose tools available in the market as well that can build chatbots from the ground up, such as Google Dialogflow or Amazon Lex. Building a bot from the ground up requires* significant amounts of resources and time, therefore most companies elect to customize an existing chatbot.

The Tess system has a conversation library of 800 different supportive interventions, consisting of* over 3,000,000 unique conversations. Over 50 coaches and psychologists have engineered the conversations available through Tess and these conversations are personalized to each user's needs to deliver a wide range of emotional wellness intervention—from cognitive behavioral therapy to deeper, psychodynamic strategies. It is vital that the authoring and crafting of these conversations are done according to high-quality standards. These conversations are used by thousands of people who chat with the chatbot. Ethical considerations need to be part of the quality control process, for example, in order to ensure the content will not include any bias [6].

Tess processes quantitative and qualitative feedback from users to automatically enhance the system and improve the user experience. Conversations with the highest helpfulness ratings—measured by Tess asking the user about the helpfulness of the conversation after every intervention—are prioritized to be delivered before others to ensure relevancy and utility. Through each conversation Tess tailors the frequency of conversation initiation, timing of check-ins, and increases the capacity to identify emotions.

Economic Impact

How a Chatbot Could Change the Economics of the Employee Benefits Industry

Employers purchase an employee assistance program (EAP) for their employees as part of a benefits package. These programs offer extensive

benefits ranging from mental health support, personal legal assistance to financial planning. The potential for change in the economics of this niche industry can illustrate how the health care industry can toward technology adoption.

Historically, a high level of trust existed between EAP providers and employers. Employees were pleased with the introduction of new support offerings, and utilization was measured by the hours clinicians billed and considered successful at 15–25%. As a result, employers happily shared the benefits of better rates as EAP providers discovered lower rates as they bundle demand; a \$10 price per employee per month (PEPM) was sustainable and led to cost savings for employers overall.

A downward trend in both utilization levels and PEPM have created a vicious cycle, due to numerous reasons we do not have bandwidth to cover in this chapter. Currently the industry-wide average utilization hovers around 5%, with a PMPM as low as \$1.25. Several factors which maintain this balance are starting to change. First, we will list the factors that have contributed to the status quo. Then, we will explore which of these strategies can be used to counteract the negative effect of these factors. Finally, we discuss practical takeaways and considerations on how to implement these strategies in order for EAP's and eventually the industry as a whole—to shift back to higher utilization and higher PEPM rates.

Factors Causing Low Utilization

1. A low PEPM leaves less marketing budget. Limited resources allocated to marketing makes it hard to reach and engage the employee population. Benefit fairs require travel and the* hourly costs of staff being at the fair.
2. The EAP offering does not often match employee needs. If an EAP only offers face-to-face sessions, then individuals who could be helped with low-cost self-help interventions will instead use costly face-to-face sessions. Higher costs of service delivery results* in less budget for marketing to drive utilization.
3. Face-to-face counseling is costly, and thus there has to be a strict eligibility check

procedures* in place. Accessing online self-help resources require an eligibility check in order to track utilization. Requirements such as entering a username and password to access any EAP resource serve as barriers for those in need.

Utilization Strategies of Change

1. Partner with an innovative startup. The way the marketing dollars are deployed can make a big difference in the utilization that is achieved. Therefore marketing budgets can be expected to remain the same. Informing members about their benefits through social media creates a direct relationship between the member and the EAP, making these benefits more accessible. The standard way of improving social media marketing returns is to pay for a professional marketing firm, or provide time-consuming social media training for current staff members. To test if such an investment is worthwhile for your population, the most cost-effective way could be to work with an innovative technology provider. These companies offer digital products to members and have a low marginal cost, allowing their products to be used as much as possible.
2. Cut costs and scale support with a digital mental health solution. Face-to-face sessions are the most trusted way of providing support for mental health issues. For many EAPs this is also the only option offered to get support with any mental health issues. However, a large percentage of members might not need any face-to-face sessions in order to cope. Sometimes a conflict with a coworker can lead to high levels of anxiety, for which a digital intervention could suffice. Wait times for face-to-face sessions often range from a few days to many weeks, whereas digital interventions are available on demand. In this way, members get easier access to care, while EAPs save funds as digital interventions cost a fraction of face-to-face sessions.
3. Streamline the eligibility process. A strict eligibility policy brings down utilization and drives costs for the EAP call center, as members need support to retrieve their login

credentials, or verify while on the phone. However, services which have a lower marginal cost, such as blog posts and informational content, do not need to be accessed only after an eligibility check. Alternatively, tracking utilization can also be done through the use of a chatbot. The chatbot only needs to do a verification once and afterward it recognizes the member by phone number. Then, when the chatbot recommends a blog post or an article, the utilization gets tracked automatically.

Factors Causing Low PEPM

1. Measuring utilization is easy, which provides the purchasers with a very strong negotiation position to demand lower PEPM rates.
2. Measuring ROI is hard, and research is often not generalizable. Results from research studies of EAP programs on symptom reduction and ROI are often not generalizable as specific employer populations are very diverse. It is costly to measure the impact of services offered, and either has to be done by a clinician or a nurse calling from a call center to take necessary assessments. The financial burden of this process limits funding toward research studies for each specific employee population.
3. Purchasers spend their budget on procuring counseling services directly from providers. These providers charge a fee for service, and use substantial marketing budgets to engage the population. This takes away from the PEPM budget for EAPs.

PEPM Strategies of Change

1. Use a chatbot to measure engagement. Due to the eligibility check discussed above, it is hard to show high utilization on the offering that would have been used more. Using a chatbot allows you to track exactly how much time members spend interacting with your content.
2. Reduce ROI research costs with a digital solution. ROI studies are costly, due to the cost of the intervention itself, the cost of recruitment, and gathering data. Participant recruitment and the gathering of data is often done over the phone through the call center which is expensive, whereas e-mail is not a feasible way to get

enough engagement. Digital interventions are much more accessible and can deliver surveys and questionnaires at the members convenience such as before starting the next chapter in the online course, or through a check-in from a chatbot. Digital interventions make it possible to gather pre- and post-intervention measurements, and can intervene itself as well. This fully automated research process brings down the cost of an ROI study, which makes it possible to create a custom study for every account or employee population.

3. End the competition, and start collaborating. New players in the market provide their data on high levels of engagement which are powered by large marketing budgets, and the use of social media strategies as mentioned above. In this way they compete with existing EAPs for the budget of the purchaser. In the short term, these players are able to get market share. In the long term, growth will stagnate as they become subject to the same overhead as EAPs are facing. A more efficient approach for both sides is not to compete but to partner in providing the member better access to care.

Real-World Applications

To demonstrate the impact of chatbots in real-world applications, the pages below show how versatile chatbots are and describe a wide array of different use cases.

Case Study: 24/7 Access for 430,000 People Served by a Public Health Department

This Public Health Department manages a population of 430,000 people in a region with an agricultural output of over 4 billion dollars, and provides access to mental health care to anyone in need regardless of insurance coverage or citizenship status. Many seasonal workers who come to the region are essential to the local food production industry, but these jobs are low paying and generally do not come with insurance benefits.

The Latino immigrant population greatly depends on the health department to get access to care and the demand for Spanish-speaking psychologists is high. Due to budget constraints and a shortage of counselors in the region, wait times for support were often higher than 6 months to a year. Outsourcing part of the mental health treatments to traditional behavioral health providers misaligned incentives, increased costs, and was unable to resolve barriers to accessing care. Compounded with a high demand for care in the region, the workload for existing staff contributed to an overtaxed system and feelings of burnout.

Through state-funded grant studies, the public health department found that increasing free access to care effectively lowered the total cost of care for the region's population. Through a strategic population management approach in an effort to provide quality care at an affordable cost, Public Health Department made Tess available free of charge to anyone within the region in both English and Spanish, and users could refer friends and family.

Tess is a mental health text support service available through toll-free SMS and Facebook Messenger. Similar services rely on trained counselors to exchange messages with patients, but are limited by the amount of people you can reach due to budget, staff bandwidth, and hiring constraints. Tess offers the same text support chat model but instead is automated by an artificial intelligence system which repeats pre-written mental health scripts and learns from each conversation.

To alleviate initial concerns in implementing a chatbot, a lightweight integration was created to exchange data on usage metrics to case managers. Additionally, whenever a person was in crisis and a conversation needed to be escalated, human counselors were able to take over the conversation and notify the health department of the incident.

By implementing Tess as a resource in the community, the public health department was able to increase the quality of care by offering 24/7 on-demand mental health support. The total cost of care was affected in two ways: [1] directly lowering behavioral health care costs and [2] indirectly lowering total cost of care through

increased access to behavioral health support. Traditionally, this level of care would normally cost \$2200 per treatment, whereas the use of Tess only costs \$5 per person per month.

Tess facilitated a significant increase in access to care and clients experienced a 100% decrease in wait times due to the on-demand nature of the program. In general, when a population gets access to Tess the following impact is observed. Eighty-seven point five percent move toward recovery with a reduction in symptoms of up to 50%. Additionally, the remaining 12.5% of the population sees a decrease in the severity of symptoms by 50–100%. The benchmark for a successful treatment by a counselor is a reduction of 50% in the severity of symptoms or more, proving that—in some cases—the chatbot is as effective as its human counterparts.

Case Study: AI Mental Health Support for Young Mothers in Africa

Original article: <https://www.x2ai.com/blog/duke-university-postpartum-depression-support>

In 2019 Duke University launched a new version of their Healthy Moms program, bolstered with an AI-powered on-demand chatbot, to help women navigate pre- and postpartum mental health concerns in Kenya. Both as a new form of treatment and in combination with traditional treatments, the program focused on increasing the well-being of mothers in underserved populations by reducing the chances of developing pre- and postpartum depression. Inaccessibility to care can be caused by a multitude of factors, including socioeconomic status, race/ethnicity, and demographics.

Lack of access to care affects both women and their children, leading to increased maternal morbidity and mortality, poor infant health, and poor developmental outcomes. Most cases of depression in low-to-middle-income countries go untreated due to a lack of trained professionals to assist with pregnancies and the postpartum period. Outside of Nairobi, Kenya, a staggering ratio of 1 provider per 200,000–250,000 people provides professional care.

In an effort to close this gap in care, the World Health Organization developed the Mental Health Gap Action Program (mhGAP) intervention guide to assist nonspecialist providers address in providing mental health services in primary health care settings. The Thinking Healthy Program, an example of mhGAP, is a 15-session, cognitive behavior therapy (CBT)-based intervention for treating perinatal depression. This is typically done by community health workers with no specific background in mental health. They are trained to help pregnant women identify unhealthy thinking and equip them with the resources to practice thinking and acting healthy.

Despite the potential of such programs, most women in low-to-middle-income countries who need treatment still do not have access to care due to the common complications most task-sharing models face, such as lack of funding and infrastructure. By adapting the Thinking Healthy program to be delivered through AI technology like Zuri, a chatbot created by X2, Duke University aimed to break down those barriers in low-to-middle-income countries by making it possible for anyone with a basic phone to receive high-quality, psychological support at any time, regardless of location. Duke University's Healthy Moms program utilized Zuri to deliver the mhGAP Thinking Healthy Program via technological adaptation.

A single-case experimental design using Zuri was conducted with pregnant women and new mothers recruited from hospitals outside of Nairobi, Kenya. Eligible participants would have regular conversations modeled from the Thinking Healthy program via Zuri and asked women to check in every 3 days during the 1- to 2-week randomized baseline and interventions periods to evaluate progress.

Zuri would ask participants to report their mood, asking questions such as "How are you feeling now?" If the response was positive or neutral, Zuri would respond by offering a coaching chat such as music, cooking, or passions. If the response was a negative emotion, Zuri would respond with supportive intervention such as mindfulness or relaxation. There was no limit to the number of conversations or how often

a participant wanted to communicate with Zuri. All modules, both positive and negative, were prioritized based on combined helpfulness ratings in which women reported on the utility of the modules.

Participants expressed that they credited Zuri for positive life changes based on their conversations, and that they trusted this AI technology because it was more unbiased and provided both factual and useful information. Many women said that they preferred to chat with Zuri than with a counselor because they felt they could be more open with a chatbot. When the mothers were asked what their favorite part of Healthy Moms was, many attested to the easy and relaxing exercises learned through Zuri, including meditation, breathing, and walking. They also raved about the helpful advice they received from the Healthy Mom program such as breastfeeding and how to play with the child.

Emotional well-being AI programs have great potential to address the large treatment gaps that exist in underserved populations and improve moods when used both as a new form of treatment and in combination with traditional treatments. Zuri works by engaging a patient in conversation through text messaging. Either Zuri or the patient can start a conversation, and Zuri walks the patient through a structured curriculum, like the one defined in the Think Healthy program. Zuri also has a safety measure built in to engage human counselors if additional support is needed. AI-enhanced systems such as Zuri improve over time with practice and experience just like mental health specialists and nonspecialists trained to deliver psychotherapy. Over time, Zuri's emotional recognition algorithm was updated when it interpreted the emotional responses of the participant. Adding AI chatbots as a form of care allows convenient and cost-effective interactions to keep patients engaged and on track throughout their pregnancy. It also adds an extra layer of care and support outside of office hours to ensure the mother-to-be has the care she needs to maintain her mental health.

It was concluded that Zuri was a valuable resource accepted by the sample pregnant women and new mothers participating in the

beta launch of Healthy Moms. The participant's mood improved by 7% over time. The next steps to making Zuri a more acceptable and usable platform will be to explore different channels to deliver and communicate, refine intervention conversation flow, and build Zuri into a multilingual platform to include Swahili to better support the user demographic [7].

Case Study: Supporting Caregivers and Their Patients

Chatbot technology is not limited to pre- and postnatal care for those in low-to-middle-income countries. This technology can be modified to meet the needs of many careers and individuals to boost moods and reduce signs of depression and anxiety. Another case study exploring the power of chatbots is the work by SE Health.

Being a caregiver is an extremely selfless career, and more often than not these individuals have a tendency to take care of everyone else and forget that they have to also take care of themselves. For the caregiver, this can be overwhelming and lead to anxiety and burnout. Most cases of caregiver self-neglect are perpetuated by a lack of time and the cost of seeking treatment, posing barriers that make it almost impossible for them to receive the support and help they need.

SE Health is a Canadian nonprofit and charitable organization that services client, family, and health system needs, primarily at home and in local communities. SE Health was motivated to face these barriers head-on and make it convenient for caregivers and patients to get the support and training they need. SE Health developed a mental health chatbot named Elizzbot using X2's technology to provide support for caregiving professionals, patients, and family caregivers.

Elizzbot was repositioned to be a "helpful friend" built with a positive personality in mind the conversations are meant to be informative, empowering, and encouraging.

SE Health chose to customize an existing chatbot by taking X2AI's Tess chatbot as a starting point. Based on the knowledge of the existing staff who supports the nurses, new

content was crafted in order to make a custom version for caregivers.

Through this customizable platform and user approach, SE Health was able to gain a deeper understanding of the issues faced by caregivers and build a system that delivered personalized support to best meet each person's needs. The technology also put a focus on reinforcing the skills practiced in previous conversations through check-ins, helping to build resilience, and create unique conversations for each user [8].

An analysis of engagement patterns showed that 461 text messages on average were exchanged between Tess and the participants. The satisfaction rate was observed at an average of 88%. The chatbot measured the satisfaction rate by simply asking "Did that help?" after each chat. A positive reply was considered when the patient indicated that the intervention was helpful. Additionally, findings from a satisfaction survey found that participants felt the chatbot responded effectively with relatable topics [9].

With proof of Elizzbot's ability to support caregivers, SE Health is continuing their research and plans to strengthen the body of knowledge on psychological AI to conquer many of the traditional obstacles of mental health care many patients face. Today, Elizzbot offers emotional support at any time as a way to decrease burnout and improve prosperity to employees at SE Health, as well as signed up visitors on Elizz.com. At SE Health, these resources were evolved and scaled to support the staff, patients, and public supporters across Canada and around the world.

A new version of Elizzbot was launched as part of a grant study funded by the Baycrest Center for Aging and Brain Health Innovation (CABHI). During this study, a version of Elizzbot was offered which would read out loud the messages it would normally send. The individuals chatting with Elizzbot are also able to reply by speaking out loud. This design was found to be more appealing for older adults. The downside of this approach is the hardware cost, as a Google Home is required in order to access Elizzbot in this way [8].

Case Study: Addressing Comorbidities in Childhood Obesity, Prediabetes, and Mental Health Struggles

Many families feel the strain of childhood obesity. Along with the physical concerns, such as the potential for diabetes and hypertension, youth who are facing obesity often experience psychological symptoms. Low self-esteem and self-image can lead to disorders such as depression. It is difficult to commit to treatment goals due to missed school and work days, logistical difficulties around distance and transportation. The financial burden of co-payments and unreimbursed expenses, which could include dietitian visits and enrollment in fitness activities are barriers to care. These disorders have a 70% chance of continuing through adulthood making intervention critical in a child's long-term health.

Technological services have the potential to be utilized to help reduce these barriers, both for consumers and society as a whole. Behavioral intervention technologies (BITs) provide solutions that incorporate the benefits of technology and psychology to tackle different health needs through multiple avenues. BITs help patients in many ways, including proving accessibility*, an increased capacity for engagement, as well as a decreased cost and stigma, particularly among youth.

Artificial intelligence is one example of the most recent forms of BITs being utilized for behavior and mental health. Chatbot platforms are used for many BIT use cases as an extension of an office visit, where work done between clinician and patient can be reinforced between sessions through targeted conversations that are customized to each patient. In conjunction with a pediatric weight management program, obesity treatment, and prediabetic intervention, chatbots have the capability to build access across the tiers.

X2's chatbot Tess was customized with Nemours Children's Hospital for a weight management program for youth dealing with obesity and/or prediabetes. Nemours Children's Hospital integrated the intensive behavioral counseling recommended for weight management programs, paired with behavioral mental health approaches.

Youth with obesity symptoms enrolled in a multidisciplinary weight management program and were able to access Tess through a text-capable mobile phone number or an existing account, like FB Messenger or WhatsApp, without needing to download a separate application. The Tess integration within existing electronic health record (EHR) systems autopopulates data directly into the system without requiring extra work from the physician. Additionally, if a physician updates the EHR with mental health issues a child is experiencing, it can automatically trigger an invitation text message to be sent to the patient.

For 5 years Nemours Children's Hospital tracked which "targeted behavior" changes were most effective. For example, a young patient might have a goal of becoming a ballerina, and the strategy to reach that goal is to practice dancing for 1 h per day. This dataset of targeted behavior changes was then anonymized and shared with X2AI to develop the clinical scripts, where the physicians' responses were converted into a form that Tess could deliver. From there the scripts were read, edited by the physician and health coaches, and tested until both teams were satisfied with the outcome. The chatbot used motivational interviewing to learn which strategies the patient would want to use to achieve their goal. In the weeks after the chatbot would remind patients of these individually chosen strategies.

To measure the usability of Tess, common digital health intervention metrics were used such as satisfaction rate, engagement levels, the quantity of messages exchanged, as well as more behavior metrics including progress toward goals. Data collected based on conversations were screened three times per week during the first 2 weeks, and once per week during the following weeks. Approximately 5% of human intervention was applied for quality assurance during the early stages of this study, whereby alerts that the conversation needed support (e.g., system error or received "no" answer to a question) were sent to a person who would take over the conversation until it was corrected and Tess could resume. One such change implemented due to human intervention was the increase of conversations focused on

positive emotions, rather than a focus on negative emotions.

The results from the first cohort showed that a total of 4123 messages were exchanged between participants and Tess, resulting in 267 total conversations, which is an average of 12 conversations per patient. Adolescent patients reported experiencing positive progress toward their goals and targeted behaviors 81% of the time and patients indicated that the chats with Tess were helpful 96% of the time.

The use of an AI chatbot was found to be feasible as an adjunct to treatment, based on the adolescents in a weight management program who rated their conversations useful. The large number of messages exchanged between the chatbot and the teens, combined with the high helpfulness ratings, illustrate that this chatbot service may be an influential and engaging support tool for youth who are facing childhood obesity [10].

Abstract

Substance Use Disorders (SUD) including alcohol and drug dependence are one of the major healthcare challenges in industrialized countries. Since substance use does not always result in SUD, it is essential to

understand the complex interplay between environmental triggers (e.g., access to drugs, traumatic experiences) and biological factors (e.g., genetic predispositions, drug-induced brain alterations) that shape the development of SUD. Machine learning (ML), a subfield of artificial intelligence, has emerged recently at the forefront of medical research due to its data-driven approach and ability to model multivariate factors. It is used in SUD research to perform tasks such as disease diagnosis, predicting treatment outcomes, and identifying significant risk factors. However, the field of ML applied to SUD research is still in its infancy and faces many methodological and systemic hurdles. This chapter surveys some initial promising ML studies in SUD and discusses the main challenges for the field such as unreliable disease labels and the

sensitivity of ML algorithms toward small and heterogeneous data sets. In particular, the chapter outlines how the advances in ML coupled with an increasing availability of large and longitudinal SUD data sets could potentially transform the diagnostic process and treatment of SUD in the future.

Machine learning · Deep learning · Substance dependence · Substance use disorder · Substance abuse · Addiction · Artificial intelligence

Introduction

The United Nations estimated that about 5.5% of the global population or 271 million people reported having consumed one or more drugs in the year 2016 [1]. In that year alone, alcohol was directly responsible for about three million deaths [2], and opioids caused a further 585 thousand deaths [1]. Direct deaths from drug use, in general, have increased over 60% from the year 2000 to 2015 [3]. Therefore, alcohol and other substance dependence is one of the major public health problems of the present times. Consuming alcohol and other harmful drugs is clinically called “substance use.” A “substance” here includes legal drugs such as alcohol, tobacco, as well as illegal drugs such as opioids (heroin, morphine, and other prescription painkillers), stimulants (cocaine, methamphetamine), hallucinogens (LSD, psilocybin mushrooms), inhalants, sedatives, depressants, hypnotics, and anxiolytics. Substance use can cause various scales of substance-induced disorders related to anxiety, mood, sleep, and sexual functioning and in rare cases can trigger psychosis [4, 5]. These effects can last anywhere from a few minutes to a few weeks based on the type of substance, the extent of intoxication, and the manner of injection. When such substance use becomes chronic and starts impairing one’s health, work, and social relationships, it is diagnosed as a psychiatric disorder called “substance dependence” or “substance use disorder” (SUD). As opposed to

substance use, substance dependence is generally characterized by an impaired ability to control the use of the substance and a persistence of use despite harm and adverse consequences [4]. For people with SUD, the motivation for substance use can begin to outweigh the drive for social and security needs such as keeping a job, saving money, and maintaining social relationships, and in adverse cases can even outweigh the need for basic physiological needs such as getting enough sleep, food, and shelter.

Challenges in Diagnosis and Treatment

Not all substance users develop a substance use disorder (SUD). Among the estimated 271 million people who consumed one or more drugs in the year 2016, only about 13% had a SUD [1]. For diagnosing SUD, medical practitioners around the world refer to the guidelines of International Classification of Diseases (ICD-11) [4] or the American Diagnostic and Statistical manual of Mental disorders (DSM-5) [6]. These diagnostic manuals suggest the clinical assessment of subjects for symptomatic addictive behaviors and effects of addiction. These include signs of inability to control substance use, substance use becoming an increasing priority in life, increased tolerance to the drug’s effects, and experiencing withdrawal symptoms [5]. While ICD-11 [4] identifies two stages of SUD development: (1) harmful pattern of substance use and (2) substance dependence, DSM-5 categorizes SUD development into three stages: (1) mild, (2) moderate, and (3) severe SUD, depending on how many of its 11 diagnostic criteria are met [6]. The current diagnostic systems, ICD and DSM, rely on clinical symptoms and signs of addiction for diagnosing and treating psychiatric disorders. They are criticized for being agnostic to the pathophysiology and the neuro-psychological mechanisms that underlie psychiatric disorders such as SUD [7, 8]. Hence, there is a shift toward developing new ways of classifying psychiatric disorders based on neurobiological measures and dimensions of psychological behavior instead [7, 9].

Over the years, researchers have identified many risk factors that contribute to the development of SUD in substance users. These risk factors can be categorized into environmental and genetic factors [10]. Prominent environmental risk factors include the ease of access to drugs, age of exposure to substance use, social facilitation, adverse life events, lack of familial support or supervision, stress, and social issues [8, 10]. Particularly, social issues such as poverty, unemployment, lack of access to housing, abusive childhood experiences, and so on form a complex web of traumatizations that contribute significantly to the development of SUD [11]. Genetic risk factors are predispositions that make an individual more prone to develop a SUD. These include neurochemical vulnerabilities in the brain [12, 13], cognitive styles [14], and other co-morbidities such as anxiety disorder and depression [15]. Such biological vulnerabilities interact dynamically with the environment, adverse life events, and the substance being consumed to ultimately determine if a substance user would develop SUD or not [8, 10, 12]. Therefore, diagnostic tools that can identify the biological vulnerabilities (or biomarkers) directly from brain imaging or even genomics would significantly improve the sensitivity of the existing diagnosis methods [7].

Active research is undergoing to identify biomarkers directly from the brain structure or function in SUD patients [16]. To study and characterize alterations in the brain, different neuroimaging techniques are employed such as structural Magnetic Resonance Imaging (sMRI), functional Magnetic Resonance Imaging (fMRI), Positron Emission Tomography (PET), and single photon emission computed tomography (SPECT). For instance, studies using PET and SPECT imaging have shown that dopamine levels in subcortical reward circuits and prefrontal cortex are associated with substance use [16]. Similarly, fMRI studies have revealed how stimulants such as cocaine and methamphetamine affects brain areas such as nucleus accumbens to produce euphoria and subsequent cravings [16]. For alcohol use disorder (AUD), a type of SUD caused by problematic consumption

of alcohol, sMRI, and fMRI studies identified numerous neurotoxic correlates in the brain such as enlarged ventricles, grey and white matter loss in frontal and reward-related brain areas, as well as altered functional connectivity in the amygdala and nucleus accumbens [17, 18]. However, these biomarkers alone are not very reliable as diagnostic tools due to their variation across the population and their overlap with other mental health problems such as depression and anxiety disorders [15]. Further advancements in neuroimaging techniques coupled with modern artificial intelligence (AI) methods could provide more reliable biomarkers from brain imaging. Section “[Machine Learning for Drug Dependence](#)” describes how current AI-based methods are being employed in SUD research to discern the effects of different biological dispositions and environmental risks, and understand their interaction with the drug itself and the employed treatment programs.

Another line of research for identifying biomarkers looks directly into genetic data for signs of SUD vulnerability. The heritability of different SUDs is estimated to range between 40% and 70% [10]. Genetics have been shown to modulate the amount of intoxicating or aversive effects caused by substance use [8]. For instance, studies have linked the susceptibility of an individual to the neurotoxic effects of chronic alcohol use with the dysfunction of the serotonin transporter (5-HTT) gene [12]. However, such genetic findings report statistical associations of risk but do not necessarily translate to diagnostics [7]. Genetic predispositions can also influence cognitive styles that can make individuals more vulnerable to SUD [9, 14]. Brain circuits that modulate certain vulnerable cognitive styles and behaviors in individuals have been associated with candidate genes such as D2 receptor, serotonin transporter (5-HTT), and the dopamine transporter (DAT) [13]. However, caution must be exercised as the risk of developing SUD due to marginalizing social factors (e.g., unemployment or restricted access to the housing market) might wrongly be affiliated to biological traits [11]. AI methods could be used with genomic data in the future

to perform multivariate analysis of genetic influences, disseminate the complex pattern of gene expressions, and identify drug targets. Thus far, the field of AI applied to genomics is still in its inception and it might require few more years for studies to emerge in this field.

Since SUD is a chronic disorder, treatment programs for SUD advocate long-term care with several follow-up sessions [19]. These programs can include medically-assisted detoxification, behavioral counseling, therapy sessions, and alleviation of withdrawal symptoms [20]. Not only can different drugs have different effects on a person's physical and mental well-being, but also the same treatment approach might show differing responses on individuals, depending on their environmental influences and their biological dispositions [20]. The disease trajectories can also be highly individualistic and include several phases of losing and regaining control over drug intake [21]. To further complicate the issue, many SUD patients usually consume more than one drug causing polysubstance effects [16]. All of these factors make the treatment of SUD not only challenging but also highly individual since no single treatment is right for everyone. To discover better treatment methods and design more individualistic treatment programs (called precision medicine), major medical research centers around the world are carrying out large-scale studies involving the gathering and analysis of data from multiple modalities such as brain imaging sessions, clinical assessments, and genomics [22, 23, 24, 25]. Furthermore, the widespread availability of smartphones and wearable electronic technology has permitted researchers to monitor behavior, cognitive-emotional states, stress reactivity and environmental exposures under real-life conditions [21]. Artificial intelligence methods can be used to analyze such large and complex data and model the effects of multiple data modalities and triggers. These AI models can then be used to predict the success of treatment programs, understand disease trajectories, and design personalized treatment programs [26, 27, 28]. AI-based studies on SUD treatment are further explored in section "Machine Learning for Drug Dependence."

Role of Artificial Intelligence

Traditionally, computer programs used for medical applications have been rule-based. This means that human programmers and experts provide explicit instructions to the computers on how to process the medical data and make decisions. In contrast, a subfield of AI called "machine learning" (ML) consists of programs that are capable of learning from example pairs of input data and the expected output to perform a specific task, without being explicitly instructed on how to perform the task. After learning the mapping between the input data and the output decision or label, the ML algorithm can be used to make predictions about new, unseen data. ML algorithms can automatically figure out the relationship between the input and the labels to solve the pre-defined task. Therefore, ML methods can be applied to complex problems consisting of several variables and data types, complex mechanisms, or unknown factors of influence, where it would not be feasible to develop rule-based methods anymore. ML is a particularly promising approach in healthcare research, since the relationship between the observed data (e.g., MRI) and the output (e.g., disease labels) can be complex, sparse, noisy, latent, and distributed across several data modalities [29]. Therefore, in the last decade, ML has emerged at the forefront of medical research in computer-assisted healthcare [29, 30].

Classically in ML, the raw data such as MRI, EEG, clinical assessments, or biochemical test reports are first processed to extract features that are deemed useful by experts for the task. For instance, for psychiatric diseases, this stage might include extraction of regional cortical thickness from sMRI or connectivity matrices from fMRI [31]. However, this step is still prone to introduce human bias into the learning process. In contrast, a new class of ML algorithm called "deep learning" is capable of learning complex and hierarchical relationships directly from raw data such as medical images or genomics [32]. Deep learning methods have surpassed human performance at tasks such as classification of images and speech recognition [32]. In medical imaging applications including skin cancer

diagnosis and brain tumor segmentation, they currently hold state-of-the-art performance [30]. Some initial promising deep learning studies based on neuroimaging data have also been published for psychiatric diseases such as Alzheimer's disease and schizophrenia [45].

Section “[Data Sets for Machine Learning](#)” highlights the significance of data sets to ML research by introducing some of the popular data sets in SUD. Next, section “[Machine Learning for Drug Dependence](#)” surveys the preliminary ML-based studies in substance dependence and discusses their ongoing contributions to the field of SUD research. Finally, section “[Challenges and Outlook](#)” discusses the current challenges that must be overcome to build reliable ML solutions for SUD diagnosis and treatment. The section also presents the promises of ML and its possible future applications in substance dependence.

Data Sets for Machine Learning

As discussed in section “[Challenges in Diagnosis and Treatment](#),” SUD is a chronic disorder that is characterized by the complex interactions between environmental and biological risk factors. To congregate these different influencing factors and understand their complex interactions, a number of multi-site studies have been carried out, e.g., IMAGEN [22], UK Biobank [23], NCANDA [24], and ENIGMA [25]. These studies acquire large data sets consisting of hundreds or thousands of subjects and for each subject, multiple domains of data are collected depending on the study design. Such data modalities, for example, include brain imaging, genomics, clinical assessments, psychiatric tests, self-reports, and demographic data [22, 23, 24, 25]. To better understand the dynamics of losing and gaining control over drug intake in SUD, longitudinal and – if possible – real-time data (e.g., acquired via smartphones) are essential [21]. Such large-scale data collection initiatives are the key to future research in SUD and other major psychiatric disorders. These data sets not only facilitate large-scale

statistical analyses but also enable the development of novel methodologies based on ML and particularly deep learning.

Machine Learning for Drug Dependence

In this section, existing ML studies in SUD are surveyed and their implications to SUD research are discussed.

ML methods promise a data-driven approach to diagnosing SUD, generating individualized treatment recommendations, and predicting treatment outcomes. Since its inception, a number of different ML methods have been invented [32] and some of them have been applied to SUD. These include Logistic Regression, Random Forest, Decision Trees, and Support Vector Machines (SVM) that are applied to hand-crafted features (e.g., regional brain volumes extracted from sMRI) [26, 27, 28, 31, 33, 34, 35, 38, 39, 40, 41], as well as modern deep learning methods such as Fully-Connected Neural networks (FCN), Convolutional Neural Networks (CNN), and Recurrent Neural Networks (RNN) [42, 43, 44] which can be directly applied to raw data (e.g. sMRI). These ML models are trained either on a single data domain (e.g., just sMRI) or a combination of multiple domains (e.g., demographic data in combination with cognitive testing and sMRI) [26, 33, 36, 37, 38]. ML models have been trained to perform several tasks such as separating patients with SUD from healthy controls and mild substance users [26, 31], predicting the development of SUD in the future [26, 37], predicting treatment success [27, 28], and identifying the most informative risk factors [37, 38, 40]. Figure 1 demonstrates how ML is used to solve some of the challenges in SUD diagnosis and treatment.

So far, most ML studies focus on AUD, since alcohol dependence is one of the prominent SUDs and large data sets are available for it [22, 24]. A common application is to infer the influence of different risk factors and data domains for the onset of AUD. Squeglia et al. [37] trained ML models on the data of adolescents in the age group of 12 to 14 to predict the development of moderate to high alcohol use at the age of 18. They trained on a combination of demographic,

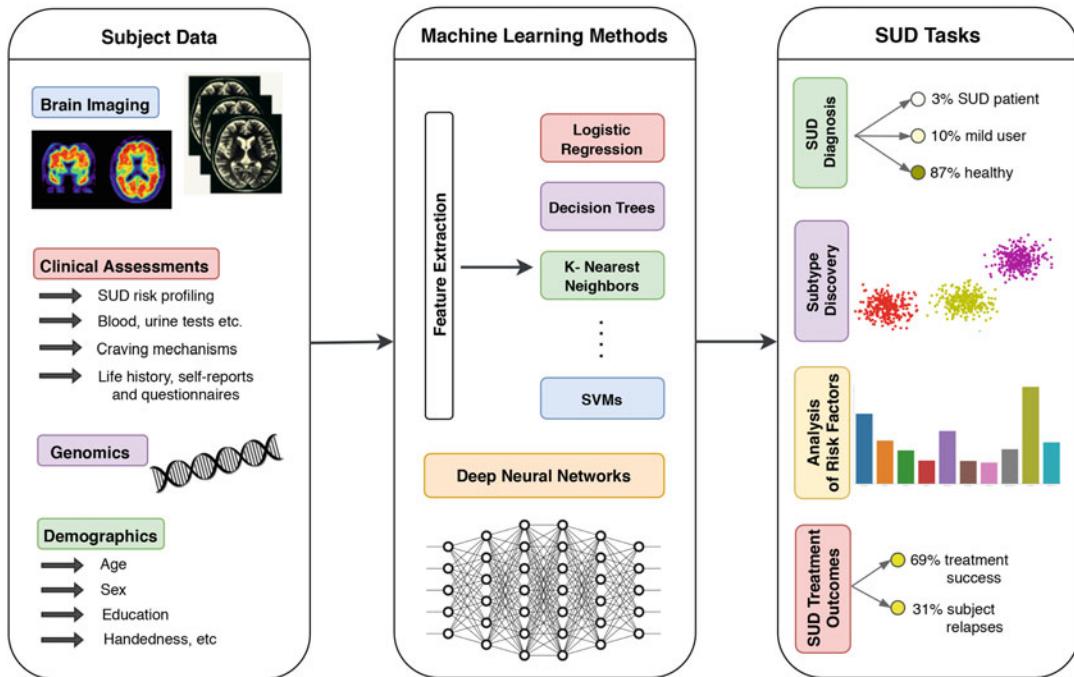

Fig. 1 An illustration of how Machine Learning (ML) is used in Substance Use Disorder (SUD) research. The first column lists some of the commonly used data modalities including brain imaging and clinical assessments, and the second column lists some of the classical ML and deep learning methods. The models can be trained on a single

data domain (e.g., brain imaging) or on multiple data domains (e.g., clinical, demographic and imaging data). The third column lists some of the common applications in SUD including diagnosis, discovering neurobiological disease subtypes, determining the influence of different risk factors, and studying treatment outcomes

neurocognitive, and neuroimaging data and identified 34 factors which best predicted future development of alcohol abuse. These included worse executive functioning, behavioral factors, thinner cortices, and reduced activations in frontal and temporal areas of the brain. A multi-data-domain study showed that brain connectivity matrices obtained from resting-state fMRI were best at predicting alcohol use severity, compared to other data domains such as demographic data, sMRI, or task-based fMRI [36]. Another study based on resting-state fMRI data reported that the so-called reward network and the executive control network in the brain were most informative for diagnosing AUD [35]. The largest classical ML study so far has been performed on the IMAGEN data set by Whelan et al. [26] who report an AUC (Area under the receiver-operator characteristic curve) of 0.90–0.96 for the separation of 14-year old binge drinkers of alcohol and

14-year old controls and an AUC of 0.75 for predicting binge drinking at 16 years. Here, a combination of history, social experiences (e.g., romantic relationships), and brain features was shown to be most predictive, supporting the hypothesis that multiple causal factors shape later alcohol use. Guggenmos et al. showed that an experienced radiologist scored 66% at diagnosing AUD from sMRI data, while their ML method achieved a balanced accuracy of 74% on the same sMRI data [31]. These results imply statistically significant neurophysiological differences among AUD and healthy controls. Few recent studies have also applied deep learning models to identify subjects with AUD [43, 44]. They trained Convolutional neural network (CNN) models on 2-dimensional slices of sMRI data and reported accuracies of up to 97% in discriminating patients with abstinent long-term chronic AUD and healthy controls.

ML studies have also been performed on subjects with other substance dependencies. A multivariate ML study found that different clinical assessment factors are useful for identifying subjects with heroin dependence as compared to subjects with amphetamine dependence, suggesting that predictive markers can be very substance-specific [39]. In a small-sample study on subjects with cocaine use disorder, researchers showed that phenotypes of high impulsivity were most predictive of developing cocaine dependence [40]. For cannabis dependence, a study based on the IMAGEN data set identified a risk profile containing psychosocial and sex-specific brain prognostic markers, which were likely to precede and influence cannabis initiation [41]. This study also underlines the importance of considering sex as an influencing factor in SUD. A very recent ML study found that the main prognostic features for development of SUD changed with age [38]. While psychological dysregulation best predicted SUD during childhood and early adolescence, social and interpersonal interaction problems were most predictive features in late adolescence and thereafter. Another line of research is to use social media with deep learning methods to identify the risk of alcohol, tobacco, and drug use [42]. While acknowledging the user privacy issues that must be addressed, they show that this could be a potentially new way of estimating substance use risks [42].

ML methods have also been applied to develop treatment programs for SUD and predict treatment outcomes. A recent study used decision trees to predict whether an individual with AUD seeks treatment and found that the total drinks consumed in lifetime and not having depression or other substance disorders were the strongest predictors of seeking treatment [28]. Similarly, in [27] the performance of different classical ML have been compared in order to predict SUD treatment. Another direction of research involves using smartphones or personal digital assistants to monitor psychological profiles and detect drug use in real-time [21]. ML methods can be used along with these ambulatory data to automatically perform interventions, recommend treatment programs, and study the outcome of treatments [47].

Challenges and Outlook

The field of ML applied to healthcare is still in its infancy [30]. The previous section surveyed preliminary ML-based research in SUD that generally used small sample sizes and have not yet undergone rigorous and independent replication tests. Their findings have also not yet been critically assessed in a clinical setting. Therefore, one can conclude that the true potential of ML (and especially deep learning) are still under-exploration in SUD research [30]. Currently, there are several hurdles for implementing reliable ML methods for SUD. The foremost challenge is the ambiguity of clinical labels in SUD and their high overlap with other psychiatric diseases [9]. Current psychiatric labels defined by ICD-11 or DSM-5 were designed to characterize observable symptoms of addiction and identify problematic behaviors. They are often criticized for having a multifold biopsychological basis that overlap between multiple mental disorders [5, 7]. Therefore, existing psychiatric labels are not reliable enough for designing a learning framework for ML models due to their heterogeneity in clinical presentation and reliance on clinical symptoms rather than neurobiological substrates. Another major hurdle in ML is the need for reliable, large-scale, and open-access data sets for developing methods and benchmarking progress in the field. One of the primary reasons for the success of ML in applications such as computer vision and natural language processing is the availability of high-quality data sets with large sample sizes (for example, a popular image classification data set, ImageNet has 14 million images) [32]. Large-scale data collection and harmonization initiatives have only just begun in SUD research [22, 23, 24, 25]. Furthermore, data sets in medical domains such as neuroimaging can have high variability based on factors such as the imaging site, the imaging protocol, and the instruments used [22]. This heterogeneity across data sets (and sometimes within a data set collected in multiple sites) poses a challenge for developing generalizable ML solutions. In order to overcome this, data collection studies are required to not only harmonize their acquisition protocols, tools,

and pre-processing pipelines across several imaging sites but are also required to collect a large number of samples per site that is representative of the population distribution. The chronic nature of SUD further exacerbates the problem. It mandates the collection of longitudinal data of subjects over several years so that one can reliably capture the dynamics of relapse and triggers, understand the complex trajectories in the development of drug dependence, and quantify the success of treatment approaches [21]. ML also struggles with several methodological challenges in applications such as medical imaging. For instance, neuroimaging data such as sMRI or fMRI have usually a low signal-to-noise ratio and thus current ML methods require large sample sizes and computational capacities to learn the underlying useful signal for the task [30]. Prevailing ML methods like deep learning have an algorithmic bias toward natural images. They are also criticized for being a black-box as their decisions are currently hard to interpret, although adhoc visualization techniques exist [45, 46]. However, these hurdles can mostly be attributed to the field of ML and deep learning still being in its initial stages of research in medical applications [30].

Conclusion

Substance use disorder (SUD) is a chronic mental health disorder that is affected by a complex interplay of several environmental triggers (e.g., access to drugs, traumatic experiences) and biological factors (e.g., genetic predispositions). Machine learning (ML) and artificial intelligence, in general, have emerged as promising tools in the field. Despite some methodological hindrances, ML has proven to be capable of capturing associations from multiple influencing factors and model the complex interactions in psychiatric disorders such as SUD [26, 37]. Therefore, as more and more large-scale and standardized data sets become available for SUD, ML methods would exceedingly contribute to SUD research in novel and beneficial ways. Due to its data-driven approach, ML can help in the discovery of neurobiologically valid psychiatric labels, in

contrast to the existing labels. In the future, methods based on ML could lead to the development of new methods of diagnosing SUD [29] and understanding the relationship between SUD and other mental disorders. Furthermore, ML could be the key to enable precision medicine by recommending personalized patient treatments, predicting treatment outcomes [28, 27], and guiding the development of new therapies [47].

Abstract

Post-traumatic stress disorder (PTSD) is a relatively recently defined mental disorder which is diagnosed with the aid of a set of criteria specified by the DSM. PTSD results from a traumatic event and involves clusters of symptoms which together disrupt the psychological, physical, and social functioning of the person.

Although about 70% of people will be exposed at least once in their lifetime to a traumatic event, and that about 4% of them will develop PTSD (chronic or not), screening and diagnosis of the disorder is often seen to be primarily a matter for specialist psychiatrists. Not only is there a lack of awareness of PTSD among health professionals and insufficient training in identifying the disorder, there is also a shortage of relevant diagnostic tools in routine clinical practice. The identified determinants and risk factors for PTSD are of little use in either explaining the disorder satisfactorily or identifying it effectively. This has an effect on primary and secondary prevention, while few treatments, either chemical or non-chemical, have been shown to be effective to date. It is therefore worth asking whether artificial

Intelligence might make a contribution in any of the dimensions mentioned above: prediction, diagnosis, etiology, or cure. Could AI improve understanding of the disorder, compared to the more traditional techniques of clinical research and epidemiology? And might it be an important advance in the management of PTSD? Few existing studies on AI and PTSD, and it is difficult to make comparisons between those that do exist.

PTSD: A Complex Clinical Disorder

PTSD: A Psychological Disorder that May Appear After Exposure to a Traumatic Event

PTSD is a psychological disorder that usually occurs within the first 3 months of exposure to a traumatic event. This syndrome can also appear sometime after the traumatic event, with a delay of a few months or even years. Exposure to a traumatic event – a sudden situation that leads to a person's mental defense mechanisms being overwhelmed – is one of the conditions needed for a diagnosis of PTSD. Almost 70% of people will experience in their lifetime at least one traumatic event among a set of 29 traumatic events designed by the WHO World Mental Health (WMH) Surveys and required for a PTSD diagnosis [1]. Traumatic events may be intentional, as, for example, in interpersonal violence, (fighting, torture, mutilation, physical violence, sexual assault, murder of a loved one), or they may be unintentional, as in road accidents, natural disasters and serious illness (Table 1). Not all those who experience traumatic events go on to suffer from PTSD, however, since among adult individuals exposed to at least one traumatic event, lifetime prevalence of PTSD stands at only about 4% [1]. The identification and

nosological diagnosis of PTSD is recent. Diagnostic criteria have evolved since the first appearance of PTSD in the third version of the Diagnostic and Statistical Manual of Mental Disorders (DSM) in 1980, while in its current version (DSM-5) the presence of seven other criteria are needed for a diagnosis of PTSD (Table 2). PTSD is a multi-faceted, primarily clinical diagnosis that is likely to include numerous combinations of more or less specific symptoms [2]. The variability in the clinical expression of PTSD explains part of the difficulty in using classifications such as DSM-5 in screening for this disorder, since the aim of the DSM is to provide standardized diagnoses for comparability and reproducibility in research and is not designed for clinical use and diagnosis.

Screening for psychological symptoms that might indicate PTSD is essential for patient referral and for preventing the development of disabling complications, so healthcare professionals need to be trained in screening in order to provide valid diagnoses. Current diagnostic tools are accessible to all doctors, but their use requires specific experience in psycho-traumatology, while clinical interviews or self-report measures for PTSD are time-consuming and not necessarily well-suited to routine clinical practice.

Specify whether with dissociative symptoms (dissociative subtype of PTSD). In addition to meet the full criteria for PTSD, the individual persistently or repeatedly experiences one of two dissociative symptoms following: depersonalization or derealization.

PTSD: A Disorder that Is Currently Difficult to Explain and Predict

There have been numerous studies on the predictive factors and determinants of PTSD since the disorder first appeared in the nosography. This research is essential for understanding and screening for the disorder and referring individuals to specific care pathways. Certain determinants explain the disparity that has been noted between the frequency of exposure to a traumatic event and the frequency of PTSD. Although several clinical

Table 1 Classification of different types of potentially traumatic events by intentional or non-intentional origin

Non-intentional events	
1.	Accident, serious injury or illness
	Natural disaster
	Man-made disaster
	Toxic chemical exposure
	Life-threatening motor vehicle accident
	Other life-threatening accident
	Life-threatening illness
	Life-threatening illness or injury of child
Interpersonal violence	
2.	Experience of sexual violence
	Raped
	Sexually assaulted
	Stalked (sexual harassment)
	Any other private event
3.	Experience of physical violence
	Beaten up by spouse or intimate partner
	Beaten up by someone else
	Beaten up by caregiver (childhood physical abuse)
	Having been witnessed intimate partner violence or domestic violence
	Mugged or threatened with a weapon
4.	Exposure to organized violence
	Relief worker in war zone
	Civilian in war zone
	Civilian in region of terror
	Refugee
	Kidnapped
5.	Participation in organized violence
	Witnessed death or serious injury, or discovered dead body
	Witnessed atrocities
	Combat experience
	Unintentionally caused death or serious injury
	Purposely injured, tortured or killed someone
6.	Other
	Unexpected death of loved one (homicide, accident, suicide, fatal illness)
	Other traumatic event of loved one (kidnapped, tortured, or raped)
	Any other traumatic or life-threatening event

determinants have been proposed, studies have shown that the results on their identification and their respective weight in the occurrence of PTSD are variable and sometimes contradictory. One study found that pre-traumatic factors, such as gender, with women being more likely to suffer

PTSD (OR = 1.98, IC95% 1.76–2.22) [3], may be more predictive than other factors, while for other researchers, a peritraumatic factor (peritraumatic dissociation) and a post-traumatic factor (lack of social support) were more predictive of PTSD, albeit with a contribution that was modest (mean correlation coefficient r : 0.35 and 0.40, respectively) and heterogeneous (r = 0.14 to 0.94 and r = −0.02 to 0.54, respectively) [4, 5]. Conversely, a 2019 meta-analysis that included more types of traumatic events and referred to several parameters to evaluate the strength of the association showed that the existence of physical vulnerability or a family history of psychiatric disorder are the best predictors of PTSD [6]. Other types of determinants that facilitate the diagnosis of PTSD, such as potential biomarkers, including neuroendocrine, genetic, neuroanatomical, and neurofunctional abnormalities, have also been identified [7]. There is still some speculation about the role of these biological correlates in the occurrence of PTSD (they lack robustness and validity for use in current practice) but they do contribute to a better understanding of the biopsychological mechanism of PTSD and have specific implications for the future: specifying PTSD via these biomarkers may make it possible to achieve a more accurate diagnosis and offer more targeted therapies.

Due to the high number of potentially traumatic events, any kind of doctor, whether in a hospital or in primary care, may well encounter a patient with symptoms of PTSD. Professionals' lack of awareness of psychotraumatic stress and the absence of diagnostic tools that can easily be used by any doctor lead to under-diagnosis of PTSD.

The Evolution of PTSD Over Time May Be Complex and Chronic, and Associated with Physical and Mental Disorders of a Different Nature

The symptoms of PTSD, particularly certain symptoms, may evolve over time. In half of cases, PTSD symptoms disappear within the first 3 months. Conversely, PTSD may become chronic with the persistence of symptoms for

Table 2 DSM-5 diagnostic criteria for PTSD [41]

A. The person experienced, witnessed, or was confronted with one of the following traumatic event(s): actual or threatened death, serious injury or sexual violence
B. 1 (or more) of 5 reexperiencing symptoms:
Intrusive, repetitive and disabling recollections
Repetitive distressing nightmares
Acting/feeling as though event were recurring (dissociative flashbacks)
Psychological distress when exposed to reminders of the traumatic event
Physiological hyperreactivity when exposed to reminders of the traumatic event
C. 1 (or more) of 2 avoidance symptoms:
Efforts to avoid recollections, thoughts or feelings about the traumatic event
Efforts to avoid external reminders (people, places, talking, activities, objects or situations) that trigger recollections, thoughts or feelings associated with the traumatic event
D. 2 (or more) of 7 negative alterations in cognition and mood:
Inability to recall important aspects of the traumatic event (dissociative amnesia)
Negative beliefs or expectations about oneself, other people or the world
Cognitive distortions about the traumatic event leading to blame oneself or other people
Persistent negative emotional state (e.g., fear, horror, anger, guilt or shame)
Diminished interest or participation in significant activities
Detachment from others
Inability to experience positive emotions or feelings
E. 2 (or more) of 6 hyperarousal symptoms:
Irritability or angry outbursts with verbal or physical assaults towards people or objects
Reckless or self-defeating behavior
Hypervigilance
Exaggerated startle response
Concentration disorders
Sleep disorders
F. Duration of the symptoms is at least 1 month
G. Requires clinically significant distress or functional impairment (e.g., social, occupational)
H. Exclude differential diagnosis

12 months or for several years [8]. The medium to long-term evolution of PTSD is characterized by the frequent co-occurrence of at least one other mental disorder (e.g., depression, anxiety disorders, substance use disorders) [9] and an increased risk of suicide (RR = 2.7, 95% CI 1.3–5.5) [10]. It is also associated with a negative perception of one's health, the appearance of numerous unexplained physical complaints, and an impact on social life (e.g., social isolation) and work (e.g., losing one's job) [11]. The physical impact may be even greater, and related to the different neurobiological reactions to stress, for example, an increased risk of cardiovascular events. The impact of PTSD on a person's life thus seems to be all-embracing and profound. At the very least, it can be part of a complex and disabling clinical and biographical picture, whether as a cause,

consequence or comorbidity. All these complications contribute to masking or aggravating the symptoms of PTSD and can lead to delayed diagnosis, inappropriate management of the disorder and its comorbidities, and ultimately, to a burden on the healthcare system.

Improving Screening for and Diagnosis of PTSD

There are therefore strong arguments for improving screening and diagnosis of PTSD in order to ensure that treatment of people who may have this disorder is conducted early, or at the very least, delayed as little as possible. To date, none of the current treatments available are highly or even systematically effective. However, the earlier the

diagnosis is made, or even anticipated (through secondary prevention following exposure to trauma), the easier it will be to circumvent the effects of PTSD on the social and individual functioning of the person.

In general terms, the issues related to PTSD, to date, can be categorized as follows:

- (i) Diagnosis, screening (particularly by non-specialists) and patient referral within the healthcare system, which are all problematic because of the high cost and the shortage of specialists able to deal with this widespread problem and because current diagnostic tools (DSM and evaluation scales) are essentially oriented towards epidemiological research.
- (ii) Primary and secondary prevention: ideally, following exposure to trauma, occurrence of PTSD should be avoided and if it does occur, its duration and its impact on the social and individual functioning of the person should be limited.
- (iii) Therapies.
- (iv) Research: better understanding, better definition, and better characterization of PTSD, its different forms and expressions, and its evolution over time; research into causes; research into associations with other psychological and physical diagnoses in order to improve understanding of the network of multiple causes and consequences which PTSD is part of.

The purpose of this chapter is to examine the potential value of AI in relation to PTSD from two complementary perspectives:

- (i) In relation to existing diagnostic, explanatory and predictive methods
- (ii) For possible new/original uses, unique to AI or enabled by it

Present Advances: AI and PTSD

The use of AI in PTSD is still marginal when compared to its use in other psychiatric disorders, although there is recent and growing interest in exploring new predictive methods based on

it. There are applications in two main areas: prediction and diagnosis. Data sources that can be used in models are varied and of different types, including clinical, biological, genomic and neuroimaging data.

AI and PTSD Prediction. AI for Clinical Practice and Practitioners

In this section we discuss the potential contribution of AI in predicting (i) a diagnosis of PTSD, and (ii) response to treatment. With regard to diagnosis, it is accepted that a diagnosis of PTSD can only be made 1 month after exposure to a traumatic event. A central question may therefore be whether during this period one is able to identify and anticipate that PTSD may occur within 1 month – or more – of exposure to trauma. With regard to treatment, as in all 4P medicine, the aim is to predict and personalize the care and treatment of individuals. In mental health, perhaps more than in other fields, where therapeutic indications may be porous, depending on which diagnosis is made, and response varies greatly from one person to another, it is valuable to know if AI can help practitioners to estimate the potential effectiveness of a potential treatment and to be more precise and so save time. Unsurprisingly, the majority of studies to date have been secondary, retrospective analyses of cohort epidemiological data or cohorts reconstituted from hospital data.

Early Prediction of PTSD

Identifying subjects at risk of developing PTSD after a traumatic event is still a challenge for standard determinant approaches. Early prediction of PTSD by AI on initial data alone and before the disorder is diagnosed conclusively (1 month later) would enable more rapid intervention and hopefully avoid the emergence of chronic, invasive, and disabling symptoms.

Few studies have used AI for early prediction of PTSD, the majority having been conducted in hospital, more specifically, in emergency departments.

Several researchers have used various types of clinical, biological and psychological data collected in emergency departments for the early

prediction of PTSD [12–16]. Initial data were collected immediately “at the patient’s bedside” in the emergency room and sometimes supplemented by other data, particularly psychological or biological data, collected within 10 days of the traumatic event [14–16]. The clinical data included physiological variables usually measured in the emergency department (e.g., heart rate and blood pressure) and the biological data collected in the emergency department or at discharge included standard biological variables or salivary, urinary and blood neuroendocrine variables involved in the response to stress. Prediction using only data collected in the emergency department showed a prediction capacity ranging from accurate to good ($AUC = 75$ to 85%) regardless of the type of data used in the prediction model. The best predictive performance was obtained by combining both clinical and biological data, in contrast to the predictive capacity of biological data alone ($AUC = 72\%$ in Schultebraucks 2020; $AUC = 67\%$ in Galatzer-Levy 2017). Predictive performance on data collected in two stages was similar ($AUC = 82\%$ in Galatzer-Levy 2014) or even slightly better ($AUC = 88\%$ in Galatzer-Levy 2017), but insufficient if based on biological data alone ($AUC = 66\%$ in Galatzer-Levy 2017).

The use of biological data collected in emergency department seems appropriate as it can be collected from technical platforms available to doctors, but its use alone does not lead automatically to improvement in predictive performance and early detection. Biological data alone is not enough to predict PTSD, and this is corroborated by the fact that no biological determinants have been clearly identified as predictive of PTSD. The fact that predictive models performed best when psychological variables were taken into account underlines the pre-eminence of clinical data in the early prediction of PTSD. This finding is consistent with the definition of PTSD based on symptoms; the use of questionnaires in an emergency context, however, seems difficult to transpose into routine because it requires time and human resources.

There is less research on PTSD amongst children. However, researchers have collected several types of clinical and biological data amongst

children aged 7–18 years who were hospitalized following severe injuries [17]. The ability to predict PTSD at 3 months based on early data was accurate regardless of the method used and similar to previous results ($AUC = 79\%$ when combining all variables and $AUC = 74\%$ after feature selection).

PTSD is not often studied in relation to a specific trauma, but rather to “trauma in general.” This can lead to bias when interpreting and comparing studies. Few authors focus on a well-defined trauma and its association with PTSD. One study, however, focused on the trauma produced by exposure to combat in a context of armed conflict. Researchers were able to establish good performance in predicting PTSD on clinical and psychological data collected prior to military deployment ($AUC = 84\%$), while the integration of data collected after deployment only marginally increased the performance of the prediction model ($AUC = 88\%$) [18].

In addition to clinical and biological data that can be easily collected in hospitals or outpatient clinics, some authors have examined the use of neuroimaging data and smartphone questionnaire data for the early prediction of PTSD in different contexts: Li et al. (2016) obtained accurate performances in predicting PTSD at 6 months using neuroimaging data collected between 10 and 20 days after the trauma (Accuracy = 76%, Se = 73%, Sp = 76% with 49% PTSD prevalence after 6 months) [19]. And Wshah et al. (2019) collected mainly psychological data the first month after the trauma using a brief questionnaire sent to a smartphone, by combining an abbreviated 8-item version of PTSD Checklist for DSM-5 (PCL-5) and an additional item from PCL-5 assessing sleep with a tenth item assessing pain, managing to predict PTSD within 1 month, with the best performance for a scale using only 7 items ($AUC = 89\%$) [20].

Lastly, studies conducted outside hospitals are limited to mainly retrospective cohorts and secondary analyses. To our knowledge, no studies have focused on the prediction of PTSD in non-hospital contexts.

Data from retrospective studies based on the WHO WMH Surveys has been used to predict

PTSD, with one study focusing on a large number of traumas and another on trauma caused by sexual violence. They are based on a limited number of determinants (pretraumatic and peritraumatic factors, with trauma characteristics for the sexual violence study) [21, 22]. Based on these initial data alone, the results were variable, with excellent predictive performance in the study on all types of trauma ($AUC = 98\%$ in Kessler 2014) and poor for the sexual violence study ($AUC = 64\%$ in Scott 2018). The prediction algorithms used were not the same in both studies, with the superlearner set of algorithms giving better predictive performance than the single algorithm (logistic regression) used by Scott et al. Kessler et al. constructed a prediction model for any type of trauma but the challenge is to transpose these results to prospective data for external validation on just one type of trauma, since the prediction model for all types of trauma from a large cohort is not easily transposable to a smaller population or to a limited number of traumas. Similarly, two retrospective studies from large cohorts that each focused on a traumatic event (soldiers exposed to combat and earthquake victims) used initial data to predict PTSD (i.e., characteristics present before the trauma and those collected in the immediate aftermath in the case of the earthquake victims) [23, 24]. The predictive performance obtained was either good, in earthquake victims ($AUC = 79\%$ with a set of algorithms or super learner) or excellent, in the military ($AUC \geq 89\%$ with algorithms used separately).

Prediction of Response to Treatment

Once PTSD has been diagnosed and treatment is required, AI can also be employed to provide doctors with tools to help predict response to treatment. The use of AI is still rare in this field, with only two studies identified. The studies use neuroimaging data to predict the response to treatment in patients suffering from PTSD, but the very small number of subjects limits the relevance of the results. Zandvakili et al. used early (pre-treatment) EEG data to compare its capacity to predict response to treatment by PTSD patients and patients with depression who had been

exposed to combat [25], the treatment applied was repeated transcranial magnetic stimulation targeting identified neural network abnormalities: a treatment validated to treat pharmaco-resistant depression, still in the experimental stage for PTSD. Results indicated poorer performance in PTSD patients ($AUC = 71\%$) than in depressed patients ($AUC = 83\%$). Another example, Yuan et al. used functional MRI data prior to treatment to predict the response to an antidepressant treatment, Paroxetine, in earthquake-affected PTSD patients [26]. The predictive capacity of the Paroxetine efficacy at 3 months was accurate with $AUC = 72\%$ ($Acc = 72.5\%$, $Se = 67\%$, $Sp = 77\%$).

AI, Characterization and Diagnosis of PTSD. AI for Basic Research

The main focus of AI use in PTSD is for diagnosis. This can take two specific forms. It can be used to:

- (i) Provide diagnosis as a complement or substitute for measurement criteria or scales, should AI have at least one of the two advantages of (a) greater performance (sensitivity, specificity, accuracy) or (b) greater practical use and wider accessibility (e.g., less costly in terms of time, resources, and training of professionals). Making a diagnosis may also involve distinguishing it from diagnoses of other disorders, as PTSD, particularly in its chronic form, is frequently associated with other mental pathologies;
- (ii) Characterize the different initial and progressive forms of PTSD over time, as well as their relationship and combination with other disorders, especially mental disorders. This would be not so much a question of individualizing and personalizing diagnoses as of trying to identify whether there are particular types and subtypes of PTSD in order to ensure they are not ignored and to provide differential care and treatment if the associated consequences (response to treatment, duration of the disorder, severity of the

functional repercussions, associated disorders, etc.) differ significantly.

The majority of studies that use AI for characterizing PTSD (differential diagnoses, subtypes) are based on the use of genomic data and, particularly, neuroimaging. This can be explained by the need to associate types with a neuroanatomical or neurofunctional substrate, but the approach may prove to be limited in the sense that it does not take into account the broader syndromic expression of possible different types of PTSD. Another current limitation would be in the usefulness of this type of approach in routine clinical practice and primary care: the use of genomics or neuroimaging is not part of standard clinical examinations — and unlikely to be so for some time to come. These studies should therefore essentially be seen more as basic research, in advance of possible clinical applications.

The Use of Genomic and Neuroimaging Data by AI

Genomic Data

A person's genetic make-up may go some way to explaining their vulnerability to PTSD. A number of genes involved in the hormonal regulation of stress response (hypothalamic-pituitary-adrenal axis) have been identified as associated with the disorder. They are not specific to PTSD, however, as they are also found in other psychiatric disorders. One study on combat-exposed soldiers has used another panel of genes involved in immune and inflammatory system regulation as a genomic substrate to predict PTSD within 3 months of the soldier's return from deployment [27]. Data was taken from a blood sample. Although only a small number of soldiers were included in the study, two distinct prediction models based on the level of genomic expression, gene-expression, and exon-expression, respectively, showed good predictive performance, particularly the second model (Acc = 90%, Se = 100%, Sp = 80%).

Neuro-Imaging Data

Exposure to a traumatic event, particularly if complicated by PTSD, will have an impact on the

structure and functioning of the brain, mobilizing two types of substrate: neuroanatomical and neurofunctional. Once already established, PTSD is more difficult to detect and evaluate. This can be explained by the absence of pathognomonic symptoms and the presence of symptoms common to other psychiatric disorders. The evolution of PTSD is marked by the frequent appearance of mental disorders, with individuals with PTSD being more likely than those without PTSD to have symptoms that meet the diagnostic criteria for at least one other mental disorder (e.g., depression, anxiety disorder, bipolar disorder, etc.). This overlap is confusing for the clinician who needs to attribute symptoms to one or another disorder in an objective manner. In this context, neuroimaging can help to clarify the diagnosis of PTSD, as the various neuroimaging techniques employed pick up different levels of identifiable substrates. Research on the use of AI in this context has been limited to a limited number of traumatic events (road accidents, natural disasters, and exposure to combat), so the observations are valid for these events and are not necessarily transposable to other traumatic events likely to lead to PTSD. A series of examples have been selected for analysis in greater detail below in order to illustrate how the contribution of AI in neuroimaging can be used to help characterize PTSD in a variety of situations.

AI for the Diagnosis and Differentiation of PTSD from Other Mental Illnesses

Below we look at two specific examples that use retrospective data to compare different groups of exposed individuals with and without PTSD and mental illness: (i) differentiation of PTSD from the syndromic expression of the consequences of head injury [28]; (ii) differentiation of PTSD from depression [29].

(i) Mild traumatic brain injury can occur in a variety of traumatic situations, such as when soldiers are exposed to combat. Genuine PTSD can develop simultaneously with mild brain injury and further treatment can be complicated by the presence of neurocognitive symptoms which may be attributed to either.

In this study, AI and neuroimaging based on one type of neurofunctional substrate was 84% accurate in distinguishing soldiers with PTSD from soldiers with PTSD and brain injury.

- (ii) Depression is often associated with PTSD, suggesting a common susceptibility to both disorders. Symptoms of depression may overlap with symptoms with depressive connotations defined in Criterion D of DSM-5 for PTSD, when the symptoms of the latter are predominant, so impeding a diagnosis of PTSD. In this specific context, one study used neuroimaging and neurofunctional substrates to identify individuals with PTSD (especially PTSD associated with depression), achieving good predictive ability (AUC = 85% and Accuracy = 77%).

In both of these cases, the studies on AI coupled with neuroimaging supports the idea that a diagnosis of PTSD may be made some time after the traumatic event. Neuroimaging makes it possible to distinguish a disorder from others with which it is associated due to its intrinsic evolution. This clarification of the boundaries benefits the patient, for whom a customized diagnosis can be proposed with a focus on the therapeutic management that will result.

The Use of AI to Characterize Subtypes or Subsyndromic Forms of PTSD

The dissociative subtype of PTSD was included for the first time in the current version of the DSM-5. It defines a person who persistently or repeatedly experiences one of two dissociative symptoms: depersonalization and derealization. The dissociative form does not constitute a diagnostic entity that is independent or separate to standard PTSD; it is still PTSD, and to which can be added the two dissociative symptoms already contained in the PTSD criteria, i.e., flashbacks and dissociative amnesia). The dissociative form is relatively frequent, as according to the WHO WMH Surveys, it has been found in almost 14% of individuals with PTSD [30]. The distinctiveness of the dissociative form has also been highlighted by neuroimaging studies which have shown that there

are specific neurological pathways in subjects with dissociative symptoms. This data suggests that the distinct group with the dissociative form of PTSD possesses its own neurobiological and epidemiological characteristics. Neither the PCL-5 nor the CAPS-5 interview – two types of PTSD evaluation scale – are specifically designed to detect the dissociative form of PTSD. Neuroimaging coupled with AI can be used in prediction to compensate for this lack. This has been shown in two studies carried out by the same researchers. The studies had similar characteristics, differing only in the choice of neurofunctional substrates (balanced accuracy = 80%, in Nicholson 2020; balanced accuracy = 85–92% in Nicholson 2019) [31, 32].

Similarly, neuroimaging can also help to identify relationships between neurofunctional correlates and clusters of PTSD symptoms, those defined in criteria B to E of the DSM-5. In addition to the standard method of establishing a diagnosis by satisfying the required criteria, AI and neuroimaging would make it possible to identify subsyndromic forms of PTSD and to identify the class of dominant symptoms on the basis of neurofunctional correlates. Regression algorithms coupled with neuroimaging have shown that there are associations between neurofunctional correlates and PTSD symptom clusters, including avoidance ($R^2 = 0.23, p = 0.034$) and reexperiencing symptoms ($R^2 = 0.29, p = 0.002$) [33].

The Contribution of AI in Linking Basic Research to Clinical Applications. Neuroimaging Data

Most studies that have used AI coupled with neuroimaging (with magnetic resonance imaging) for diagnosing PTSD rely on group comparisons between healthy individuals and/or individuals who have suffered trauma but have not been diagnosed with PTSD. The studies have similar characteristics in terms of the type of data collection (retrospective), the type of traumatic event studied (limited to combat, earthquakes and road accidents), and the small size of the study group (57–140 individuals) [34–37]. The types and combinations of neuroimaging data input into prediction models varied according to the studies,

with a combination of the two types of correlates (neuroanatomical and neurofunctional) for one and use of one type of correlate for the others (neuroanatomical or neurofunctional). Predictive performance was good to excellent when predicting PTSD among healthy individuals (e.g.: accuracy = 91% in Gong 2014; AUC = 90% and accuracy = 89% in Zhang 2016), compared to the population exposed to trauma, where they were either, at best, accurate (e.g.: accuracy = 67% in Gong 2014; AUC = 72% and accuracy = 68% in Zhang 2016; accuracy = 77% in Salminen 2019) or inconclusive in one case (accuracy = 55% in Li 2020).

In order to diagnose PTSD, other researchers have combined AI with another type of functional neuroimaging technique, magnetoencephalography, which measures the electrical activity of neurons whose synchronous neural interactions constitute a different type of PTSD neurofunctional substrate [38, 39]. Predictive performance for identifying PTSD among combat-exposed male soldiers was excellent in these studies (AUC = 90% in Zhang 2020; AUC ≥ 93% in James 2015).

A final example of the possible use of AI based on functional neuroimaging data is for predicting the evolution of PTSD over time [40]. The authors of one five-year study followed 30 subjects who had survived a fire in the underground, all of whom developed PTSD at the first assessment at 1–2 months. Models for predicting the evolution of PTSD in the medium (about 1.5 years after the trauma) and long term (about 2.5 years after the trauma) discriminated little when their performance was related to the prevalence of PTSD in these intervals, with accurate performance for fairly high prevalence (AUC = 73% medium term with PTSD prevalence of 77%; AUC = 77% long term with PTSD prevalence of 48%). The last very long-term prediction model was insignificant for PTSD prevalence of 12%.

Potential Trends and Future Challenges

There are still few studies on the contribution of AI to PTSD, but they are mainly focused on two fields: prediction in a clinical context, in particular

the early prediction of PTSD, and prediction of response to treatment. AI has been used in basic research on genomic data, and more particularly, on anatomical or functional neuroimaging, either to identify specific substrates of PTSD in relation to other mental pathologies, or to explore the finer detail of the structure of PTSD, in its initial clinical variety or in its different evolutions over time.

There seems, therefore, to be a desire to use AI to help redefine or refine the diagnosis of PTSD, in particular by basing it on anatomical, physiological, and clinico-biological (including genetic) findings and correlates. No really significant finding has yet been made. The search for typologies, variants and syndromic trajectories in the same disorder is typical in mental health research, but it rarely involves the majority of the research community. And while the identification of subtypes may be of interest in itself, it is often limited in practical terms, as the subtypes are not necessarily easy to identify in an already difficult main diagnosis which is often overlooked, or they are not necessarily associated with significantly different consequences or treatments, if they even exist at all. Lastly, the majority of studies conducted to date focus on the use of AI in replacing current tools that are difficult for practitioners to use (complementary examinations that are difficult to access or interpret, and evaluation scales) or tools whose initial design, validation and use are the result of research (scales, DSM criteria). Nevertheless, these studies are mostly limited to traumas of all types, for people in emergency departments or hospitals, and do not allow us to be categorical about their real usefulness. They do, however, offer reasonable hope for more affordable, perhaps more effective and more operational means for health professionals to be able to diagnose PTSD.

The studies available employ mainly secondary use data, i.e., data from epidemiological cohorts originally constituted for other purposes, or reconstituted hospital cohorts. This data is clinical and biological, sometimes genomic, and very occasionally “real life” data collected via smartphones. The use of neuroimaging data is more specific to the field of mental health and is reserved for upstream research. The use of electronic medical records in outpatient clinics has not been explored to our knowledge.

Most of the studies, including those concerned with the use of AI in a hospital context, are related to laying the groundwork and providing prototypes that will enable the future conception of algorithms for general use. We are therefore only at the very beginning of the process of rigorous development of predictive or decision-support algorithms in this field. All the standard questions are still open with regard to the following steps. These include issues to do with the real possibility of integrating the algorithm in practitioners' working environments and information systems; resistance to variability in the quality of the data collected, among systems and among observers; prospective independent validation of algorithms on other data; the real acceptability and appropriation of this algorithm by the health professionals concerned. More fundamentally, the possible biases found in standard studies on PTSD and the collection of data used in the development of algorithms must be systematically detected and compensated for. This is the case for the most common biases encountered: those linked to ethnicity, geographical origin, gender, and age. Furthermore, the effort undertaken in other sectors of biomedical research to improve the quality and usefulness of research, for example, through randomized trials (CONSORT) or observational studies (STROBE) and through sufficient reporting to ensure the transparency of research and its reproducibility, should be replicated in research on AI. With regard to ongoing research and its goals (predictions and search for typologies), it would be mainly a matter of aiming for essential improvements: in experimental design (cross validation, prospective validation, transition to real life, and clinical tests, etc.); in reporting (metrics selected, a minimum of respect for TRIPOD guidelines, etc.); in research on the different traumatic events rather than a mixture; and in research on the prevalence of the outcome in the samples used).

AI seems promising as it provides the opportunity to unravel and describe existing interrelationships in terms of multiple causalities and consequences, both amongst symptoms constituting PTSD well as amongst associated pathologies (depression, for example), regardless of the nature of their relationship (simple association, common

mechanisms leading to two pathologies, consequences of each other, one variant of the other, etc.).

In all cases and whatever the scenario, there should be research and support on the place of AI and its acceptance by health professionals, while the use of AI could be extended to those who are not trained doctors, such as trained nurses, or even administrative staff in some cases, and possibly those working on traffic accidents, the military, etc. AI could be used as an alternative to health professionals when there is a shortage of qualified personnel or if training costs are high; it could also be used by those who are less qualified than specialists, for diagnosis, screening, or referral in the care system; and it could also help specialists themselves. Regardless of the professional using these algorithms, there will be an imperative need for high quality data collection (from medical observations and symptom collection) to input into the algorithm.

Abstract

Over the past decades, the burden of eating disorders (ED) and comorbidities increased worldwide. Assisting diet monitoring with AI

methods and Automated Dietary Monitoring (ADM) can support ED risk prediction, diagnosis, tracking associated symptoms, and medical guidance during a long-term behavior change process. This chapter gives an overview of important directions in AI in the field of EDs and obesity. State-of-the-art methods and technologies for ADM are summarized in connection to digital biomarkers that reflect diet-related behavior in general. Two sensor-based ADM examples are detailed: food type classification and eating timing estimation. On the example of anorexia nervosa (AN), diet-related psychological parameters are detailed

Introduction

To facilitate intervention and therapy in eating disorders (ED), long-term monitoring of the patient and their eating behavior is crucial. Traditionally, dietary monitoring has been done by diaries that the patient completed on a daily basis. This chapter addresses Automated Dietary Monitoring (ADM), which intends to replace manual data logging by sensor-based inference, as far as reasonable. ADM is motivated by the insight that diaries are challenging to maintain by respondents and suffer from over- and underreporting. However, accurate information on the individual's actual diet is key for dieticians, physicians, and psychologists to support behavior and lifestyle changes over months and years. While EDs, including anorexia nervosa (AN), have been traditionally considered separate from obesity, there are substantial commonalities regarding the relevance of psychosocial, biological, and genetic components [1]. In particular for disordered eating that is related to forms of undernutrition, identification of symptoms and diagnosis can be challenging. Consequently, another stream of AI-related research addresses the multilevel diagnostics and symptom interpretation in EDs. The chapter covers AI methods and Machine Learning (ML) approaches on EDs and malnutrition.

AI for ED

According to psychiatric classification schemes like the ICD-10 or the DSM-V [2, 3], EDs can be classified as AN, bulimia nervosa, and binge

eating. Disordered eating, especially bulimia nervosa and binge eating disorders, may be considered not only an important risk but also a maintaining factor for obesity [4, 5]. Hence, obesity can be a consequence of EDs, metabolic overweight, and unhealthy food. The increasing burden of EDs, obesity, and comorbidities worldwide [4] requires new inventions to tackle the problem. AI can have an impact on the field by improving effectiveness of medical diagnoses, interventions, and therapies. For example, ADM-based digital biomarkers could help patients to understand and track eating behavior, and potentially adapt lifestyle more easily. Similarly, dietitians could leverage ADM to provide more fine-grain, real-time guidance in daily life, compared to using questionnaires or diaries. Finally, AI can support diagnoses of EDs based on genetic and other data inputs.

Monitoring of Dietary Behavior

Wearables, including smartwatches, in-ear headphones (which come with microphones and other sensors), or smart eyeglasses (e.g. [6–8]), can be used to acquire different behavioral and physiological data, which is used to determine biomarkers. Figure 1 shows often used devices and sensors to monitor dietary behavior.

Following the processing pipeline (cf. Fig. 1), AI and ML methods include data segmentation into meaningful subsequences, feature extraction, inference, and the estimation of digital biomarkers, which in turn can be used as guidance information or to direct interventions. Starting with the segmentation, acoustic data acquired from bone-conducting sensors at the head could be divided into subsequences of individual chewing sequences, i.e. instances of bites being chewed. Segmentation can be a multi-stage process, e.g. the audio chewing sequences could be further segmented into individual chewing cycles, i.e. data subsequences extending from one mandible closing to the next. Automating segmentation can be referred to as the most challenging part of the ADM pipeline (e.g. Paessler et al. [9, 10], Amft et al. [11, 12]). Depending on the time series to be analyzed, features include maxima of the sequence, MFCC features, and edge-based features in images. The resulting feature vectors are used for

inference, and the result can be interpreted as digital biomarkers. The inference can be achieved by classifiers, including Support Vector Machines (SVMs), unsupervised techniques, e.g. clustering, and regression. The devices and sensors utilized in the ADM pipeline illustrated in Fig. 1 are discussed in section “[Methods in Automated Dietary Monitoring \(ADM\)](#),” and the process to derive digital biomarkers, such as chewing timing or nutrients, including processing steps from AI and ML is detailed in section “[Digital Biomarkers for AIM in EDs](#).”

Methods in Automated Dietary Monitoring (ADM)

ADM aims at retrieving digital biomarkers, including the consumed food type, nutritional information, and food amount with as few user interactions as possible. ADM helps to integrate dietary information to daily life routines, which gives to medical staff and coaches a more representative picture of the patient’s eating behavior. Toward a more complete impression of dietary routines, various technological approaches have been taken. Many dietary measurement approaches produce similar biomarkers but use different sensor types and recording devices, which imply distinct AI techniques for processing the data. The different ADM approaches are summarized, and the challenges associated with each technique are highlighted, considering (1) wearable-based, (2) smartphone-based, and (3) ambient-based ADM. For each of the three approaches, the most important surveys are presented, and differences between the methods are discussed.

Wearable-Based ADM

Wearable devices can measure time series that capture phenomena during eating.

Figure 2 provides an overview on typical wearable devices used for ADM. To retrieve digital biomarkers, like food type, eating timing, and intake, accompanying phenomena, different signal types, and wearables can be exploited. Amft [13] summarized on-body measurements scenarios, particularly, the result of the device positions and

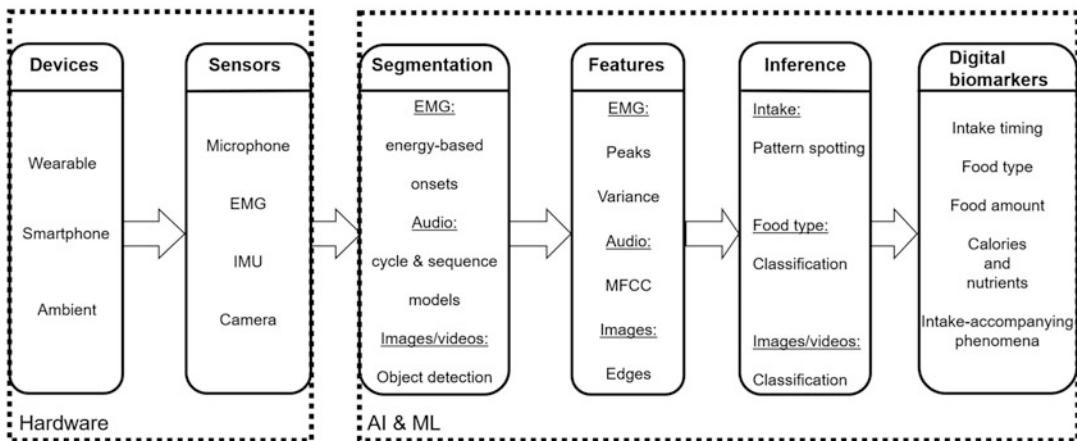

Fig. 1 The ADM data-processing pipeline with examples. Devices are equipped with sensors that record time series. The data is processed to yield feature vectors, which are used for inference of digital biomarkers

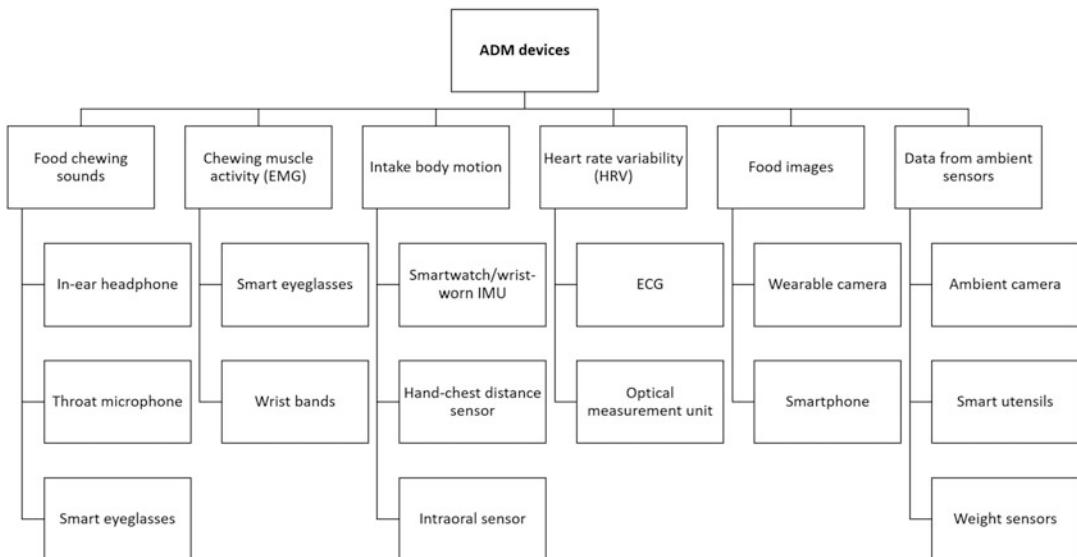

Fig. 2 An overview of frequently considered devices for ADM. Devices may be equipped with several sensor types

phenomena that can be acquired at the body positions. Eating Monitoring was grouped into different stages. Intake motions, i.e., the process of maneuvering a food item into the mouth, can be captured by inertial sensors or magnetic position sensors at wrists and chest. Inertial sensors can be used for chewing assessment too, by measuring head movement amplitudes. A variety of wearable sensors were found to capture chewing activity, including capacitive sensors, electromyographic (EMG), acoustic sensors, and dental implants.

Deglutition can be assessed with similar sensor types. The survey by Amft also addresses the use of temperature sensors to measure thermogenesis in response to food intake, and electro-gastrographic measurements to capture peristalsis movement to propel and process food. Heart rate and blood pressure sensors can be used to monitor diet-related physiology. Body composition is captured by bioimpedance sensors in supine position.

Schiboni and Amft [14] provided a comprehensive overview of the different wearable-based

ADM techniques, and expert models that describe food processing. The authors compared ear-worn devices to eyeglasses, mouth-embedded sensors and throat microphones in the context of chewing monitoring. Eyeglass-based dietary assessment includes EMG monitoring (Zhang et al. [6, 15–17]), piezoelectric strain (Farooq et al. [18]), load cells (Chung et al. [19]), and vibration sensors (Zhang and Amft [20]). Smart eyeglasses can be used for eating timing detection, as well as food type classification. Schiboni and Amft point out that full integration of these sensors into one wearable device is a benefit of this approach, as they are invisible to the user, while wearing during the day is comparatively convenient. The review paper also covers ear-worn devices. Ear-worn devices, such as in-ear headphones with integrated microphones are mostly used to record audio data [10, 12, 21–23]. The audio data coming from ear-worn acoustic sensors can be used for many different digital biomarkers, including eating timing, food type, intake quantity, or hydration timing. Audio data enables analysis of chewing microstructure. Since ear-worn acoustic sensors are located in the same place as hearing aids or earphones, it is convenient for patients to use them. On the downside, in-ear devices can occlude hearing, and their acoustic signals are perturbed by ambient noise. Intraoral sensors include inertial sensors [24] or strain gauge [25] and are mainly used for eating timing detection. Intraoral sensors can directly capture chewing motions. However, intraoral sensors are invasive, e.g. artificial teeth with embedded sensors require surgery, temporary implants may change oral sensation and behavior, and there is a risk that the sensor might be swallowed by the user. Another audio-based approach are throat microphones. Bi et al. [26] as well as Olubanjo and Ghovanloo [27] used this technology for eating timing detection. The main advantages of throat microphones, according to Schiboni and Amft [14], are the accessibility of both mastication and deglutition sounds, and the location can be also used for other physiological measurements. But microphones are also perturbed by ambient noise, speaking, and neck movement. The throat microphones require tight sensor-skin contact, and their

position is not ideal for wearable accessories and convenient use in daily living. Schiboni and Amft provide a similar comparison of approaches for ADM techniques dedicated to deglutition analysis. Furthermore, the survey provides insight about the use of wearable cameras to monitor food consumption of patients. In visual eating scene analysis, a camera is mounted to the user chest, head via cap, etc. to capture egocentric video and images. The resulting data can be used to get a more complete picture of intake events and nutritional data of the user. It has to be noted that continuous recording of camera footage causes privacy concerns due to unwanted images included in the material. Schiboni et al. investigated egocentric camera position further [28]. The authors implemented a camera on a cap's visor pointing downward. As a result, the unwanted privacy-threatening content decreased. Furthermore, the researchers proposed a dietary event-spotting algorithm based on video data coming from the device.

Vu et al. [29] presented another review of wearable techniques in ADM. Acoustic, visual, inertial, EMG/ECG, and piezoelectric sensing is covered. Apart from discussing advantages and disadvantages as well as current applicability and challenges, the authors outline the user comfort of different devices. Inner-ear devices for acoustic measurements are, for instance, classified as moderately comfortable, whereas visual approaches are seen as highly comfortable for the user. Information fusion approaches are an important focus of this chapter. Information fusion is considered as combining two or more wearable approaches in ADM. Combining sensors can increase accuracy or facilitate signal processing. As a prominent example, the authors point out the combination of acoustic and visual sensing. Liu et al. [30] designed a device, which embeds both a camera and a microphone for dietary assessment. As another sensor fusion idea, the survey of Vu et al. [29] mentions the possibility of combining inertial and visual sensors. Sen et al. [31] used the inertial measurement unit (IMU) of a smartwatch combined with a smartphone's camera that is triggered by the IMU data.

Smart eyeglasses with integrated sensors is a promising approach of using wearables in ADM. Introduced by Zhang and Amft [8], the idea has been utilized by different researchers. Zhang and Amft incorporated EMG electrodes and a measured chewing from muscle activity [20] and a vibration sensor to measure the skull vibration during chewing. More details of their approach are also illustrated in section “[Digital Biomarkers for AIM in EDs](#).” Furthermore, Wahl et al. [32] placed an accelerometer and gyroscope, as well as an optical heart beat sensor (photoplethysmography), into the eyeglasses frame. The setup enables investigators to detect daily activities, i.e., brushing teeth, reading, cycling, and jogging, which could be incorporated to assess daily activity of, e.g. obesity patients to complement their nutrition diary.

Smartphone-Based ADM

Sen et al. [31] used smartphones for dietary assessment. The authors combined smartwatch-based monitoring with a smartphone that communicates with an image recognition server. Adding a smartphone to the ADM-processing chain has been tried by various research groups.

Schembre et al. [33] summarized app-based approaches for dietary monitoring. Their focus is on mobile device-assisted ecological momentary diet assessment (mEMDA). mEMDA is an extension of ecological momentary assessment (EMA), also known as “in the moment assessment” or “experience sampling” [34]. The survey by Schembre et al. summarizes mEMDA protocols that have been used in research. The authors conclude that mEMDA compared to EMA can reduce participant burden and recall bias. An overview of several smartphone-based studies is given. The authors incorporated 20 studies using unique mEMDA protocols. A majority of these protocols (60%) asked the study participants to report their dietary data on the smartphone. Others were Internet-based applications. Some apps use social media (Twitter) to retrieve data. Sample periods vary from 3 days to 3 months, where most are in the range of 1 week. Data collection is done in three different ways: Some applications use

image-assisted dietary records, where images are taken before and after the meal with fiducial markers. Others prefer dietary records, where food ought to be chosen from different options or food groups. One approach used voice-annotated videos including time stamps. Data processing and nutrient analysis were also addressed. Furthermore, the review mentions smartphone-based nutrient analysis.

Villinger et al. [35] looked at app-based eating analysis too. The survey aimed at assessing the usability of methods to improve nutrition behaviors and related indices, including body mass index (BMI) and blood lipid concentration. The authors searched seven databases from 2006 to 2017. They included 41 studies and assessed them in a heatmap regarding the 25 Consolidated Standards of Reporting Trials (CONSORT) criteria. The survey quantifies behavior change technique (BCT) across the different studies and shows a forest plot that illustrates the effects of app-based mobile interventions on nutrition behaviors and other nutrition-related health results. Furthermore, the authors quantify the effects of app-based intervention on short-term, intermediate-term, and long-term follow-up intervals.

Ambient Technology-Based ADM

Sensor devices in the dining room, objects, e.g. cutlery, a fridge, etc., have been considered to track dietary habits, which Amft [13] summarized as ambient ADM technology and techniques. The survey distinguishes different targets to be monitored by the ambient sensors. Routine monitoring by looking at recurrent daily activities can be achieved by RFID-tags or a sound sensor [36]. Tags might be placed at arbitrary objects, while the RFID reader must be worn by the patient. Food preparation may be guided by recommendations generated by the ambient ADM system. To design an ambient technology-based recommender system, RFID, weight sensors, cameras, force sensors, or magnetic sensors could be integrated in kitchen trays, utensils, and furniture [37]. Intake monitoring, which is one of

the main applications of wearable-based ADM, can also be implemented in an ambient context. RFID-tags, weight sensors, or cameras are the preferred sensors and may be integrated into a dining table. Weight sensors could also be embedded into plates to measure food weight. Behavior tracking using vision-based observation, namely by surveillance video installations, has been used, e.g. at ceilings [38, 39]. Another option is to automatically register food products, which could be done by smart cards or RFID-tags put onto the products in the refrigerator or kitchen cabinets with the reader close by [40].

Digital Biomarkers for AIM in EDs

Intake Timing

The life of ED patients is often accompanied with irregular meal times due to, e.g. skipping meals or overeating. Irregular meal times and snacking could be revealed by intake time. Intake time can be detected with several sensor modalities. Amft et al. [11] applied an in-ear microphone for ADM. An eating detection algorithm based on the C4.5 Decision Tree classifier yielded an accuracy of 99%. Farooq et al. [18] used a temple-attached piezoelectric strain sensor and an accelerometer integrated in eyeglasses. A two-stage eating detection algorithm (Support Vector Machine and Decision Tree) yielded an average F1 score of 99% and area under the curve (AUC) of 0.99. Dong et al. [41] applied a naive Bayes classifier on wrist-worn motion data (accelerometer and gyroscope), yielding 81% accuracy, 0.6 min average intake start error, and 1.5 min end error. Thomaz et al. [42] used wrist-worn accelerometers to capture intake gestures in free-living with a Random Forest classifier, reporting 66% precision and 88% recall. Bedri et al. [43] used a wearable device called EarBit integrated with IMU and proximity sensors to capture free-living data. Eating detection based on the Random Forest produced an accuracy of 95%. Zhang et al. [44] proposed a neckband integrated with IMU, ambient light, and proximity sensors for free-living eating monitoring. A F1 score of 77% was

achieved using an eating detection algorithm based on Friedman's Gradient Boosting Model. Most of the above works evaluated the retrieval performance yet rarely reported absolute intake timing errors.

Chewing is often the most time-consuming process during eating solid and semisolid food [45]. Therefore, chewing duration can be regarded as a proper approximation of intake time. An example of deriving intake timing using EMG sensors embedded in a smart eyeglasses frame is detailed below. Temporalis muscles contract and relax during chewing. Stainless-steel EMG electrodes were used bilaterally in temple ear bends of 3D-printed eyeglasses to capture the contraction of Temporalis muscles of the wearer, yielding two channels of EMG signals (see Fig. 3).

Various eating detection algorithms were investigated [6, 17]. Eating detection algorithms can be categorized into top-down (detect eating from data directly) and bottom-up (detect chewing then eating) strategies. For example, a top-down approach is to apply a sliding window on rectified EMG data and extract features for a one-class Support Vector Machines (ocSVM) classifier with the Radial Basis Function (RBF) kernel. A label (eating or non-eating) was predicted by the trained ocSVM classifier and the overlapping labels were merged by majority voting, resulting in chewing segments. Finally, the gaps between two adjacent chewing segments less than 5 min were filled since they were considered as the natural breaks during an ongoing meal. A gap-free eating segment was considered as an eating event with its start, end, and duration representing the intake time.

In the bottom-up detection approach, individual chewing cycles were first detected, and chewing segments derived by clustering temporally close by chewing cycles. Gap handling, identical as in the top-down algorithm, was applied to the merged eating segments, yielding predicted eating events.

Following the above example, algorithms were analyzed in a smart eyeglasses dataset from ten participants, containing 44 eating events (meals and snacks) with durations ranging from 47 s to 36.2 min, totaling 429 min. F1 score and timing

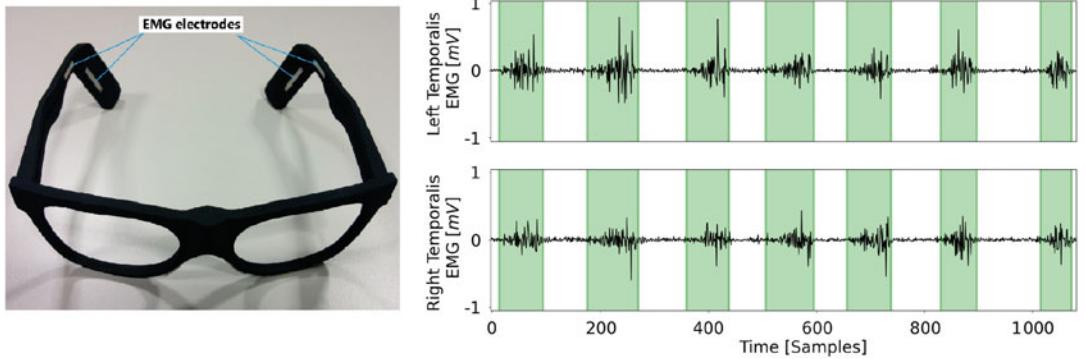

Fig. 3 Left: dietary monitoring smart eyeglasses integrated with bilateral EMG electrodes [16]. Right: example chewing EMG signal recorded with the eyeglasses. Labels indicate chewing cycles

errors were used to evaluate the chewing time detection algorithms. Precision and recall were computed as: precision = $\frac{T_{\text{tp}}}{T_{\text{ret}}}$ and recall = $\frac{T_{\text{tp}}}{T_{\text{gt}}}$, where T_{gt} was the summed duration of all eating events according to the reconstructed annotations, T_{ret} referred to the summed duration of all retrieved eating events, and T_{tp} was the sum of overlapping duration of retrieved eating events and reconstructed annotations.

Timing errors are computed as the difference between reconstructed annotations and the temporal boundaries of an eating event:

$$\Delta \bar{T}_s = \frac{\sum_{i=1}^M \min \left(\left| \hat{T}_s(j) - T_s(i) \right| \right)_{j=1,2,\dots,N}}{M}. \quad (1)$$

$$\Delta \bar{T}_E = \frac{\sum_{i=1}^M \min \left(\left| \hat{T}_E(j) - T_E(i) \right| \right)_{j=1,2,\dots,N}}{M} \quad (2)$$

where $\Delta \bar{T}_s$ is the start, and $\Delta \bar{T}_E$ the end timing error averaged across M eating events, and $\hat{T}_s(j)$ and $\hat{T}_E(j)$ are the start and the end of the retrieved eating event j , respectively. N is the number of retrieved eating events.

Zhang et al. [6, 17] reported performance on the above example data and detection algorithms. The top-down algorithm achieved $F1 = 95\%$ with $\Delta \bar{T}_s \approx 21.8\text{s}$ and $\Delta \bar{T}_E \approx 14.7\text{s}$. The bottom-up

algorithm achieved $F1 = 99\%$ with $\Delta \bar{T}_s \approx 2.4\text{s}$ and $\Delta \bar{T}_E \approx 4.3\text{s}$. In summary, chewing and intake time can be detected, e.g. from Temporalis EMG data, with timing errors of below 5 s in everyday life situations.

Food Type

Distinguishing food types, e.g. chips from apples or baguette, has been tackled by different ADM approaches and classification algorithms. In this section, an overview of food type recognition using image and audio data is given.

Image-Based Food Type Recognition

In image data, food is detected using segmentation and classification algorithms. Wen Lo et al. [46] surveyed different image processing pipelines. The authors show that image recognition techniques can be used for both, food type classification and food amount estimation. For both digital biomarkers, the authors distinguish between traditional, manually designed feature-based image processing using, e.g. Scale-Invariant Feature Transform (SIFT) features, classified by Support Vector Machines (SVMs), and deep learning approaches, e.g. Convolutional Neural Networks (CNNs). Among traditional models were nearest-neighbor classifiers and SVMs with different feature sets, including SIFT, Difference of Gaussians (DoG), or Histogram of Oriented Gradients (HOG). Deep Learning approaches mostly used

CNNs, including extensions, such as inception. Apart from self-recorded data, which several research groups used, e.g. Schiboni et al. [28], three different standardized datasets were used for image-based food type classification, including Food-101, UEC-FOOD100, and UEC-FOOD256.

Audio-Based Food Type Recognition

Different food types can also be inferred from audio data. Schiboni and Amft summarized audio-based food type recognition [14]. Breaking of the food objects in the mouth produces texture-dependent sounds that are characteristic for foods. Chips, for instance, are categorized as dry-crisp, whereas an apple has a wet-crisp sound texture (see Amft et al. [11]). Baguette, in contrast appears to be lower in amplitude and less “crisp.” Fig. 4 shows the difference between audio sequences of potato chips and baguettes.

The audio signal of food processing in the mouth contains chewing sequences from intake to deglutition with multiple chewing cycles. Chewing cycles are short periods starting by the

crushing of the food by the mandible until the next crushing-caused transient [14]. The difference between the audio signals of chewing cycles of potato chips and baguette is displayed in Fig. 5. Time series segmentation is one of the most challenging aspects of audio-based food type and amount estimation. For both, sequence and cycle level, effort has been spent to model the time series using patterns. Paessler et al. [9, 10] divided chewing sequences into 2–3 parts: begin, middle, and end phase. They designed a Hidden Markov Model (HMM)-based sequence model, which consisted of different HMMs, one for each phase. The transition between the phases was modeled by a Finite State Grammar. For chewing cycles, Amft et al. [11] proposed a model, where the chewing cycle audio data is divided into four phases:

1. Closing of the mandible, to crush food material
2. Pause
3. Opening of the mandible, where material is uncompressed
4. Pause

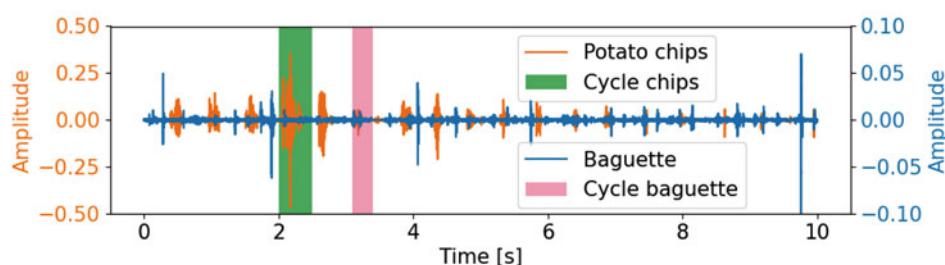

Fig. 4 Acoustic data sequences from two food samples. Potato chips have more prominent transients. Baguette transients are less prominent. One chewing cycle of potato chips and one chewing cycle of baguette are highlighted

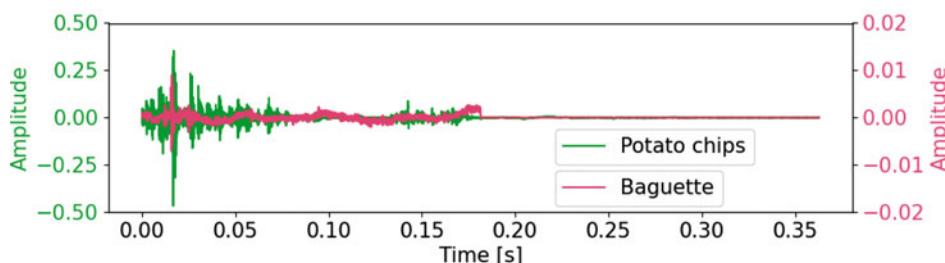

Fig. 5 Acoustic data from chewing cycles from two different food types. Potato chips have more prominent first and third phase. Baguette's amplitude is lower (max. displayed amplitude 0.02), and patterns are less distinct

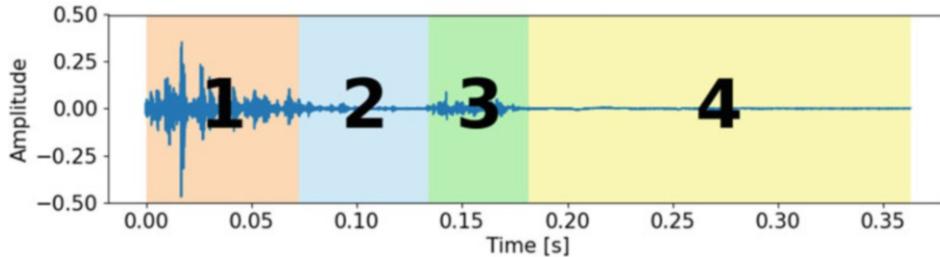

Fig. 6 Chewing cycle of potato chips with four phases

Figure 6 shows how the four phases are divided in a chewing cycle. Potato chips are a very illustrative example, where both the sequence model with begin, middle, and end phase as well as the four-phase cycle model can be applied. For other food types, where the amplitude of the transients is lower, the proposed sequence and cycle models are harder to infer (see the baguette cycle in Fig. 5). Segmentation was investigated by considering chewing cycles and swallowing events as symbols and adapting a probabilistic parser [47]. Another idea involves performing a multi-objective search to group chewing cycle patterns into subsequences [48]. Apart from time series segmentation, the audio data derived from acoustic sensors can be used for food type classification. Amft used a hierarchical approach [49] with a wearable earpad sensor to distinguish 19 food types. Furthermore, data of different sensor types were combined to determine food type. Mirtchouk et al. [22] used both in-ear audio data and wrist motion to classify food information. Lee et al. [50] used a Sonar placed close to the throat to record chewing signals. They extracted features and trained a neural network that could differentiate six food types. Mirtchouk et al. [22] distinguished 40 food types where audio and motion sensor data has been fused. The data was classified using hierarchical clustering.

Evaluation Metrics for Food Type Recognition

To evaluate algorithms that segment time series from food consumption or classify the different food types, different metrics need to be

considered. For example, Paessler et al. [10] reported classification by chewing sequence accuracy. For classification problems, the authors used accuracy to assess the quality of the outcome. Accuracy in this case is defined as:

$$\text{Accuracy} = \frac{|S_{\text{correct}}|}{|S_{\text{total}}|} \quad (3)$$

where S_{correct} is the set of all chewing sequences that have been correctly classified and S_{total} are the sequences in the dataset. A similar approach could be used for evaluating image classification algorithms.

Food Amount

ADM can determine the amount of consumed food in several ways. Wen Lo et al. [46] summarized how images can be segmented to estimate food amount. The different techniques include four categories: (1) Stereo-based approaches use multiple frames to reconstruct the 3D structure of food objects; (2) model-based techniques use pre-built mathematical models together with model scaling and rotation to determine the amount of food consumed; (3) others use depth-cameras, which can be used to determine the actual object scale without using fiducial markers, and perspective transformation refers to estimating object volume based on one single image; and (4) apart from the aforementioned techniques, deep learning models were used as well to estimate the volume of different foods.

Amft [13] looked at food amount estimation based on nonimage sensors. The estimation approach builds on the correlation of chewing cycles with food amount for a given food type and individual. Amft et al. [51] developed linear regression models to estimate food amount from chewing cycle count and food type information that was captured by an acoustic sensor. Prediction errors varied between 20% and 30% (Amft and Troester [23]). Food amount has also been estimated during drinking using magnetic position sensors [52]. Acoustic and EMG signal patterns during bolus swallowing were used to estimate fluid amount and viscosity too [53]. Further investigation by Mirtchouk et al. [22] confirmed and extended the food amount estimation principle by counting chewing cycles.

Determining calories and nutrients of consumed food is crucial to improve the lifestyle of patients. Schiboni and Amft [14] provided an overview of calories estimation methods. According to the authors, caloric amount can be inferred in different levels of granularity, e.g. calories per dietary event, and calories per bite. Dong et al. [54] used an indirect approach, where intake gestures were counted and a fixed calorie value per bite was considered. The authors' assumption is a simplification, as morsel weight or caloric value varies in foods and by the user's eating habits.

Calories are also retrievable from image data. Pouladzadeh et al. [55] applied using image processing and nutritional fact tables. Kirkpatrick and Collins [56] offered an introduction to nutrient estimation by ADM methods. Mankoff et al. [57] used shopping receipts to generate suggestions about healthier food items by scanning and passing them through an optical character recognition system. Rahman et al. [58] used the photo-acoustic effect to characterize liquid food in terms of their nutritional properties. They proposed a mobile system called Nutrilyzer. Anthimopoulos et al. [59] proposed a computer vision system to estimate carbohydrate consumption of diabetes type I patients using food images from a smartphone. Food images were segmented and

recognized using texture features and a nonlinear SVM. Carbohydrates were estimated by simulating the volume with a 3D model of the foods. Given the estimated volume, carbohydrates were determined from a dietary database.

All of the methods involving manual labor, e.g. picturing food, scanning receipts, etc., do not ensure that food amount was actually consumed by one individual.

Intake-Accompanying Phenomena Related to EDs

Triggers and Stressors

Excessive consumption of fatty foods and vitamin deficiencies due to an unbalanced diet are just two examples of malnutrition that can lead to serious health problems or be associated with EDs. Overall, there is little literature on AI regarding intake-accompanying phenomena. One of the most studied ED in this context is anorexia nervosa (AN), where AI methods have been applied. Possible triggers and stressors associated with EDs are manifold and can be related to, e.g. emotional problems, misperception of the body, or food stimuli (smells, e.g. of greasy food). Cravings in binge eating disorder, or avoidance of food in AN, may be triggered as a result. Furthermore, various authors have implicated that perceived stress may play an important role in the development of EDs (e.g. [60–62]). The following section "[Example: AI in Anorexia Nervosa \(AN\)](#)" will review AI-based approaches to support AN diagnosis and therapy. section "[Prospects for AN](#)" offers some insight on possible digital biomarkers for AN.

Example: AI in Anorexia Nervosa (AN)

AN is among the most common psychiatric ED. The prevalence accounts for 0.3% of all girls aged 13–18 years [63] and 1.1% of all female adults [64], with an increase in frequency over the past decade [65]. AN usually develops in early

adolescence and in 30–40% of patients becomes chronic leading to high morbidity and mortality [66]. However, diagnosing AN early is a major clinical challenge. Initial symptoms can be masked behind the pursuit of health or fitness goals, supported by family, peers, and health care professionals [67]. The field of possible application of AI in AN is broad, but not yet fully explored.

In 1998, Buscema et al. [68] made a first attempt to use ML methods to test the accuracy of neural networks in recognizing anorexic and bulimic patients. Data of 172 subjects with four different EDs was collected. The data base was composed of 124 variables, ranging from, e.g. generic information, alimentary behavior, menstrual cycles, weight, and height to psychodiagnostic tests. Six experiments were conducted, using a Feed Forward Neural Network (FFNN), with each of the six experiments using different variables. Decreasing the number of diagnostic conditions increased classification accuracy up to 100% for both AN and bulimia nervosa (BN) patients. Authors concluded that using variables from personal, social, and family data, chemical blood tests, and psychodiagnostic tests as input for the FFNN, it is possible to recognize AN and BN patients without knowing body weight and possible amenorrhea.

Guo et al. [69] also used ML methods in conjunction with genome data to predict the risk of AN. Whole genome genotyping data of 3940 AN cases and 9266 controls was analyzed. Model training was performed using a Lasso-regularized logistic regression (LR) model with tenfold Cross Validation (CV). For model testing and assessment, in addition to the LR model, Support Vector Machines (SVM) and Gradient Boosted Trees (GBT) were trained. A receiver operating characteristic curve (AUC) was derived to assess the performance of the different classifiers. The LR model generated an AUC of 0.693, while SVM and GBT reached AUCs of 0.691 and 0.623, respectively.

Furthermore, proof of the concept of an ML-based early-warning-system (ML-EWS) was

shown for AN patients [70], including 4,049 observations of 36 AN patients. Predictor variables of the ML-EWS models included 16 parameters ranging from, e.g. BMI, respiratory rate, oxygen saturation (SO₂%), heart rate, postural drop, blood investigations, and age. Predictive performance for Random Forests and naive Bayes classifier was assessed using 50-fold CV, yielding AUC of ~0.8 to 0.9. Despite performance drop from independent samples to multilevel analysis, multilevel RF slightly outperformed the existing EWS (AUC = 0.916), which did not use ML techniques.

Another interesting field for applying AI methods in AN is neuroanatomy [71, 72]. For other individual disease diagnoses, e.g. Alzheimer's and Parkinson's disease [72–75], ML techniques have been shown to reliably identify imaging biomarkers with an accuracy of above 90%. Lavagnino et al. [71] present a multivariate ML approach utilizing structural neuroanatomical scan data. T1-weighted magnetic resonance imaging (MRI) scans of 15 female AN patients and 15 demographically matched controls were acquired, and neuroanatomical volumes were extracted. The volumes served as input into the Least Absolute Shrinkage and Selection Operator (LASSO) multivariate ML algorithm with fivefold CV. Validity of the model was assessed using accuracy, sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and AUC. Moreover, correlation of the results with “drive for thinness” and BMI were evaluated. The model achieved an accuracy of 83.3% (sensitivity 86.7%, specificity 80.0%). A linear relationship between drive for thinness clinical scores ($r = 0.52, p < 0.005$) and BMI ($r = -0.45, p = 0.01$) was shown.

Ceresa et al. [72] also assessed the feasibility of ML methods for extracting neuroimaging features. A total of 17 AN patients and 17 healthy controls were analyzed. Principal Component Analysis (PCA) was applied to structural T1-weighted MRIs. SVM algorithm was used to perform classification with 20-fold CV. Maps of the voxel-based pattern distribution of structural

brain differences were created. When using 31 PCA coefficients, accuracy, specificity, and sensitivity reached their best values of 0.85, 0.73, and 0.93, respectively. Consequently, using standard morphological brain images, SVM can extract neuroimaging biomarkers and accurately classify individuals with ED.

Zhao et al. [76] developed a predictive model for early diagnosis of AN based on the correlation between the concentration of six elements (Zn, Fe, Ca, Mg, Mn, and Cu), gender, and age. Data of 90 hair analyses (62 nonanorexic cases and 28 anorexic cases) was analyzed, and Partial Least Squares (PLS), Back Propagation Neural Network (BPNN), and SVM were applied. Classification accuracy revealed superior performance of SVM with an accuracy of 52%, 65%, and 87%, for PLS, BPNN, and SVM, respectively.

Another approach to predict risk or diagnose AN can be found in ML language-processing methods. Identification relies on medical reports, posted comments on the Internet, or self-reports of AN patients [77–79]. In 2018, Paul et al. [77] presented the results of using ada boost, LR, SVM, and RF classifiers on the Conference and Labs of the Evaluation Forum (CLEF) eRisk 2018 datasets. The authors used characteristic features obtained via Bag-of-Words (BOW) and Unified Medical Language System (UMLS) for model training and tenfold CV. The experimental analysis on the training set of AN patients showed that SVM classifier using BOW outperforms the other methods (precision = 0.97, recall = 0.98, F1 = 0.98, and ERDE₅₀ = 8.63%). In the same challenge, Wang et al. [78] use a classifier (TF-IDF) based on a Convolutional Neural Network (CNN) and weighting words with inverse document frequency. On the eRisk 2018 dataset, the model achieved decent Early Detection Error (ERDE₅) of 13.65%, ERDE₅₀ of 11.14%, and F1 = 0.67. Furthermore, Spinczyk et al. [79] used Natural Language Processing (NLP) methods in 44 female AN patients and presented a computer-aided ML-therapeutic diagnosis method for sentiment analysis of AN patient's statement. The intensity of five basic emotions

and six areas of difficulties [79] were analyzed by means of Natural Language Processing, Recurrent Neural Network (RNN) with two layers of Gated Recurrent Units [80], and Adam optimization. Compared to the dictionary-based method, the proposed RNN shows to be more effective (72% and 51%, respectively) in analyzing patient's body sentiment.

In summary, risk prediction has been the most widely used analysis objective in terms of AI in the field of AN. From the field of AI techniques, SVM, NN, PCA, and NLP techniques were successfully applied in risk assessment, establishment of early warning systems, and diagnosis of AN and showed promising results. Variables ranged from biological, genomic, to neuroanatomical parameters as well as language features from posts on the web or during therapy from the patients themselves.

Prospects for AN

Adolescent girls with AN undergo high levels of stress [81, 82], which has been shown as a risk factor in the development of EDs (e.g. [60–62]). Widely examined autonomic indices for stress reactivity are heart rate (HR) and heart rate variability (HRV, RR intervals (RRI) in electrocardiogram) [83]. A pilot study in adolescents showed associations between these two parameters and loss-of-control (LOC)-eating in the natural environment [84]. Peyser et al. [67] reviewed the current state of the art concerning HRV as a biomarker for AN and concluded that most studies show consistently elevated beat-by-beat variance for AN compared to controls. Thus, HRV features may act as a discriminating biomarker independent of low body mass or bradycardia [67] and may be used as input feature to different AI methods in the future.

Figure 7 shows an exemplary recording of RRI and derived HR. Measurements were performed using a wearable device worn on the biceps during a body exposure intervention session. Over the course of the intervention, the patient was confronted with a previously taken photo of her body twice. However, and in contrast to literature,

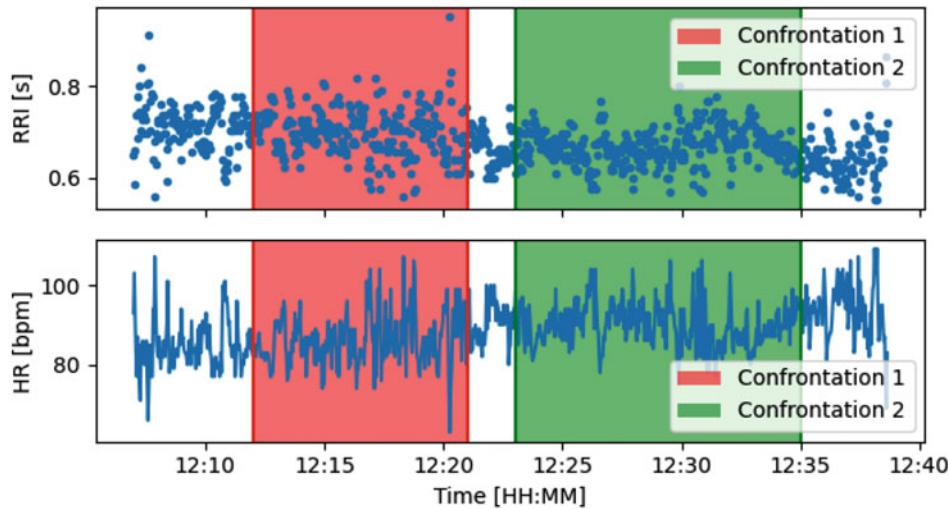

Fig. 7 Raw RRI and HR measurements during an intervention session. In contrast to literature, no clear HR increase or RRI decrease can be observed during body confrontation

no clear HR increase or RRI decrease was observed during the two body confrontation sessions, indicating that the variable relation may be inconsistent, even in controlled settings.

Furthermore, long-term measurements of HR and HRV in a controlled setting have not been conducted. Information on stress reactivity in general, and in relation to potentially stressful situations (e.g. social interactions or mealtimes) in particular, may be a future challenge for AI techniques in AN. Thus, possible correlations and risk predictions can be derived with different research objectives targeting AN.

Other promising biomarkers may be derived from activity monitoring as excessive physical activity is a common phenomenon in AN [85]. Enhanced activity could not only be used as a deliberate strategy to lose weight, but has also been discussed as an emotion regulation strategy [86]. Physical hyperactivity is an important prognostic factor in AN [87]. Correlations between physical hyperactivity and biological markers, including Leptin, Kisspeptin, and Ghrelin, have been shown [88]. However, there is no common definition of physical hyperactivity. Analyzing and classifying movement patterns and physical activity via means of AI methods has been

successfully shown in other clinical diseases, i.e. stroke and Parkinson's disease [89–91]. Applying AI techniques to AN motion data would offer the possibility of automatically detecting, extracting, and classifying movement patterns and other physiological features as biomarkers relevant to AN. Additionally, using these biomarkers as input to train adequate ML models could provide new tools to relate the biomarkers to ED-related psychopathology, to predict risk and disease/therapy progression, or to establish an early diagnosis.

As an example for motion data, Fig. 8 shows time series signals acquired by inertial measurement unit (IMU) sensors worn by the patient at each leg across a 12 h period. Labels for eating events and physical activity were taken from a paper protocol and superimposed on the signal. With the IMU data, AN-specific movement artifacts related to meals or leg bouncing, so-called feet fidgeting [92, 93], may be detected. AN-specific movements may potentially result from imposed stress and are just two examples of promising features that could be extracted and interpreted as possible digital biomarkers for AN. Measuring physical activity along with RRI and HR (see Fig. 8) may provide additional

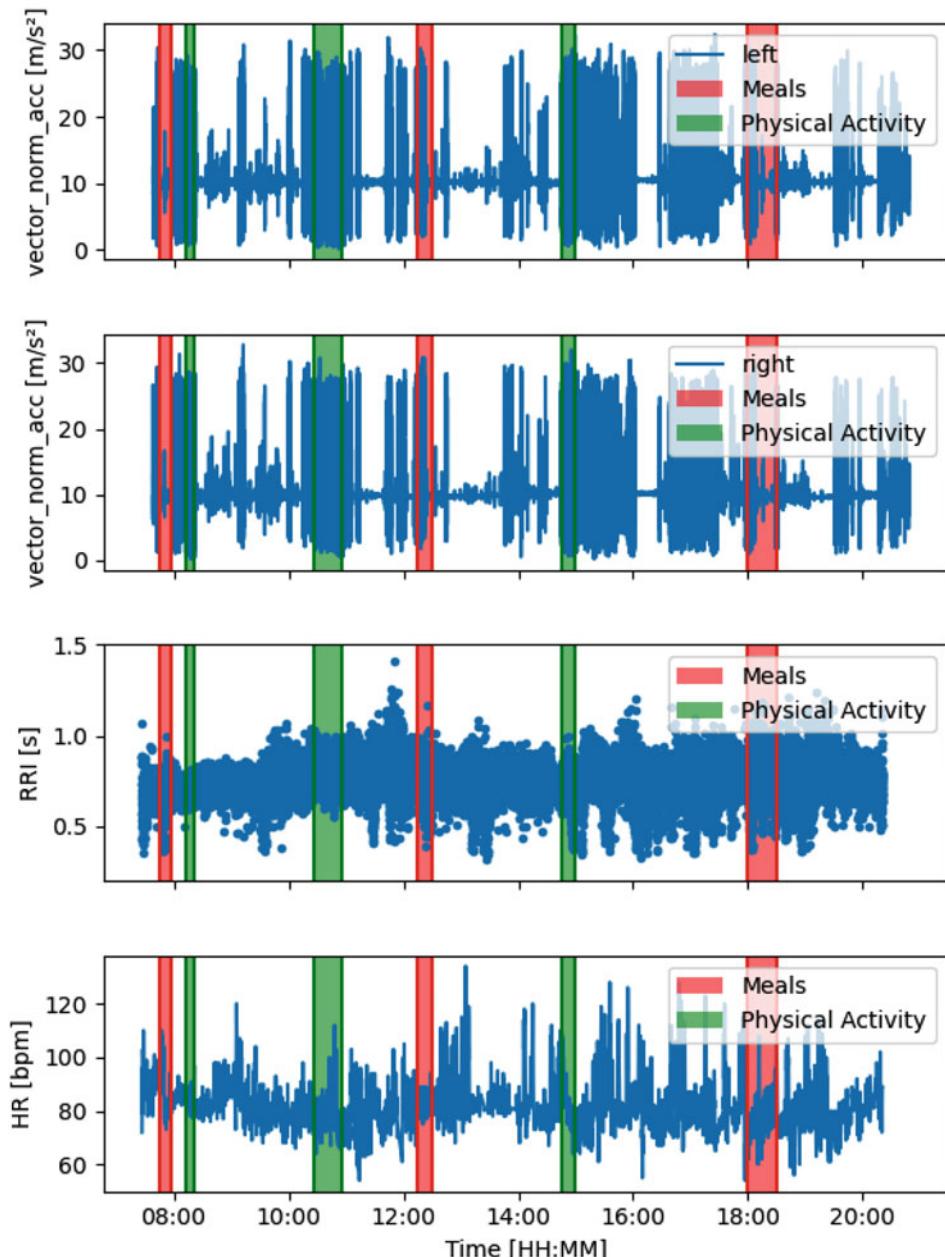

Fig. 8 Example of vector normalized time series signal of linear acceleration of both feet and cardiac measurements (RRI and HR) taken from the same subject and day

context information and enrich the input for different ML approaches.

Abstract

This chapter describes the advancement of neurological treatment through artificial intelligence (AI)-driven tools and applications. It

AI as the protagonist for the better prognosis of childhood medulloblastoma with efficient subtype diagnosis

Supplementary Information: The online version of this chapter (https://doi.org/10.1007/978-3-030-64573-1_189) contains supplementary material, which is available to authorized users.

introduces the need for AI research in neurology and a description of the components of AI for an AI-specific application. The role of AI in neurology and the mechanism of a machine learning (ML) or deep learning (DL) model can be found as the main context of the description. For a deeper level of understanding, this chapter also focuses on a case study that provides a stepwise guideline for the development of an AI application for the classification of medulloblastoma tumors to impart practical knowledge of the methods and methodologies involved in the formation of such AI models. Challenges of a clinical and AI-based observation for patient treatment, advantages of an AI-driven model, its need and usage, and industry transition are some discussions at the

later part of the chapter. Overall, this chapter focuses on the amalgamation of clinical observation with AI research and how AI can play a supportive role in neurological assessments.

Keywords

Medulloblastoma · AI · Neurology · Machine learning · Deep learning · Computer vision · AI diagnostics

Introduction

Artificial intelligence is the technique of feeding human decision-making or understanding capabilities to machines to mimic natural intelligence in problem-solving. AI has already been a solution to many natural object detection or scene understanding problems [1–3]. Recent advances in AI are seen in the healthcare sector that play a major role in the detection and identification of healthcare problems [4–6]. A report by [7] provides an overview of ML methods by neurosurgeons across the globe and its impact. As stated, AI has witnessed a recent rise with the advent of machine learning (ML) [8–12] and deep learning (DL) solutions particularly in the field of neurosurgery. ML and DL methods are domains of AI that use computer programs to automatically learn and identify problem data and give a predictive outcome. Until the introduction of AI in the field, the neurologist was the principal investigator of the diagnosis and prediction of a neurological disease involved in the decision-making process of any operative process, tumor resection, or post-operative risk and prognosis [11]. However, the individual decision of a neurosurgeon cannot be generalized to every patient because each patient has their own variant of patient history to account for. The number of patient records and information has given rise to an exponential rise of big data problems, which requires computer-based analysis and solutions. The processing of these huge patient records to give a predictive decision is beyond the scope of a medical practitioner. With the invasion of AI tools and applications in the medical and healthcare domain, it is possible and

necessary to assist neurosurgeons in integrating this patient information into reliable decision-making models for improved stratification.

AI generally comprises three learning models: supervised, unsupervised, and reinforcement. The supervised models are based on a training set of data with predefined classes of output where we know the actual class of the training data, and we need to train the machine based on this data to correctly identify the classes. On the other hand, unsupervised learning does not have labeled training data. Here the training data is automatically classified based on similarity measure that the training data exhibit among the same classes. Reinforcement learning is based on model feedback, where the model automatically learns to train itself based on the feedback it sends to itself after prediction, e.g., self-driving car. Generally, for medical data, the learning is supervised with prior knowledge and collected medical data.

[13–16] studies the impact of machine learning algorithms on neurosurgery data. The introduction of AI can generate the risk factors associated with any prognosis decision [17]. AI and its tools have a wide variety of applications in neurological treatment. A study was made where AI is used to access the suicidal risk factor and prevent suicide [18]. AI-based models have been studied to predict dementia, autism, and Alzheimer [19–23]. It is used to study neuro traumatology [24] to predict mortality associated with accidents and identify brain hemorrhages and strokes [25, 26] in neuro-imaging. It is used in neuro habitation for implementing robotic arms [27]. AI can be used to sense and analyze the patient data and generate a single decision-based system to give a predictive outcome integrating all the factors associated with the patient data [28, 29] to give the most favorable outcome. ML and DL algorithms are used in radiological or pathological image understanding for neurological data by image feature study [30, 31]. AI methods are also used in the preoperative stage, where information from a set of radiological images are preprocessed for better understanding using AI image processing methods or image segmentation techniques to get a clear understanding of the clinical region of interest from these images [32–34]. AI is also used

in making a postoperative decision by classifying and identifying the grading of a neurological tumor from a medical slide after a postoperative biopsy [35–37]. We can also find AI in the molecular study that could be useful in determining the pathogens in a neurosurgery sample [38, 39]. ML for neurology has a high range of publications from recent years [40–42]. The advent of AI in neurosurgery has made it possible to perform robotic surgery to assist the neurosurgeons [43]. AI-based ML models have also been used in the survival prediction of patients based on the grading and differentiation of tumor cells [44]. AI is also used in pathological scene understanding of the biopsy tissue samples for tumor grading and identification of a neurosurgery sample [45]. Modern methods of AI and data mining have already given pathways in generating prediction models for neurological oncology treatment [46]. Central nervous system (CNS) tumors (Fig. 1) are highly malignant and the leading cause of death among children [47]. As reported, nearly 4000 cases per year are diagnosed with these types of tumors in the United States, which causes 25% of cancer-related deaths. The overall incidence of brain tumors is highest in children with less than 5 years of age accounting for 75% of the cases in less than 10 years of age. The diagnosis of such tumors is difficult to obtain from children due to the difficulty in communication and clinical observation among infants and the prolonged delay for the implicative results of the tumor. There exists a substantial difference in the molecular biology of adults and children giving rise to the distinctive study of pediatric brain tumor. Astrocytoma, glioblastoma, oligodendrogiomas, ependymoma, and medulloblastoma are a few CNS tumors to name for [47, 48]. As defined, these tumors contain diverse pathological entities and are complicated for interpretation by a general pathologist and often require the guidance of an experienced neuropathologist as the intervention of samples between a general pathologist and a neuropathologist is high. The need for diagnosing such tumors is challenging, and this highlights the need for collaboration of multiple clinical research institute and computer scientist. In further reading, the steps in the application of AI

models in diagnosing these CNS pediatric brain tumor is explained with a special reference to childhood medulloblastoma tumor.

Childhood Medulloblastoma

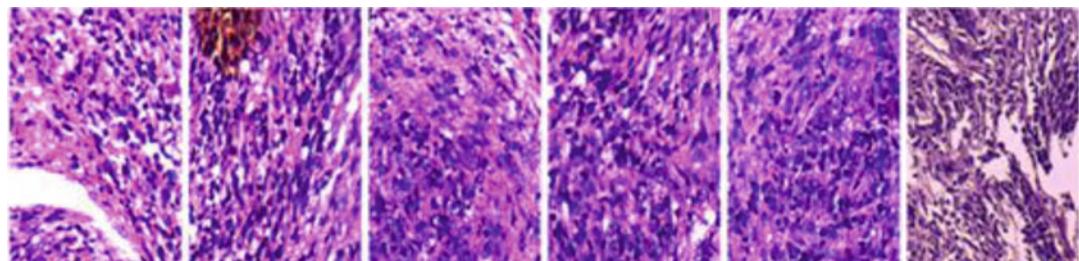

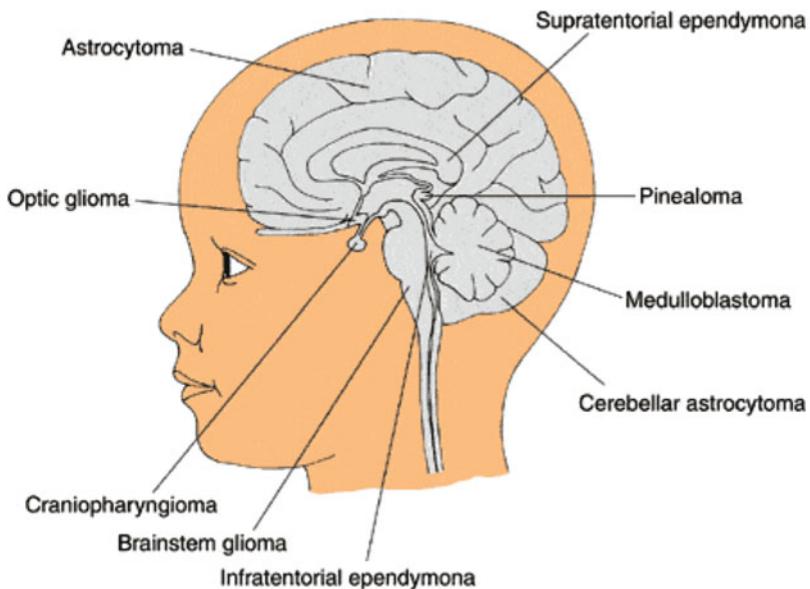

Childhood medulloblastoma (CMB) is a pediatric nervous system tumor that arises from the roof of the fourth ventricle in the cerebella hemisphere. Its peak incidence is seen in children from 5 to 6 years of age. The World Health Organization has graded it as a highly malignant grade IV tumor [49]. It has four different subtypes, namely, large cell, desmoplastic, classic, and nodular, each having a separate histological variant [50]. The author gives the pathological description of the different variants. The prognosis and survival rate depend on the different subtypes of the CMBs. The large subtype is highly anaplastic. The nodular subtypes have nodular patterns of cell arrangement, while the desmoplastic contains a network of collagen fiber, the classic subtype is most prevalent, and its cell arrangement can be microscopically found the same as the large except that it is non-anaplastic [51]. Macroscopic observations of these tumors are finely granular of grayish pink to purple with soft consistency accumulated lesion. Microscopically, these are carrot-shaped cells with scanty cytoplasm. Patients with CMB are often seen with headache, failure to thrive, cerebella symptoms, and nausea [52].

For malignant regions, it has a high density of cells with scanty cytoplasm and irregular cell structures, while in normal regions, the cells are not highly distributed and also have smooth round cells in shape.

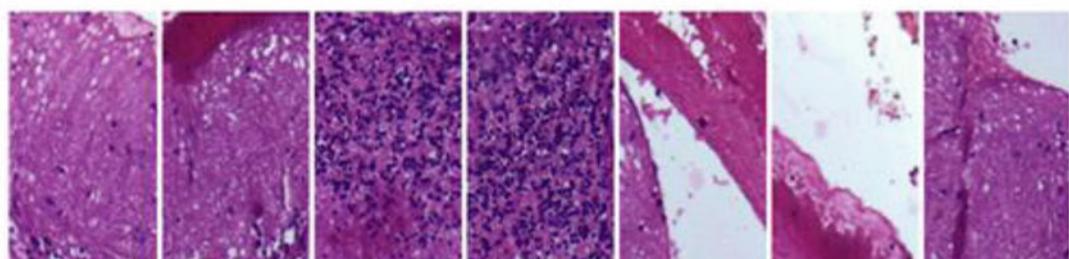

Methods and Materials for AI Application

Any ML-based classification for histopathological images will have the following steps, as shown in Fig. 4. To make it more clear, we discuss the following case study. The study [53–59] was made for biopsy images at both low power and high power microscopic observations, as

Fig. 1 The figure shows different types of CNS tumors with different region of origin. (Image courtesy: <https://childrenswi.org/medical-care/macc-fund-center/conditions/oncology/braintumors>)

a) Architectural view of malignant region

b) Architectural view of normal region

Fig. 2 Image showing the microscopic captured image of the (a) malignant regions and (b) normal cell regions in biopsy samples for brain tumors

observed by a pathologist for histopathological samples. The low power view would be referred to as an architectural level and high power as a cell level. The classification model was built for both

binary (Fig. 2) and multiclass (Fig. 3) at both levels. The binary classifier classified between normal and CMB sample [57], whereas the multiclass classified the subtypes of the CMB [56].

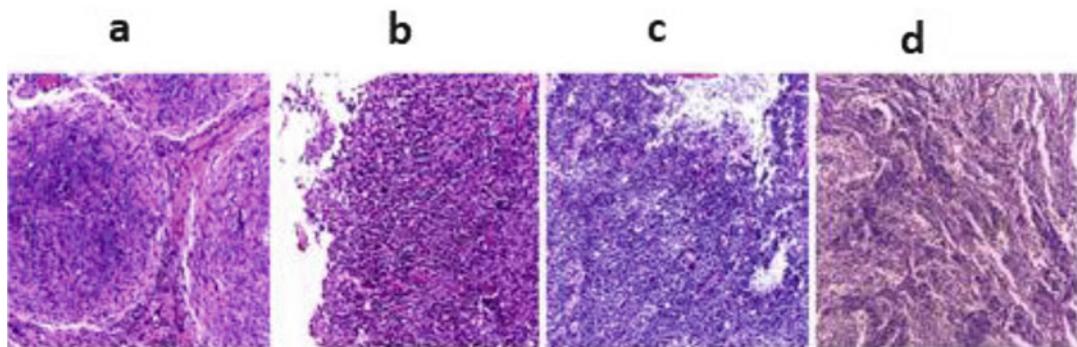

Fig. 3 Image showing the different subtypes of childhood medulloblastoma samples from microscopic image capture. (a) Nodular, (b) classic, (c) large cell, and (d) desmoplastic subtype

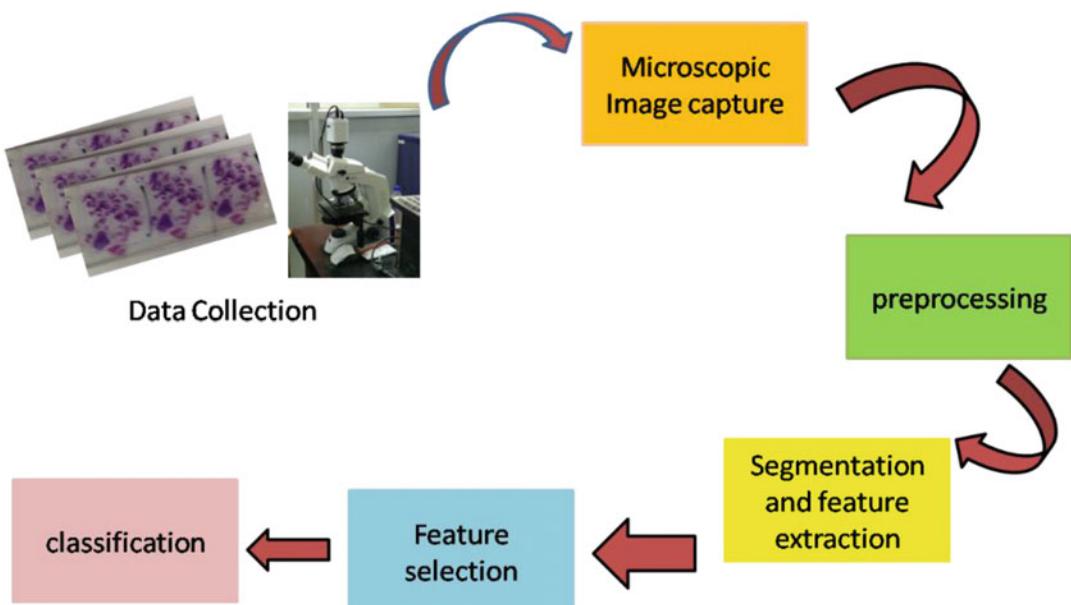

Fig. 4 Image classification steps for an ML classification

Data collection: The microscopic images are collected from the medical slides that were prepared from the tissue specimen collected from the postoperative procedure of tumor resection. The images were collected at $10\times$ and $100\times$ magnification in RGB standard color format and stored with a .jpg image extension [60].

Data preprocessing: Preprocessing is an additional step and is only done when the required information in the data needs to be highlighted or filtered for gaining insightful details from the concerned ROI. Preprocessing of the data was

done for $10\times$ images, which were used for classification at the architectural level. Color channeling was used for the identification of the color channel that gives us a good visualization of the tumor spread. The RGB image was decomposed into various color models and its constituent channels. Later, a color enhancement filtering on the selected color channel was performed.

Ground truth annotation: Any medical AI model would require the substantial support of ground truth for performance validation. This ground truth can only be marked and validated

by a clinical practitioner. However, the generation of ground truth data is a very tiring process and requires patience and devotion from a medical expert. A total of 1260 ground truth information was generated to identify the cells from the underlining smear images captured at $100\times$ [55]. The ground truth cell annotations were further processed by a machine learning K-means clustering algorithm to capture this ground truth and convert it into binary information for machine understanding. The ground truth marked cells are now identified by 1 (white) and the background as 0 (black). The ground truth information extraction is shown in Fig. 5.

Feature extraction: Texture study [56, 57] was made at the architectural level to study the structural arrangement of the tumor cells. Five different texture features were extracted. Both first-order and second-order features were studied. For first-order features, we considered a histogram-based feature of the pixel intensities that gave kurtosis, skewness, mean, probability of intensity value, etc. Total, there were 14 histogram-based features. For second-order intensity information, four features: i) the GLCM in four directions, ii) GRLM, iii) LBP, and iv) Tamura feature were used to understand the pixel relationship among the neighboring pixels. All total, it was 171 features for binary and 99 for multiclass. At the cell level, color and shape features were extracted in addition to these texture features. For a cell level feature understanding, the information from the ground truth annotated cells were used. The malignant cells tend to have a high color chromaticity and irregularity in shape as compared to normal cells, and so these were important

biomarkers for our study. All total, there were 259 cell features.

Feature selection: The selection of features is equally important as the extraction of important features. If the features are not valuable and do not contain a high set of information, this would adversely affect the classification performance. Stacking the classifier with unnecessary features will only increase the complexity of an ML model, decreasing the performance. For a DL network model, these features are automatically extracted by the model, while for ML methods, we have to perform a manual extraction and selection of features. A forward selection method was used for feature selection where at first, the individual accuracy of features was measured for classification, and then they were grouped in subgroups of features to extract the feature subset that carries maximum information.

Feature reduction: A high dimension of features has the probability of having a high amount of redundant features. In machine learning, there is an underlying curse of dimensionality associated with large feature sets that affect the performance of an ML classifier. For this, it is required to understand the contribution of each individual feature toward the identification of the classification problem. Feature reduction is the technique of reducing the dimension of a feature set without loss of information. Feature reduction was made using principal component analysis (PCA). The features obtained from feature selection were converted to their principal component and arranged in descending order of their eigenvalues. The accuracy of the classification algorithm was then measured based on the number of principal

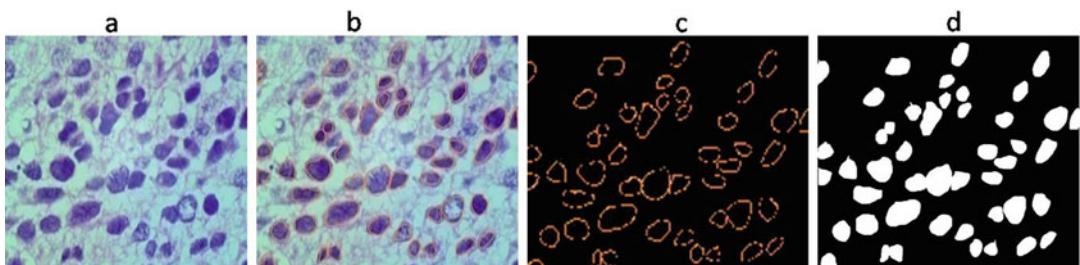

Fig. 5 Image showing the extraction of cells from the annotated ground truth. (a) is the original image, (b) is the annotated ground truth image where the boundary of the cells is marked in red, (c) is the extraction of the

boundaries of the individual cell from the annotated images, and (d) is the final binarization of the extracted cell boundary where cells are colored white and the background as black

components. This, therefore, reduced the above set of obtained feature set for the classification task.

Dividing training and test dataset: Every ML or DL classification model needs to be trained on a set of training, validation, and test data. The data is divided into train and test set initially as per choice. These training sets then use a k-fold cross-validation strategy. This helps to monitor the bias and variance trade-off in a classification model. A k-fold cross-validation could divide the entire dataset into k subsets where the training is done for the k-1 training set, leaving one subset as the validation set. The process is repeated for k times where every element gets to be in the train and test set, removing data biasness.

Classification using ML method: There are numerous ML classifiers available in the literature, and there is particularly no definite rule as to which model will fit your data best. The classification [55] was done using six classifiers, namely, decision tree, logistic regression, KNN, SVM, linear discriminant, and quadratic discriminant classifier. The best classifier was chosen based on the average performance of the classifier for the different sets of features tested during feature selection. A fivefold validation was used for the whole process.

Classification using the DL method: A DL classification method is trained by passing the input image into a series of convolution layers. An activation function is present in each layer to introduce nonlinearity in the features. Pooling layers are available for reducing the dimension of the input data and capturing maximum information. The DL

classification [58] was done using two transfer learning model of AlexNet and Vgg16. This model was trained on ImageNet dataset of natural images with 1000 classes. The model was trained to fit our two-class and four-class classification problems. Image patches were generated from the captured 10x images to feed as input to the network models. The input size of the images was 227×227 . The extracted features of these models were also compared using machine learning SVM classifier. The features extracted by VGG-16 showed a higher performance for the collected dataset.

Cell segmentation using ML and DL methods: Segmentation is the extraction of defined ROI without including the background information. The cell segmentation [59] was done using 8 ML segmentation algorithms and four deep learning semantic segmentation methods. The segmentation of the cells was both semantic and instance-based. Segmentation for ML was achieved using fuzzy C-means, entropy segmentation, k-means, adaptive thresholding, Otsu, HSV color space segmentation, YCbCr color space segmentation, and watershed method (Fig. 6). There is no training or test set involved for performing traditional segmentation, while for DL, we need to train the network using a training test set. The training is supervised and consists of a set of images with a targeted class. The DL segmentation method performed a two-class classification of the image intensity value by giving a probabilistic estimation value of a pixel belonging to the cytoplasm or

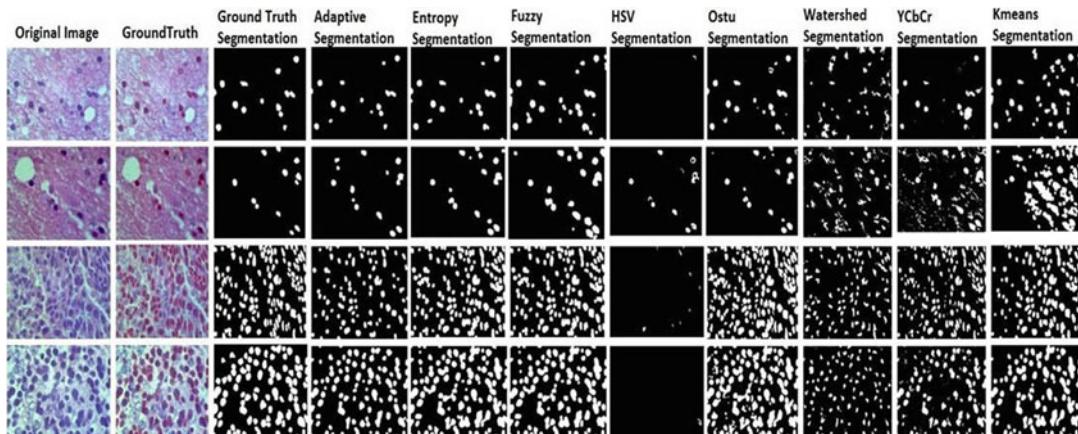

Fig. 6 Image showing the cell extraction by different segmentation methods [59]

nucleus. It consists of an encoding layer to extract valuable features from the input data, followed by a decoding layer that maps this encoded information back to the original image size. The encoding layer has a series of convolution and max pool layers for image understanding, while the decoding layer consists of convolution and up-pool layers. The training images consist of RGB images with the ground truth annotations as the targeted class image. The images were trained with an image size of 96×128 . Fractal-UNet, UNet, and SegNet are few semantic segmentation networks meant for segmentation tasks. As an output, the RGB $100 \times$ images were converted into a binary image with cells as white and the cytoplasm as black. Necessary elimination of noise was performed through morphology operation in the segmentation. Comparing the ML and DL technique of segmentation, the Fractal-UNet performed the best, while for ML methods, entropy-based segmentation performed better than all other methods.

Conclusion: The authors were, therefore, able to design an AI-based solution for the classification of CMB into the WHO grading system. A DL method depends on the architecture of the network and could be customized as per the problem and expertise of the researcher. The classification performed in the study was with a sequential DL classification network model. However, graph-based models like GoogleNet, Inception, ResNet, and DenseNet are more deep and complex and incorporate latest evaluation network architecture.

Significance of an Accurate Detection in Prognosis

Accurate detection in prognosis for medical data is highly essential not to end in under- or over-treatment. An effective prognosis can give risk-centric information to chronic syndromes [61]. The studies by [62, 63] suggest a prognosis framework for the clinicians in their decision support. An accurate biomedical diagnosis could integrate information on pathological, psychological, environmental, and behavioral factors that could channelize the treatment selection for acute

diseases. Aging factor in population is adding complexity to diagnosis and required healthcare professionals to consider numerous factors such as side effects, comorbidity, and medical interaction [64] in aged patients.

Challenges of a Clinical Observation

It is discussed that erroneous medical reports are the third-highest cause of mortality for patient care due to substandard care or poor guideline of treatment [65] [66]. has discussed a few of the important aspects of challenges faced for neurological diseases. One prime challenge discussed is the evolution of neurological disease with time, which often turns very difficult due to ambiguity at the onset and variation of defined markers that progress over time during follow-up visits. Secondly, the success of a neurological treatment is based on the early detection and intervention of the treatment. An optimized outcome is the result of an early and effective prediction and duration of treatment, which is delayed in clinical observation. Monitoring and proper follow-up of patient treatment are the next significant difficulty for an unpredictable course that requires prolonged care. Also, the diagnosis by clinician observation has variation in the treatment course and reports across various medical centers. Clinical observation is very challenging for CNS tumors and requires the experience of a neuropathologist for the appropriate report. Increase patient volume is another drawback in proper assessment under pure clinical observation. Patients from a diverse population can also have a significant complexity in the diagnosis process.

Advantages of AI-Driven Solution

An AI-driven solution can be an effective tool for precise radiological or pathological report generation. It can integrate big data information into a single decision support model for effective prediction. Moreover, an AI solution would have a faster response time than a manual testing model. It could be used to evaluate complex cases and

reports that are not possible to compute through natural intelligence. Apart from biomarkers, it would also integrate computer-based features for detection in healthcare. An AI solution could minimize Type I and Type II errors caused by manual testing. AI solutions could also be region- and application-specific and could be created with local data.

Challenges of an AI-Driven Solution

The main challenge of AI is getting access to medical data. The generation of ground truth is not possible without medical guidance and supervision. Collaboration with a medical expert is a problem as it expects dedication and time of medical collaborator, which is difficult for a medical professional to devote to such a high throughput of patients. Ethical clearance is another aspect that works as a drawback for the work, as clearance from all research collaboration needs to be acquired. The study by [67] has discussed the demerits of an AI solution. Patient data privacy and security need to be addressed for an AI solution. Training of the AI solution should be based on indigenous samples more than artificial data or benchmark dataset. Rigorous testing of the solution should be made at different clinical centers. The AI solution should be able to handle unknown problems. Overfitting of data should be handled in such applications. Equipment malfunctioning could increase surgical error, developing a single system of AI for human anatomy. Most of the study pertains to an inspection of only a single clinical task.

Scope for Industry Transformation

As stated in a market analysis [68], there is a high demand for the AI healthcare market in the world and is estimated to grow manifold by 2025. Health and economy are linked together. People in advanced countries are realizing the value of major advances in technology in healthcare with higher economic and quality of life benefits. The people in the lesser advanced countries will

benefit only if they can overcome barriers to technology implementation. Research scientists require collaboration from industries and a long time effort for the proper transition of algorithms to a product. This could lead to practical and real-life applications with proper field testing. Proper training to clinicians for the use and operation of such devices might help to mitigate such solutions [67].

Summary

The transitions of AI in neurology have already been started, as discussed in this chapter. Various studies and medical research are being made every day for refinement of prediction results and achieving a complex task. It is a fact that AI solutions could deliver better than human intelligence, and neurologist should be flexible and supportive enough to adapt to the change of AI-driven solutions. However, we could not deny that every application or innovation has its own set of disadvantages. AI will be adapted in neurology only when it will show proven results in prediction, incurring a low cost [69]. The aim of AI is never to replace medical supervision but to assist clinicians in a better understanding of their patient information. Both medical society and computer scientists should collaborate for the human good for building the transformation in neurological sciences. The transition has already started, and in a few decades, AI will soon be an integral part of a neuronal diagnosis.

Abstract

Parkinson's disease and dementia are two of the most debilitating neurodegenerative disorders to ever plague humankind. They cause significant biopsychosocial and economic burden on society and affect the community and carers in particular, necessitating holistic multidisciplinary care.

The rise of artificial intelligence for medical applications in recent years, including disease prediction, diagnostics, disease progression monitoring, risk stratification, and prognostication, has also seen the development of applications for Parkinson's disease and dementia. This chapter explores the use of artificial intelligence and machine learning in terms of the diagnosis, management, and prognosis predictions for these two neurodegenerative conditions.

We discuss the medical and the surgical applications of AI for Parkinson's disease and also highlight the artificial intelligent models that have been used for various forms of dementia. The chapter begins by introducing the reader to the impacts of AI on dementia diagnosis, treatment, and prognosis, extending the discussion to dementia with Lewy body disease before tackling specific aspects of AI related to Parkinson's disease.

Keywords

AI parkinson's disease · Dementia · Vascular dementia · Frontotemporal dementia · Deep learning · Deep brain stimulation

Introduction

Dementia, and its predominant form Alzheimer's disease, remains the commonest neurodegenerative disorder; every 3 seconds someone in the

world is diagnosed with the condition [1]. Fifty million people are affected by dementia and the incidence is doubling every 20 years, due to the global aging population [1]. This entails considerable physico-biopsychosocial morbidity with damaging wide-reaching global economic consequences [1]. The burden of the disease is not just limited to the patient, but to their family and carers as well. It presents with short-term memory impairment, language, problem-solving, and high-executive dysfunction with a subsequent decline to long-term memory and neurocognitive impairment.

In the same vein, Parkinson's disease is another progressive neurodegenerative disorder affecting over 7–10 million patients globally with debilitating phenotypic changes affecting motor and cognitive pathways in the brain [2]. A classical clinical presentation is a triad-state of tremor, bradykinesia, and rigidity. In studies investigating the accuracy of clinical diagnosis using traditional methods, Parkinson's disease was a post-mortem neuropathological diagnosis with a sensitivity and specificity of 88% and 68%, respectively [3]. There is thus an argument for improving diagnostic accuracy and disease progression monitoring.

The development and revolutionary impact of artificial intelligence and machine learning has now allowed various aspects of dementia to be managed. Various chapters within this compendium of works have highlighted a myriad of approaches using machine learning and AI to tackle medical problems and we summarize the main approaches in Fig. 1.

The first part of the chapter addresses the adoption of AI for various types of dementia while the subsequent part explores Parkinson's disease and its associated Lewy body dementia that has also gained AI integration. Finally, the facets of Parkinson's disease that have benefited from artificial intelligence are discussed.

Machine Learning Cycle

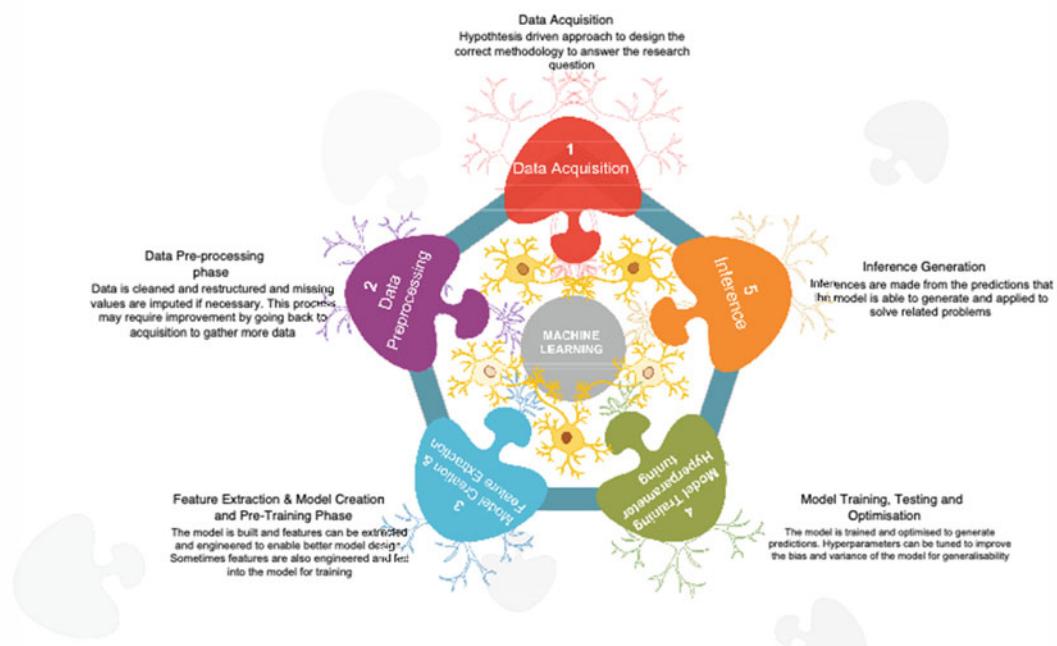

Fig. 1 A condensed variation on the machine learning cycle showing the individual aspects that are commonly used for predictive analytics

Artificial Intelligence for Dementia

Diagnosing dementia is not without its challenges. When two patients with the disease are compared, they may each present with completely different symptoms and signs of the condition including variations in their progression and treatment response. The diagnosis requires monitoring over a period of time in conjunction with imaging to correlate the clinical symptoms and signs. There are no established chemical biomarkers to aid diagnosis and as such Alzheimer's remains a clinical, neuroradiological, and post-mortem diagnosis. Computational models have been suggested to help diagnose the disease and predict its progression, and machine learning offers a chance for an unsupervised approach to feature discovery.

Results from a meta-analysis demonstrated that machine learning can be applied to neuropsychological measures with successful automatic classification as a screening tool in dementia and

as a prognostic tool identifying categories that can maximize the dementia diagnostic accuracy, thus early detection and even prevention are key [4].

AI for Dementia Diagnosis Using Big Data

Modern clinical medicine leverages impeccable detective instincts, a cooperative patient, and rapport building in a quintessential patient-doctor relationship. Dementia and its progression challenges and limits this significantly. Neurological history-taking and examination lead to the diagnosis of many neuropathological diseases, and developing approaches to augment this in dementia is therefore an area that requires considerable research investment. Attempts have also been made to incorporate machine learning in this regard. History-based Artificial Intelligent Clinical Dementia Diagnostic Systems have been

reported. In a study involving a total of 234 participants, a newly standardized and structured dementia survey was completed by members of the clinical multidisciplinary team ranging from neurologists, neuropsychiatrists, neuroradiologists, and nuclear medicine consultants [5]. The questionnaire captured brain MRI, blood tests, and neuropsychological tests as well as nuclear imaging information including Tc99m-TRODAT and Tc99m ECD SPECT. Delphi consensus style comparisons correlating history-based diagnosis of various dementia subtypes with the final diagnosis established a high degree of accuracy (76%) and identified disease severity in 86% [5].

Most machine learning algorithms rely on the need for big data to train on and make predictions. The commonest approach is usually a supervised methodology where labeled data is fed to the algorithms, which are taught to identify and learn salient properties within the data to make a prediction on diagnosis. Having a single model that is able to predict a multitude of features simultaneously is ideal, but medical datasets are often poly-dimensional and hence the single-endpoint biased predictions of the supervised approach remain suboptimal. This has led to the adoption of unsupervised artificial neural networks (ANNs) and their ability to identify latent features in a minimally biased way. ANNs offer the potential for encoding multi-modal clinical data for predictive modeling. However, clinical data is also highly sparse with missing data elements causing significant preprocessing challenges. Methods of data encoding are therefore required to overcome such limitations. However, newer methods to overcome these limitations would rely heavily on an unsupervised learning paradigm for successful implementation.

Alzheimer's disease is usually investigated using Mini Mental State Exam (MMSE) and Alzheimer's Disease Cognitive Assessment Scale (ADAS), which identify mild cognitive impairments. However, the multifactorial causes of Alzheimer's disease also contribute to its differential diagnostic heterogeneity and present a challenge for rapid diagnosis. This challenge becomes a problem that machine learning can be applied to solve. It seems reasonable that single

endpoint disease progression prediction models remain suboptimal when the disease could have variable origins and endpoints. Currently available data repositories include the Coalition Against Major Diseases (CAMD) Online Data Repository for AD (CODR-AD) [6].

Machine learning-capable mobile phone-based screening systems like DementiaTest have been built for early detection through the screening and identification of dementia phenotypes using the Diagnostic and Statistical Manual of Mental Disorders DSM V classification [7].

Frontotemporal dementia (FTD) is another area of neurodegenerative dementia affecting the frontotemporal lobe with a poor prognosis that has also seen applications in machine learning. One such work developed a reward signal-based system where an artificial intelligence algorithm (signal represented as -1 or +1) was built to retrospectively identify behavioral and language feature variants of 47 FTD patient journeys (age range 52–80) leveraging radiographic imaging and clinical time to symptom presentation [8].

Oculomics also seeks to identify early retinal changes in Alzheimer's disease. AD patients have been shown to have retinal manifestations to their disease progression with retinal amyloid plaque deposition, making it a diagnostic target and a potential biomarker to screen for in dementia [9]. As such, this has become an active area of recent scientific interest that can lend itself to potential artificial intelligence applications [9–22]. One study reported the use of highly modular machine learning techniques on UK Biobank data ($n = 52,615$; 21,547 left fundus images, and 31,041 right fundus images), utilizing methods of image quality selection and image vessel segmentation to build a classifier achieving an accuracy of 82.44 [9].

Extra-neurological and intestinal manifestations of dementia that have been considered for diagnostic biomarkers also remain a hot topic that has galvanized machine learning methods in recent decades. One such study looked at the levels of gut microbiota that were deranged because of inflammation and leveraged an unsupervised formal concept analysis model for

knowledge discovery, extraction, and management to build an AI platform for dementia diagnostics and drug discovery. It identified and implicated low-level, yet relatively abundant, fatty chain producing microbiota from the Lachnospiraceae family together with microbiota from the Enterobacteriaceae family that have previously been described as associated with AD and Parkinson's disease [23].

Conditional Restricted Boltzmann Machines in Alzheimer's Disease

Generative and energy-based models are unique unsupervised models including restricted Boltzmann machines (RBM) that draw from a sample distribution [6]. Conditional-RBMs were used by Fisher and colleagues who extracted 18-month longitudinal progression trajectories of 1909 patients with mild cognitive impairment or AD. Their unsupervised machine learning approach was conducted in two stages: (i) random synthesis of patient profiles with the same features as real patients and (ii) simulating the time-dependent evolution of these patient features [6]. The simulation aspect is a random Markov Chain Monte-Carlo-type stochastic variable prediction of the patient's disease progression that aims to capture the inherent probabilistic processes within the patient's data to forecast changes accurately. They extracted 44 covariate features including information from the individual components of the ADAS-Cog and MMSE scores, laboratory tests, and demographics. A comparison of the conditional restricted Boltzmann model with a random forest model showed similar accuracy in their results [6].

Computer Vision for Dementia Patient Video Monitoring and Analysis

Due to cognitive impairments, dementia patients are highly prone to falls. Autodetection technologies such as "SafelyYou" have been developed for fall detection [24]. In a related study, fall-prone patients were captured on 43 wall-mounted video camera systems 24 h a day, 7 days a week over a

period of 3 months in memory care facilities in the United States. The videos were reviewed on mobile device applications. The integration of computer vision is being piloted to aid the prediction of various fall contributors and thereby mitigate falls in cognitively impaired patients [25]. This presents a legal and regulatory challenge calling into question privacy and civil liberty discussions that need to be scrutinized to ensure patient safety.

AI and Assistive Robotic Technologies for Dementia

Social interaction enhances cognition in dementia patients. As such, artificially intelligent robots have been considered to augment social interaction and reduce carer burden for patients with dementia. The Care-O-Bot is a domestic mobile assistant built by the Fraunhofer Institute for Manufacturing Engineering and Automation in Germany to support activities of daily living in dementia patients. Version 4 boasts enhanced agility and a customizable modular design, and it is also economical and capable of acting as a service robot to help fetch/carry items for patients. The Care-O-Bot is also capable of evaluating a patient's mood using machine learning algorithms [1]. However, further clinical evaluation will be of interest to the scientific community.

The Robotic Assistant for Mild Cognitive Impairment Patients (RAMCIP) at home project is a European Union horizon 2020 project consisting of eight partner institutions from six countries that developed a service robot intended to aid elderly patients with mild cognitive impairment at home. This multidisciplinary process involved engaging with carers and end-users to develop the robot with the aim of monitoring for falls, medication administration, and connecting patients with family using video-conferencing [1].

Japan is leading the way in voice activated service robots and robots for dementia palliative care, such as the robotic spoon for assisting dementia patients with feeding limitations to feed themselves, and systems that aim to improve the loss of independence association with the illness [1].

Cognitive and Behavioral Biomarker, Facial Motion Assessment Using AI

The cognitive deficits in dementia range from mild depression to severe deficits, however, and symptoms may be subtle in some patients. Cognitive assessment tools such as the Montreal Cognitive Assessment have been developed and machine learning algorithms, such as logistic regression, are being used to make predictions on cognitive impairment [26].

Patients with dementia, and predominantly in Parkinson's related Lewy body dementia as discussed later, usually develop paucity of facial expression and complexion pathognomonic for neurocognitive behavioral and emotional derangements. An AI study of 121 patients presenting with cognitive impairment compared with 117 cognitively sound participants tested five deep learning models with two optimizers and built a binary classifier able to differentiate dementia from no-dementia. The facial image was expressed as a "Face AI score." The best performance was observed with the Xception model with an Adam optimizer with an overall reported respective sensitivity, specificity, accuracy, and area under the receiver operator characteristic curve of 87.31%, 94.57%, 92.56%, and 0.9717. Significant stronger correlation was also identified between Face AI score with MMSE ($r = -0.599$, $p < 0.0001$) than with chronological age ($r = 0.321$, $p < 0.0001$) [27].

Other reported approaches include using expert systems, such as SHHHH, to manage the disruptive behavioral abnormalities associated with dementia and the use of the emotional arousal and valence evaluation tasks analyzing faces for the diagnosis of cognitive impairment in dementia patients [28, 29]. One meta-analysis employing bivariate correlation and a follow-up Rutter-Gatsonis multivariate correlation HSROC curve to correct for significant correlations (47%) produced an adjusted mean specificity of 79% and sensitivity of 83% in favor of AI to diagnose for mild cognitive impairments [30].

AI-based passive radio sensing and pervasive wearable technologies have also resulted in applications for dementia in terms of monitoring

behavioral symptoms including wandering, aggression, and sleep disturbance [31, 32]. MIT's Emerald device is a low-powered radio signal emitter capable of behavioral tracking by gathering spatially mapped time-related motion data [31].

Tackling this issue from another perspective, an unsupervised nonlinear methodology using a self-organizing map was used on a multidimensional dataset to identify feature auto-clusters that helped identify the gender-determined differences in dementia diagnoses [33].

Dementia-Related Electroencephalographic Analysis and Robotic-Assisted AI

One unique study looking at the management of the neurocognitive aspects of the disease attempted to mitigate these aspects by an assessed BRAINFIT program that aims to improve the exercise ability of cognitively impaired Alzheimer's disease [34]. These patients have suboptimal exercise capability due to their cognitive deficits that lead to reduced cardiovascular fitness and cyclical independence impairment, which in turn curtails rehabilitation, making them prone to coronary artery disease insults. The team therefore developed an AI-powered robotic-assisted platform that allowed exercise training to facilitate rehabilitation and independence and reported significant reductions in EEG-discernible brain mapping of negative frontal alpha asymmetry [34]. Combined multimodality management will continue to become paramount in the management of the disease.

Deep learning and robotic microscopy were developed for dementia diagnosis to enable members of the clinical research team to monitor protein homeostasis, which led to the development of an autophagy therapeutic flux system [35]. From a multimodality imaging perspective, support vector machines extracted weight maps that were used to aid significant diagnostic performance improvements using multimodality prediction of early and late onset of Alzheimer's disease with reported accuracies of up to 96.3% [36, 37].

Vascular Dementia and AI

At the Mayo clinic, Natural Language Processing (NLP) was leveraged to reduce the heterogeneity associated with imaging reports and to examine information loss in neuroimages. It extracted information from 1000 patient CT and MRI imaging reports to identify silent brain infarcts (SBI) and white matter disease (WMD) with an acceptable interrater agreement for SBI detection, the results for the WMD and WMD grade were good ($k = 0.88$, 95% CI 0.80–0.97; $k = 0.98$, 95% CI 0.97–1.00; and Spearman = 0.985, $p < 0.001$, respectively). Patients with silent brain infarcts subsequently develop perfusion disturbance-related leukoaraiosis or small vessel and white matter disease linked to vascular dementia [38].

Convolutional Neural Nets and Model Explainability in Dementia AI Studies

Model comprehensibility and explainability remains a challenge in the field of machine learning, particularly as deep learning makes the adoption of machine learning to clinical practice difficult and problematic. The inability to identify the diagnostic pathway and thought process of a Blackbox machine learning model affects trust among healthcare professionals, which remains a problem and is a widely debated topic [39]. Circumventing this has led to the development of activation maps generated from using convolutional neural networks overlaid on volumetric scans were discussed by Marzban and colleagues [39].

Artificial Intelligence in Parkinson's Disease

Parkinson's disease (PD) characterized by tremor, bradykinesia, and gait disturbance presents a significant clinical and economic societal burden as the second most common neurodegenerative disorder in the world. A myriad of studies have looked at the pathophysiological, biochemical, and genetic determinants to derangements

associated with the dopaminergic system usually within the nigrostriatal and extrapyramidal pathways that are affected by the condition [40]. The management can either be medical or surgical, depending on the degree of neurodegeneration exhibited in the dopaminergic system and which connectivity pathways are involved, and as such careful patient selection is necessary. Several therapies have been considered and it is generally accepted, from a medical perspective, that dopamine replacement therapy can provide symptomatic treatment for a significant majority of patients for several years. The disadvantage of this is that medical therapy continues to lose its potency with increasing time as the disease progresses. The required dose increases, but the treatment benefits either remain static or usually decrease over time leading to unacceptable drug-related side effects such as motor fluctuations with significant motor and neurocognitive impairment.

Phenotypic traits in Parkinson's disease range widely from cognitive dysfunction to motor dysfunction, and in some respects autonomic dysfunction in the so-called Parkinson plus syndromes [41]. Machine learning has been suggested as an approach to aid risk stratification, patient selection, and the prediction of a variety of these effects as well as neurocognitive disease endpoints, which usually relate to Lewy body dementia. The first part of this section will therefore explore Parkinson-related Lewy body dementia and how AI is helping to diagnose and manage the disease, while the later part of this section will look at the use of artificial intelligence in various aspects of Parkinson's disease.

AI in Lewy Body Dementia

Like Alzheimer's dementia where there is pathological post-mortem identification of accumulation of amyloid plaque and Tau protein deposition in the brain, Parkinson's disease usually has an endpoint with Lewy body deposition, which also results in dementia. This section explores artificial intelligence in Parkinson's disease, but we progress our discussion from the early part of the chapter with parkinsonian

dementia and then subsequently explore the various aspects of Parkinson's disease that have benefitted from artificial intelligence methodologies. Evidence supports alpha-synuclein and amyloid beta plaque deposition in dementia associated with Parkinson's disease with three pathological subgroups [42].

Differentiating between Lewy body dementia (LBD) and Alzheimer's dementia can present significant diagnostic challenges as they have common hypometabolic profiles on single imaging modalities [43]. A metabolic reduction in the parietal association cortex in presence of preserved somatosensory and motor cortical cortex arises in both LBD and AD, meaning that ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) images fail to differentiate between them. Dysfunctional metabolic activity such as occipital hypometabolism and changes in posterior cingulate cortical activity were better discriminators, with AD demonstrating hypometabolism in the primary cingulate cortex, but normal activity in LBD. Unsupervised machine learning methodologies have been applied here and include sub-profile modeling and principal component analysis. In one such study, the authors attempted to produce spatial metabolic profiles in 50 individuals each with Lewy body dementia, Alzheimer's dementia and normal cognition to help differentiate LBD from AD through radiological profiling using modalities such as MRI, ¹⁸F-FDG-PET, and dopamine transporter (DAT) single-photon emission computed tomography (DAT-SPECT). They reported that their LBD-AD discrimination profile significantly differentiated LBD from AD with comparable accuracy to that of discriminating LBD and AD from normal individuals with an area under the curve of 93.7%, sensitivity of 94.0%, and specificity of 84.0% [43].

Other areas that have been looked at with potential artificial intelligence integration include freezing of speech deficits that can arise in LBD. Questionnaires have been designed in retrospective cohorts of 666 individuals where LBD (54.0%) showed a significantly higher frequency of positive freezing of speech (all $p < 0.001$) [44].

Motor and Gait Impairment Detection Using AI

Over two centuries after the seminal description of Parkinson's disease by Drs Parkinson, Charcot, and Gowers, we still remain limited in our current approaches to understanding the condition [41]. Categorical and periodic assessments of Parkinson's disease remain episodic and clinic based. They are also heavily reliant on patient diaries to document phenotypic abnormalities that occur during the course of the disease with specific focus on the progressively debilitating motor dysfunction. Categorizing motor dysfunction using wearable sensors appears to have gained momentum over the past decade with the aim of identifying phenotypic motor-related dysfunction and its progression [41]. This section looks at artificial intelligence in monitoring motor dysfunction in Parkinson's disease.

Bradykinesia is a key symptom of Parkinson's disease that has been studied using machine learning. DeepLabCut is a computer vision system used for the analysis of bradykinesia in the form of tapping speed assessment [45].

The NeuroQWERTY index offers a web-based visualization platform and is a recent and simple validated approach to Parkinson's diagnosis of motor impairment using the natural interaction one has with a computer keyboard within an uncontrolled and unpressured domestic setting [46]. This offers an unbiased and unpressured preliminary assessment of motor dysfunction. The approach focused on finger-keyboard interaction to assess psychomotor dysfunction and leveraged machine intelligence to algorithmically validate motor dysfunction from keyboard use. Once the algorithm is installed, the data collection occurs in the background and captures the timing information at a mean temporal resolution of 3 (SD 0.28) msec, corresponding to key press and release as well as the kinematics of any keyboard input. Analysis was then performed on an encrypted remote server only assessable by the user and software administrators to maintain privacy. A reported area under the receiver operating characteristic curve [AUC] of 0.76 and

sensitivity/specificity of 0.73/0.69 is promising and could be improved further on a larger sample size [46].

Video monitoring, as mentioned in the earlier section on Alzheimer's dementia, has been employed for parkinsonian-related motor dysfunction analysis [47]. With a train-to-test split of approximately 80:20, high-speed camera videos from 208 patients were used to train the AI algorithm to identify five motor items characteristic of the disease, such as pronation-supination, finger tapping and hand movements, and enabled screening visualization. This was assigned a performance rating score of between 0 and 4 (the higher the score, the worse the motor performance) by both the human specialist and AI algorithm. Testing was performed on 28 samples to evaluate algorithm consistency with a specialist rating score. The video-based AI rating closely correlated with specialist rating in both the main ($r = 0.862$, $p = 0.000$, Pearson's correlation) and the subscale score rating ($r = 0.537$, $p = 0.000$, Pearson's correlation) [47].

One aspect of parkinsonian diagnosis is tremor, which arises in various forms: resting tremor and action tremor; kinetic and postural forms, of which resting tremor predominates in Parkinson's disease. This is an area that has also received attention from machine learning as summarized in Table 1 below [48]. Their work utilized a naïve Bayes algorithm and also applied short-term time series Fourier transforms to a dataset of 52 Parkinson's disease patients as an approach for home monitoring of parkinsonian tremor. They used features from the Unified Parkinson's Disease Rating Scale and tested it on a cost-effective embedded microcontroller platform hosting the classification algorithm and achieved 93.8% average accuracy.

Disturbances of gait and posture characterized by shuffling and freezing are another diagnostic feature for Parkinson's disease and have been explored using machine learning algorithms [49–54]. In one study the authors described a novel Ambulosono-gait-cycle-breakdown-and-freezing-detection pattern recognition algorithm to autodetect interruptions in gait-cycle and episodic freezing [55]. Aptly named Free-D, their

AI integrates a nonlinear m-dimensional phase-space data extraction method with machine learning and Monte Carlo analysis for pattern generalization.

A summary of machine learning algorithms used for motion, tremor, and gait diagnostics by body part in Parkinson's disease is presented in Table 1.

A systematic review exploring motion and gait diagnosis for Parkinson's disease identified standard machine learning algorithms leveraging supervised learning for pattern recognition and labeled data (see reference for the in-depth review) [3]. The approaches used include electromagnetic tracking, keyboard analysis, video monitoring, inertial measurement sensing multimodal, and smartphone approaches [3, 48–54, 56–62]. Algorithms use hand-crafted features, extracted from the raw data by means of different signal processing techniques.

AI for Electroencephalographic Diagnosis and Prognostication in Parkinson's Disease

Electroencephalography (EEG) is another unconventional diagnostic modality for Parkinson's disease, but studies leveraging the analytical ability of EEG have called upon it as a use-case for AI-based diagnostics in Parkinson's disease [63]. Support vector machines and linear discriminant analysis have been compared to more advanced random forest classification with default parameterization technique. Results suggested the random forest classifier showed superior performance for prognosticating the disease with an accuracy of 77.72% [63].

AI for Parkinson's Disease Medical Management Drug Repurposing

Dopaminergic dysfunction is the culminating pathophysiological endpoint arising from nigrostriatal neurodegeneration in Parkinson's disease. As such, dopamine replacement therapy forms a cornerstone for treating Parkinson's

Table 1 Review of studies using supervised algorithms. Support Vector Machine – SVM (both linear and non-linear), Support Vector Regression – SVR, Naïve Bayes – NB, Logistic Regression – LR, Artificial Neural Network – ANN (Probabilistic Neural Network – PNN, Radial Basis Function Neural Network – RBF NN, Extreme Machine Learning – EML and Dynamic Neural Networks – DNN), k-Nearest Neighbors – kNN, Linear Discriminant Analysis – LDA, Tree-based algorithms – TREE (including Decision Trees – DT, Random Forest – RF, Random Trees – RT, Ada Boost DT, C4.5 DT, BAG

DT), Hidden Markov Models – HMM, Evolutionary algorithms (EVOL), ensembles of different algorithms(ENS). PD – Parkinson’s disease; HC – Healthy controls; UPDRS – Unified Parkinson’s disease Rating Scale; H&Y – Hoen and Yahr scale; Ac – Accuracy; Se – Sensitivity; Sp – Specificity; IMU – Inertial Measurement Unit; EM tracking – Electromagnetic tracking; FtN – Finger to nose; FT – Finger tapping; HOC – Hand opening/closing; HT – Heel tapping; SIT – Sitting; HA – Hand alternating; RT – Reaction time. Adapted from a review by Belic et al. [3, 48–54, 56–62]

Goal	Type of observed motion	Body part	Instrumentation	Subjects	Algorithm	Best performance [%]		
						Sp	Se	Ac
Diagnostic	Finger tapping	Up	EM tracking	107 PD, 49 HC	EVOL	91.8	94.6	93.5
Diagnostic	Typing	Up	Keyboard	20 PD (mild), 33 HC	ENS	97	96	
Diagnostic	Arm movements at rest, waving, and walking	Up	Smartphone	21 PD (>1 year), 21 HC	ANN	95	95	95
UPDRS scoring	FT	Up	Video	13 PD (UPDRS: 0–3)	SVM			88
UPDRS scoring	Hand tremor	Up	Smartphone	52 PD	NB			97
UPDRS scoring	FT	Up	EM tracking	107 PD, 49 HC	EVOL			≥89.7
Diagnostic	Gait	Low	Force sensor	93 PD (mild and early), 73 HC	ANN	95.89	96.77	96.38
Diagnostic	Gait, Posture	Low	Smartphone	10 PD, 10 HC	RF	97.6	98.5	98.0
Diagnostic	Gait	Low	IMU	156 PD, 424 HC	kNN			85.51
FoG detection	Gait	Low	IMU	20 PD (H&Y>2)	Linear SVM	95.6	82.2	95.4
Diagnosis	Gait	Low	Camera system & force plate	23 PD (H&Y: 2), 26 HC	RF	90	96	92.6
Classification of severity of motor disorders	Unconstrained activity	All	Multimodal	19 PD, 4 non-PD	ANN	97.1	94.9	
Assessment	FtN, FT, HOC, HT, SIT, HA	All	IMU	12 PD (H&Y: 2–3)	SVM			>95
Diagnostic	Gait, Posture, FT, RT	All	Smartphone	10 PD, 10 HC	RF	96.9	96.2	
Diagnostic (PD – H&Y I)	Gait	All	IMU	27 PD (H&Y:1–3), 27 HC	SVM			94.5

disease and Levodopa (L-DOPA) remains the main anti-parkinsonian drug of choice for clinicians. L-Dopa is not without side effects, which range from daytime somnolence and episodes of sudden sleep onset (a significant side effect for drivers who must notify the licensing authority), dyskinesias, involuntary movements, and mental disturbances (usually psychosis), due to influx of dopamine into a recalibrated brain region that is used to less dopamine [2]. This list of side effects is non-exhaustive, but one drug side effect that has been looked at for drug repurposing is L-Dopa-induced dyskinesias. There are very limited medication options to counteract this including memantine and amantadine, which also have their own side effect profiles [2]. This undoubtedly increases the issue of polypharmacy. Notwithstanding the fact that patient medications may have multiple interactions with other bioactive substances that they may already be taking. As a consequence, different methods have been considered to identify other drugs that reduce the side effect burden and interactions, and to identify newer formulations that can be repurposed for L-DOPA-induced dyskinesia. In the United States, the Orphan Drug Act facilitates the granting of special status to previously available drugs for the treatment of rare disease. In silico screening approaches using AI for novel drug re-discovery and repurposing have gained momentum with an example case study being a machine learning approach leveraging natural language processing. One online repurposing tool is Project Rephetio – a browser-based direct drug repurposing tool. Another is IBM Watson, which is used for semantic similarity ranking and has been applied to help solve this problem. For an in-depth review, the reader is directed to Johnson et al. and others [2, 64].

AI for Parkinson's Disease Surgical Management

Deep brain stimulation (DBS) is a brilliant twentieth-century translational breakthrough pioneered by Banabid et al. who identified that

reversible and high-frequency simulation is akin to ablating connectivity rich basal ganglia nuclei. The effects in some circumstances were superior to ablative parkinsonian neurosurgery [65, 66].

Advances in DBS aim to counteract the deleterious symptomatic effects of progressive motor, neurocognitive, and connectivity-related dysfunction associated with the condition [67]. DBS works using precise multimodality-linked and image-guided electrode placement into intrinsic basal ganglia structures like the subthalamic nucleus, globus pallidus internus, and thalamic nuclei. Stimulating these structures enables symptomatic improvement by modulating the well-organized and distributed eloquent brain networks and anatomical tracts that encompass the motor-cognitive pathways. These electrodes are connected to a pulse-originator with a pacemaker-like activity.

The resulting post-procedural-related quality of life is usually very good to excellent. However, it is still not without risks and complications, which include electrode fracture and malfunction, infection, electrode mal-positioning, hemorrhagic strokes, seizures, etc. [68, 69]. The subthalamic nuclei, being the most approached area for DBS electrode placement, are also not without risks and side effects such as speech impairment [68–70]. The challenge is that a lot of these impairments are highly variable, and usually patient and condition dependent. It is challenging to predict which patient with speech, motor, or neurocognitive dysfunction (or a combination of these) would benefit from surgery. Current ongoing work around the world and in the UK at the National Hospital for Neurology and Neurosurgery is investigating the use of artificial intelligence and machine learning for risk stratification.

DBS electrode placement requires precision and skill for optimal intraoperative placement. Analysis of multichannel electrode recorded (MER) signals in the STN can help the multi-disciplinary operative team to identify the optimal location for lead placement. Algorithms that have been used here include support vector machines necessary for resolving taxonomy and improved

pattern recognition of deep subcortical structures such as the basal ganglia and zona incerta and thalamic nuclei. In a six-patient cohort with UKPDS of less than 6 years and a H&Y score of <4, surgical planning was achieved with a five-channel MRI frame-link and STN-recorded MER from +10 mm target to -10 mm. A 99% accuracy was reported [71].

Ethical and Social Implications of AI for Parkinson's and Dementia

Ethico-legal concerns regarding AI have been mentioned with respect to a loss of privacy and civil liberty due to computer vision and video monitoring, loss of employment, problems of cybersecurity, and data protection, as well as the potential for misuse and the need to prevent harm. Another issue relates to the ethical implications of using robots to replace carers and the interactions between robots and patients, as potential safety concerns could arise from these interactions. Moreover, there is the question of who is legally responsible if an error occurs with the robot or AI agent [72].

Future In Vivo Detection and Management of Dementia and Parkinson's Using Quantum AI Systems

The enhanced imaging resolution for diagnosing brain disease has come a long way since the early twentieth century. MRI and its variants, SPECT and PET, have all gained respective adoption in aiding the diagnosis and management of neurodegenerative and neurocognitive disease burden. However, we are still yet to gain optimal control over how we manage these conditions. Perhaps there are other salient factors and other discoveries still to be made and this can only happen through augmented approaches that allow manipulation of matter on a quantum scale. To achieve this, better imaging resolution and systems to control matter at such scales need to be designed, built, and tested for clinical

safety and effectiveness and other out-of-the-box approaches need to be considered and developed.

This area will benefit greatly from current and ongoing advances in quantum machine learning, particularly for phenotypic and disease-specific biomarker diagnostic discovery, disease progression monitoring and prediction, with the objective of curative drug discovery and also curative surgical approaches. There is evidence that in dementia, for instance, plaque accumulation has consequent neurocognitive repercussions arising from damaging neurons, which both medical and surgical advances can help to manage in future. Preventing this process may be crucial in delaying disease onset or could potentially stop patients from developing the disease in the first place. Currently, however, medical treatment does not completely solve the problem and surgical treatment is usually reserved for cases where medical treatment options have been exhausted. As DBS continues to evolve with nanoelectrodes, other new areas that may arise include quantum surgery for neurocognitive re-calibration, Lewy body removal surgery, or precision robotic micro/nano-biotechnological ubiquitin proteosome repair using tele-platforms. Controversy surrounds whether or not plaques are implicated in cognitive dysfunction [73]. However, to see pre-mortem plaques and plot the pathological course, more evolved multimodality imaging methods will also need to be developed for dynamic surgical imaging [35, 36]. The management of neurological data to integrate connectomic aspects will also evolve to be at the medic's fingertips, and this is an area where quantum machine learning will become crucial. Pervasive devices that warn of impending danger to the cognitively impaired, robotics, etc. seem more reachable than cybernetics and cognitive transfer, but it does not mean developments will not be made in these areas. The coming decades will be exciting for dementia and Parkinson's disease management and neurological disease as a whole, and the use of artificial intelligence for both medical and surgical management will lead to significantly improved patient outcomes and economic benefits for our society.

Abstract

Amyotrophic lateral sclerosis (ALS) is a relentlessly progressive neurodegenerative disease of motor neurons with substantial heterogeneity in its clinical presentation. Survival ranges from

3 to 5 years after symptom onset depending on genetic, geographic, and phenotypic factors. Despite tireless research efforts, the cause of ALS remains unknown, and therapy development efforts are confounded by the lack of accurate prognosis markers. Artificial intelligence (AI) with machine learning (ML) methods offers unprecedented opportunities to construct accurate prognosis and diagnostic models. Pooled Resource Open-Access ALS Clinical Trials (PRO-ACT) dataset is the largest public ALS clinical trial data that various researches were accomplished on this framework with ML approach. In this chapter, we study the causal analysis of ALS with AI perspective, and also ML methods for predicting the evolution of ALS will be explained on the PRO-ACT dataset. This study reveals that AI-based longitudinal study of ALS by

Introduction

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease with predominant motor system involvement. The incidence of ALS in Europe varies between 2 and 3 cases per 100,000 individuals [1], and its prevalence is between 5 and 8 cases per 100,000 [2]. With the ever-increasing interest in artificial intelligence (AI), a large number of research papers have been recently published using machine learning (ML) techniques and predictive modeling in ALS [3, 4]. Because of the heterogeneity in ALS, the clinical progression of the disease has been difficult to assess; consequently, developing an appropriate treatment for ALS becomes challenging. The progression of ALS is generally measured by the ALS Functional Rating Scale-Revised (ALSFRS-R), which consists of 12 functional items [5]. The rate of ALS progression varies in patients and finally leads to death after about 3 years; however, various parameters, such as age of onset, clinical phenotype, geographic factors, and genetics, strongly influence survival time of the ALS patients [6]. Genetic profile of ALS provides an important layer of heterogeneity. However, specific genotype such as mutations of four genes – *C9ORF72*, *TARDBP*, *SOD1*, and *FUS* – have been associated with clinical presentation of ALS [7].

Study of clinical longitudinal dataset of the ALS with AI approach could shed new insight on the biology of its causation. Providing accurate prediction and survival estimates in ALS is challenging, because they are influenced by a wide range of demographic, genetic, and clinical factors. Typical stratifications of ALS patients

include *sporadic* vs. *familial*, *bulbar* vs. *spinal*, and *ALS-FTD* vs. *ALS* with no cognitive impairment [8]. Forecasting ALS progression is commonly based on statistical approaches and ML models. Most prognostic models have used clinical features to predict the disease progression, but recent studies enriched the clinical data with imaging measures [9, 10]. Prediction of ALS progression is typically addressed either by a classification or by a regression problem based on functional decline of the disease which is determined by the ALSFRS-R score. The Neurological Clinical Research Institute (NCRI) at Massachusetts General Hospital (MGH) constructed a Pooled Resource Open-Access ALS Clinical Trials (PRO-ACT) clinical trial database that enables greater understanding of the phenotype and biology of ALS [11]. There are various studies which proposed prognosis models based on PRO-ACT data on the basis of ML methods [12–18]. In this chapter, we will study the causal analysis of ALS disease based on longitudinal study of PRO-ACT dataset, and the prognosis modeling of ALS will be explained in order to predict disease progression from an AI perspective.

Review

ALS is a fatal neurodegenerative disorder with heterogeneity in its clinical presentation that is specified by the progressive impairment of motor functions including speech, swallowing, limb, and respiration [7]. ALS is characterized by the degeneration of both upper motor neurons (from the cortex to the brainstem and the spinal cord) and lower motor neurons (from the brainstem or spinal cord to muscle) [1]. The cause of ALS is unknown, although in 10% of individuals, ALS is caused by genetic defects in more than 30 genes [6, 19]. Because of heterogeneity in the ALS behavior, the prediction of disease progression is a challenging task. The progression of ALS is most commonly assessed by the ALS Functional Rating Scale (ALSFRS) that contains 10 functional items, and the new revised version of ALSFRS, namely, ALSFRS-R, includes 12 functional items: *speech*, *salivation*, *swallowing*,

handwriting, cutting food, dressing and hygiene, turning in bed, walking, climbing stairs, dyspnea, orthopnea, and respiratory insufficiency [5, 20].

The scores of all 12 items range between 0 (worst) and 4 (best); therefore, the overall value of ALSFRS ranges between 0 and 40, and ALSFRS-R ranges between 0 and 48.

Study of clinical datasets of the ALS with AI approach can help neuroscientists for better understanding the behavior of the disease. The disease course ranges from under a year to over 10 years, and the patients usually die between 3 and 5 years from disease onset [21]. The more heterogeneous the disease, the more difficult to predict its progression, and thereby to study the effect of a potential therapy will be a challenging task. Using a large clinical longitudinal dataset of patients with machine learning and computational methods could be a suitable approach to address the variability of ALS disease progression. This approach has been successfully applied for understanding complex diseases such as multiple sclerosis (MS), Alzheimer's, and Parkinson's [22, 23].

Clinical Trial Analysis of ALS Disease

Analyzing the behavior of a disease on a clinical trial dataset with the help of machine learning algorithms could open a door to new insights into the disease mechanisms. Prize4Life and Neurological Clinical Research Institute at Massachusetts General Hospital created the PRO-ACT dataset that includes information from over 10,000 ALS patients [11]. This dataset consists of more than 10 million longitudinally collected data points which include demographic, family histories, and clinical and laboratory data. In a crowdsourcing analysis of ALS on the PRO-ACT dataset, 3 months of trial information of the patients were given to the solvers in order to predict the disease progression over the subsequent 9 months [18]. In this challenge, the solvers used 12 months of longitudinal data for training their algorithm, and then their algorithm was evaluated on a separate test dataset not available for the training of the algorithm. The progression rate of the disease is assessed by the slope of ALSFRS

changes which is defined as Eq. 1, where m_{first} and m_{last} indicate the first and last month of prediction, respectively:

$$\text{Slope} = \frac{\text{ALSF}RS(m_{\text{last}}) - \text{ALSF}RS(m_{\text{first}})}{m_{\text{last}} - m_{\text{first}}} \quad (1)$$

The performance of methods in this challenge was measured by root-mean-square deviation (RMSD) of the predicted ALSFRS slope. The best method in this study was Bayesian tree with RMSD value of 0.544, and linear regression had the largest RMSD value of 1.30. Some features such as time from onset, age, forced vital capacity (FVC), site of onset, gender, weight, and uric acid concentration in blood have been formerly reported to predict ALS progression. This study revealed that three features – *phosphorus*, *creatinine*, and *pulse* – can be considered as predictive features to predict ALS progression which were not previously reported. Specifically, the study showed a high correlation between changes in creatinine and ALSFRS score in patients.

The great variability in ALS progression hinders to specify the effect of a given treatment, increasing the cost of clinical trials. The ability to more precisely predict the disease progression would reduce the number of patients needed for identifying the effect of a potential disease-modifying therapy. The amount of trial size reduction by using two best algorithms of this challenge was up to 20.4%, with a significant reduction in cost [18].

PRO-ACT Dataset

The PRO-ACT platform is the largest clinical longitudinal dataset, which has provided an opportunity to the study of the ALS disease with data mining and machine learning tools [24]. This dataset includes temporal clinical information from over 10,000 ALS patients, which has been collected regularly for every patient. This dataset includes the databases of 17 different clinical studies with an average duration of 12 months over the last 20 years

between 1990 and 2010 performed in ALS. The PRO-ACT dataset consists of 86 dynamic features which change over time, and the progression of the disease in each time point is assessed by ALSFRS score. The information of the patients in the dataset are divided into 13 files: adverse events, ALSFRS, subject ALS history, concomitant medication use, death report, demographics, family history, forced vital capacity (FVC), laboratory data, Riluzole use, slow vital capacity (SVC), treatment group, and vital sign. As shown in Table 1, all dynamic features of the PRO-ACT dataset are classified into 16 classes so that each class includes 1 or more features. Average values of baseline characteristics of individuals are summarized in Table 2.

Table 1 All dynamic features of the PRO-ACT dataset categorized into 16 classes in which every class contains 1 or more features

Classes	Number of features	Features names
Vital signs	6	<i>Pulse, respiratory rate, temperature, weight, blood pressure diastolic (BPD), blood pressure systolic</i>
Forced vital capacity	1	<i>FVC</i>
Slow vital capacity	1	<i>SVC</i>
Urine	17	<i>PH, protein, specific gravity, glucose, WBC, leukocyte esterase, blood, RBC, casts, ketones, appearance, color, bacteria, mucus, albumin, uric acid crystals, calcium oxalate crystals</i>
Blood proteins	2	<i>Albumin, protein</i>
Electrolytes	6	<i>Sodium, potassium, bicarbonate, chloride, anion gap, magnesium</i>
Kidney tests	3	<i>Blood urea nitrogen, uric acid, creatinine</i>
Liver tests	5	<i>ALP, ALT, GGT, AST, bilirubin total</i>
Complete blood count	20	<i>WBC, neutrophils, absolute neutrophil count, band neutrophils, absolute band neutrophil count, lymphocytes, absolute lymphocyte count, monocytes, absolute monocyte count (AMC), eosinophils, absolute eosinophil count (AEC), basophils, absolute basophil count, RBC, hemoglobin, hematocrit, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, mean corpuscular volume, platelets</i>
Heart disease	4	<i>CK, triglycerides, total cholesterol, lactate dehydrogenase</i>
Blood sugar	2	<i>Glucose, HbA1c</i>
Mineral balance	2	<i>Calcium, phosphorus</i>
Immune response	8	<i>Immunoglobulin A, immunoglobulin G, immunoglobulin M, gamma globulin, alpha 1 globulin, alpha 2 globulin, beta globulin, albumin globulin ratio</i>
Hormones	4	<i>TSH, free T3, free T4, beta HCG</i>
Coagulation measures	2	<i>Prothrombin time, international normalized ratio (INR)</i>
Amylase	3	<i>Amylase, salivary amylase, pancreatic amylase</i>

Study of ALS with Machine Learning Approach

Machine learning is a rapidly evolving branch of AI and applied mathematics which aims to develop computer software that can learn autonomously. Machine learning encompasses two main approaches: *supervised* and *unsupervised* learning. The goal of unsupervised learning is to construct a model that describes the data in the absence of output, but supervised learning focuses on mapping inputs with outputs using training samples [25]. Classification task in ALS is to link clinical features, pathological characteristics, etc. to diagnostic classes of the disease such as “ALS” or “healthy” [4, 26, 27]. Regression methods aim to infer a real-valued function from

Table 2 Baseline characteristics of the PRO-ACT dataset and their average values

Characteristics	Mean \pm SD
Age (year)	56.2 \pm 11.8
Percentage of females	40
Percentage of white	94.9
Disease duration (month)	23 \pm 17
Time from symptom onset to diagnosis (month)	11.6 \pm 9.2
Site of onset, percentage of limb onset	76
Vital capacity, percentage of predicted normal	86 \pm 24
ALSFRS score	29.59 \pm 5.84
ALSFRS-R score	38.37 \pm 5.22
Body mass index at baseline	25.4 \pm 4.4
Percentage of Riluzole use	77.5

input data, which, in the context of ALS, could be used for predicting the progression of ALS based on clinical observations [28, 29]. Regression task can design a prognosis model from longitudinal data/set of ALS that is able to predict motor decline on the basis of clinical characteristics.

Causal discovery of diseases is a suitable approach for improving the design of clinical trials, finding new therapies, and establishing a prognosis model of such illnesses, and probabilistic causality is a common method for diagnosis and prognosis in biomedical applications. In general, the cause of ALS is unknown; however, in 10% of cases, ALS is caused by a genetic defect [19]. Discovering causal factors of ALS helps physicians to find new therapies and to establish a prognosis model for the disease. Since ALS is a chronic disorder with a heterogeneous clinical course, understanding the behavior of the disease and predicting its progression is a challenging task for neuroscientists.

In a study, the authors introduced a novel learning model named PCDSD (probabilistic causal discovery in sequential dataset) for constructing a causal graph from sequential dataset (Fig. 1). They applied the PCDSD model to the PRO-ACT longitudinal dataset for predicting the progression of ALS disease [16]. In this project, a longitudinal dataset $S = \{s_1, s_2, \dots, s_N\}$ of ALS patients from PRO-ACT dataset with n-dimensional feature space $F = \{f_1, f_2, \dots, f_n\}$ is given to the model.

Every patient s_i from S contains the clinical trial information of the corresponding patient in k consecutive time points in the form of $e_{i1}, e_{i2}, \dots, e_{ik}$.

Each event e_{ij} indicates the state of the patient s_i at time point t_j that includes the values of all 86 dynamic features of Table 1 and the value of ALSFRS score that shows the progression of the disease at time point t_j . First, the values of all features changes at all consecutive events for all patients are calculated; for every patient s_i at time point t_j , the change value of feature f_l is specified relative to its value at time point t_{j-1} as Δf_l^{ij} , and if the change value Δf_l^{ij} is greater than a threshold value τ_{f_l} , then the feature f_l is considered as a modified feature in event e_{ij} . We define Ω_{ij} as a set of all modified features for patient s_i at time point t_j according to the following definition:

$$\Omega_{ij} = \{ f_l \in F | \Delta f_l^{ij} > \tau_{f_l} \text{ in sequences}_i \text{ at time point } t_j \} \quad (2)$$

In the next step, the causal features dependency (CFD) matrix M of the PRO-ACT dataset with dimension $n \times n$ is created on the basis of Ω sets of the whole patients in all time points. Every matrix index $m_{c,e}$ of M consists of the change values Δf_c of cause feature f_c and the change values Δf_e of effect feature f_e , which indicates the probabilistic causal edge $f_c \rightarrow f_e$ with conditional probability $P(\Delta f_e | \Delta f_c)$. Therefore, the rows and columns of matrix M show the cause and effect features of the causal edges, respectively. Then, the conditional probability density (CPD) function $Z(f_c, f_e, d_{ce})$ is estimated for every causal edge $f_c \rightarrow f_e$ corresponding to the matrix index $m_{c,e}$ by kernel density estimation (KDE) method, where d_{ce} is the density value at point $(\Delta f_c, \Delta f_e)$. Here, we have n^2 density functions which their causal tendency (CT) should be determined according to Eq. 3:

$$CT_{(f_c \rightarrow f_e)} = \log \frac{p(\Delta f_e | \Delta f_c)}{p(\Delta f_e | \Delta f_c)} \quad (3)$$

The higher the value of the causal tendency, the more degree of certainty of the corresponding causal relationship. The numerator in Eq. 3

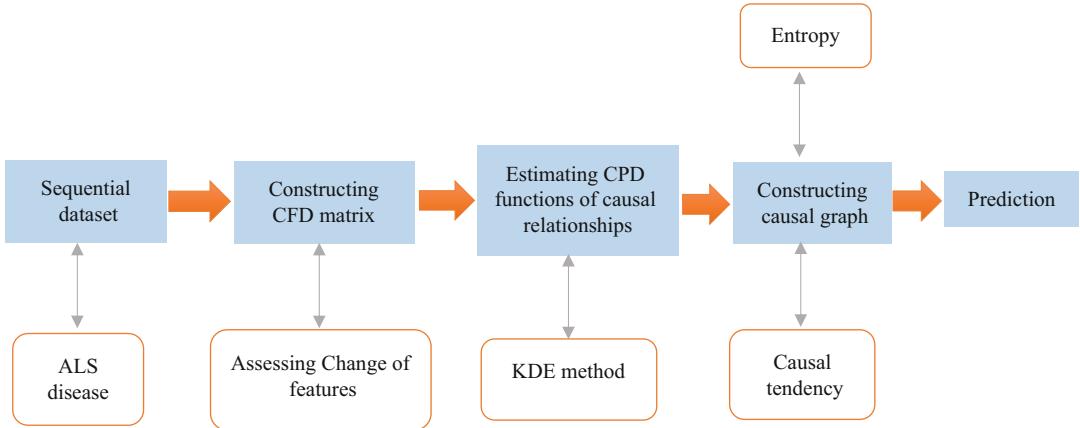

Fig. 1 Diagram of the PCDSD model for causal analysis of ALS disease on the PRO-ACT dataset

indicates the probability of changing in cause feature f_c that leads to the changes of effect feature f_e , and the denominator is the probability of changes of feature f_c which did not cause to changes of feature f_e (Eqs. 4 and 5):

$$P(\Delta f_e | \Delta f_c) \equiv \forall_{p \in \text{sequences}} \forall_{q \in \text{time points}} \quad (4)$$

$$(f_c \in \Omega_{pq} \wedge f_e \in \Omega_{p,q+1})$$

$$P(\Delta \bar{f}_e | \Delta f_c) \equiv \forall_{p \in \text{sequences}} \forall_{q \in \text{time points}} \quad (5)$$

$$(f_c \in \Omega_{pq} \wedge f_e \notin \Omega_{p,q+1})$$

In the next step, the degree of uncertainty for every CPD function $Z(f_c, f_e, d_{ce})$ corresponding to the causal edge $f_c \rightarrow f_e$ is determined by Shannon entropy measure according to the following formula [30]:

$$H_{(f_c \rightarrow f_e)} = \sum_{(\Delta f_c, \Delta f_e) \in Z} -p_{ce} \log p_{ce} \quad (6)$$

where p_{ce} indicates the conditional probability $P(\Delta f_e | \Delta f_c)$ at the corresponding point of density function. Density functions with the low entropy values show that the corresponding causal edge has a high degree of certainty so that the function has a high-density value in a small area of points. Only causal edges with the causal tendency greater than threshold value δ and entropy value less than threshold value ε are selected for constructing the causal graph G . The graph G contains different paths called *causal chains*,

and therefore every path of the causal graph could be a potential causal chain. A probabilistic causal chain $f_1 \rightarrow f_2 \rightarrow f_3 \rightarrow f_4 \rightarrow \dots$ indicates the causal dependencies between consecutive features in which every change of feature f_i leads to the change in feature f_{i+1} with high probability.

We could pursue the progression of ALS disease by tracking its features changes with the help of the set of causal chains Π . In general, searching all paths of a causal graph in order to extract most probable causal chains is an impractical task, because this procedure has exponential running time on the number of graph nodes. However, reducing the size of search space by a suitable heuristic could improve the time complexity of the algorithm significantly. In the worst case, discovering the set of most probable causal chains in a causal graph with n nodes has a time complexity of $O(n!)$, because the number of permutations of k nodes for constructing a causal chain with the length of k is $k!$, and hence the running time of the algorithm, $T(n)$, is calculated as follows:

$$T(n) = \sum_{k=1}^n k! = 1! + 2! + \dots + n! = O(n!) \quad (7)$$

In a study, the authors introduced a novel heuristic for discovering the set of most probable causal chains from a causal graph, which has a polynomial time complexity on the number of graph nodes [17]. The proposed algorithm is

based on row- and column-major processing of the CFD matrix on the causal graph G . In the *row-major* approach, the matrix M is processed row to row in order to create the causal chain until reaching to a repeated feature (row). Actually, in this approach, we move forward across causal chains in the causal graph from cause features to effect features, and the causal chains are constructed from beginning to the end (Fig. 2). In the *column-major* approach, the matrix M is processed column to column for creating causal chains until reaching to a repeated feature (column). Therefore, in this approach, we move backward across causal chains in G from effect features to cause features, and the causal chains will be created reversely from end to the beginning (Fig. 3).

Selection of the causal edges is carried out based on the causal tendency-entropy ratio ($CTER$) measure. $CTER$ is a quantity that combines both causal

tendency and entropy measures which is obtained by the following definition:

$$CTER_{(f_c \rightarrow f_e)} = \frac{CT_{(f_c \rightarrow f_e)}}{H_{(f_c \rightarrow f_e)}} \quad (8)$$

Large values of $CTER$ reveal that corresponding causal edge has more accuracy and certainty, because the large value of CT and small value of entropy indicate the high confidence level of the corresponding causal edge.

Experimental Results

In this section, the PCDSD model is applied to the PRO-ACT dataset related to ALS disease in order to discover the causal relationships between disease factors. In the training phase, trial information of the patients is given to the proposed

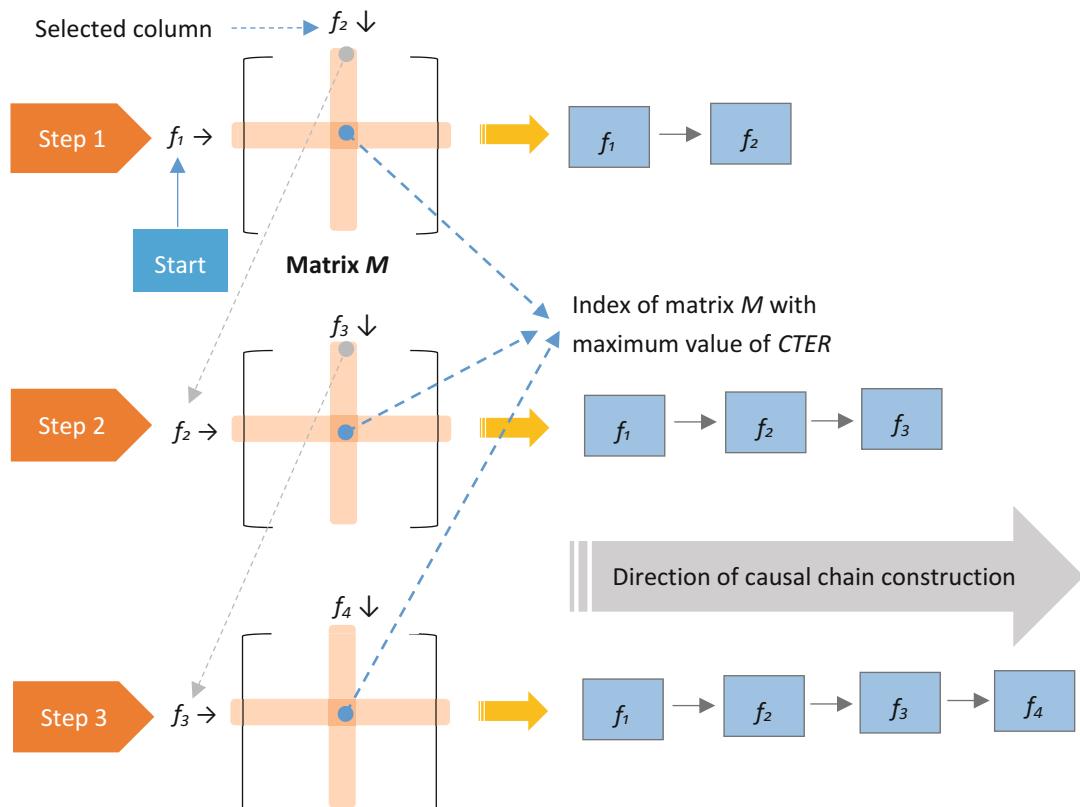

Fig. 2 The process of constructing a causal chain with the length of 4 by row-major approach

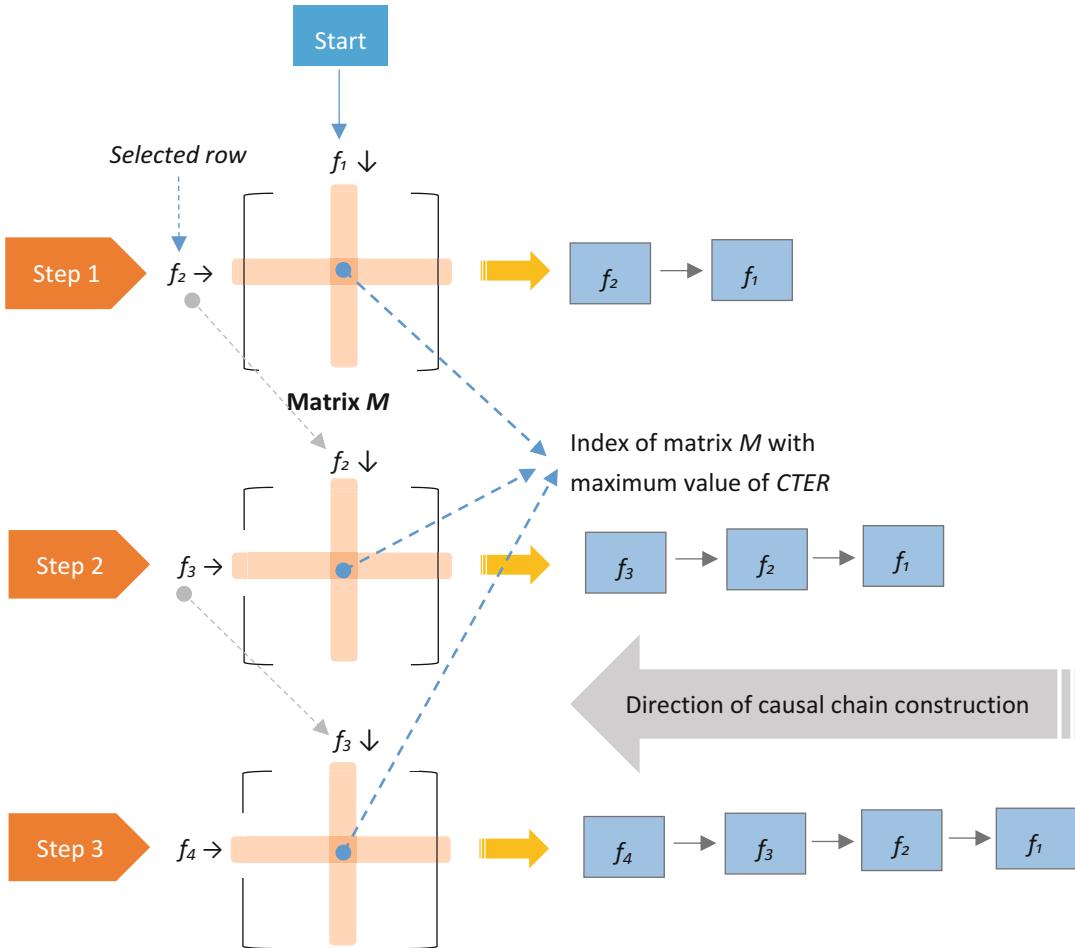

Fig. 3 The process of constructing a causal chain with the length of 4 by column-major approach

method, and after constructing the probabilistic causal graph G , the set of most probable causal chains Π from graph G is extracted. In the PRO-ACT dataset, almost 6000 cases among all 10,000 individuals have non-empty clinical trial information of dynamic features. We used 5000 of the cases for training and 1000 of them for testing the model. In this project, the causal tendency threshold δ and entropy threshold ε are set with the values 0.6 and 4, respectively. Since there are 86 dynamic variables in the PRO-ACT dataset, the dimension of CFD matrix M is $[86 \times 86]$.

The causal graph of ALS has 18 nodes and 25 edges which is demonstrated in Fig. 4. Here, we have 79% of dimension reduction in the size of feature space, because only 18 features from all

86 dynamic features are causal features. Moreover, there are $86 \times 86 = 7396$ potential causal edges wherein only 25 causal edges were selected in the causal graph, and hence, 99.7% of the causal edges were excluded in the causal graph.

The characteristics of all causal edges in the causal graph of Fig. 4 are illustrated in Table 3. The proposed algorithm discovered seven causal chains based on the row-major processing, and all of these causal chains were highlighted with thick arcs in the causal graph of Fig. 4. The proposed algorithm could not find any causal chain based on the column-major approach with a minimum length of three features.

After construction of the causal graph, in the test phase, 3 months' clinical information of 1000

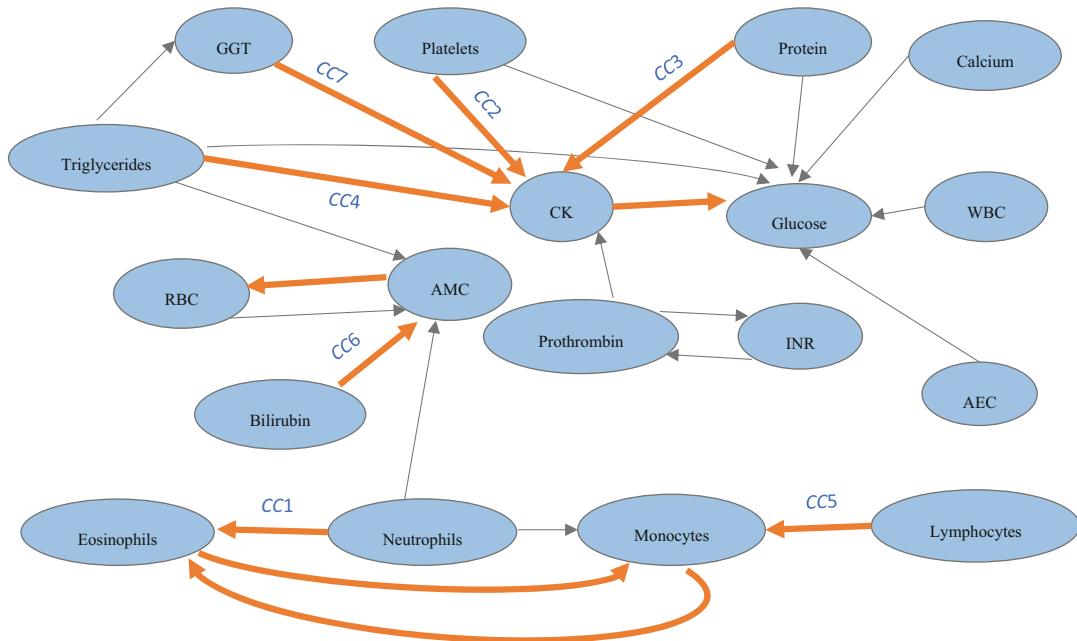

Fig. 4 The causal graph of ALS disease resulted from PCDSD model on the PRO-ACT dataset. The graph includes 18 nodes and 25 edges; most probable causal

chains of the causal graph (CC1 to CC7) are highlighted with orange thick arcs

patients are given to the model, which had not given to the algorithm previously; and the model was expected to predict the rate of ALS progression in the next 9 months (from month 4 to month 12) based on the causal graph G and causal chains Π . Diagram of the average error of ALSFRS prediction in the test patients on the basis of causal graph and causal chains is demonstrated in Fig. 5.

In order to compare the results of the PCDSD model with machine learning algorithms, the slope of ALSFRS for patients is defined as Eq. 1. Slope of ALS patients indicates the rate of ALSFRS value from the first month (m_{first}) to the last month (m_{last}) of prediction [18]. If the value of *slope* was negative, it means that the value of ALSFRS at the beginning of the trial is larger than its value at the end of the trial, and hence because of the progressive nature of ALS disease, the slope value of the patients is often negative:

The root-mean-square error (RMSE) of slope prediction for the PCDSD model and similar methods is shown in Table 4. The results show that Bayesian tree, random forest, and support vector regression outperformed the PCDSD

model. In addition, the PCDSD model (based on causal graph and causal chains) outperformed linear and multivariate regression methods with lower RMSE values.

Conclusion

The AI approach, especially ML methods, has been increasingly used in ALS causation for building diagnostic and prognostic modeling. Current ALS prognostic models rely on clinical features and laboratory tests which might not be sufficient to estimate progression rate, death risk, or survival in patients; they should account for disease heterogeneity rather than solely on the use of ALSFRS-R score to provide more accurate predictions. Study of ALS disease on the PRO-ACT framework as the largest clinical trial dataset of ALS indicates that longitudinal study of the disease with ML methods plays a pivotal role in identifying ALS causation, treatment, and individualized patient care. Discovering causal relationship between factors related to ALS with a

probabilistic approach could bring us closer to the origin of the disease. By knowing causal relations between biological and clinical factors of ALS, neuroscientists would be able to have better understanding of the disease in order to reduce the disease progression rate. Population-based epidemiological studies of ALS show that incidence of patients varies in different countries so that the incidence of ALS in countries with different ancestral population is lower than countries with homogenous population [2, 31, 32]. Since PRO-ACT is US-based dataset of ALS, based on

heterogeneity and epidemiological analyses of ALS disease, the findings from the PRO-ACT dataset could not be generalized to whole ALS population in the world. Thus, a comprehensive dataset with admixed population all over the world is required to fully understand the ALS evolution.

Abstract

Ménière's disease (MD) is difficult to diagnose objectively and evaluate the treatment outcomes. Although pure tone audiometry is the only objective test included in the diagnostic criteria, inner ear MRI technique, which was recently developed to visualize endolymphatic hydrops (EH), is useful for the diagnosis of MD. However, analyzing methods are reported

to be diverse, and sometimes, they are time-consuming and complicated. In recent years, the rapidly developing field of artificial intelligence (AI) showed outstanding performance in image recognition. In particular, convolutional neural network (CNN) based on deep learning plays a remarkable role in today's medical field, where imaging analysis is critical. We developed a CNN-based deep learning model called INHEARIT (INner ear Hydrops Estimation via ARtificial InTelligence) for automatic calculation of EH ratio in a segmented region of the cochlea and vestibule. The model can generate results that are highly consistent with those generated by manual calculation more

Introduction

Ménière's disease (MD) is a multifactorial disorder with typical symptoms of recurrent attacks of vertigo, fluctuating hearing loss, tinnitus, and sensations of ear fullness. Endolymphatic hydrops (EH) is a histologic hallmark of MD in which the endolymphatic spaces in the cochlea and vestibule are distended [1]. According to a 1995 consensus statement from the Committee on Hearing and Equilibrium of the American Academy of Otolaryngology-Head and Neck Surgery (AAO-HNS), “certain” MD can be confirmed only by the histological demonstration of EH in postmortem temporal bone specimens [2]. Therefore in 2015, a committee of the Bárány Society revised the diagnostic criteria to remove the concept of “certain MD” [3] (Table 1).

According to the diagnostic criteria, pure tone audiometry (PTA) is the only objective test used to diagnose a “definite” or “probable” MD. Other measures, such as electrocochleography (EcoG) and vestibular evoked myogenic potential (VEMP), have been used as adjunctive diagnostic tools for more than 30 years [4] as it is impossible to visualize EH but only estimate [5]. However, it is occasionally challenging to diagnose MD using only patients' symptoms.

With the advancement of imaging technology, EH can be visualized by MRI as an objective marker in patients with MD [6]. Many studies have been published regarding EH visualized by intratympanic or intravenous injection of a contrast media in MRI. However, these studies used

various methods for analysis, and sometimes, quantitative analysis takes considerable time and effort to calculate the correct hydrops ratio.

In recent years, with the remarkable development of deep learning, artificial intelligence (AI), including machine learning, is widely used in various fields of medical science [7]. Among them, image analysis using a convolutional neural network is rapidly growing [8]. This can be of great help for an automatic evaluation of EH in patients with MD using inner ear MRI. This chapter will describe the role of AI in inner ear MRI which was recently applied for diagnosing MD.

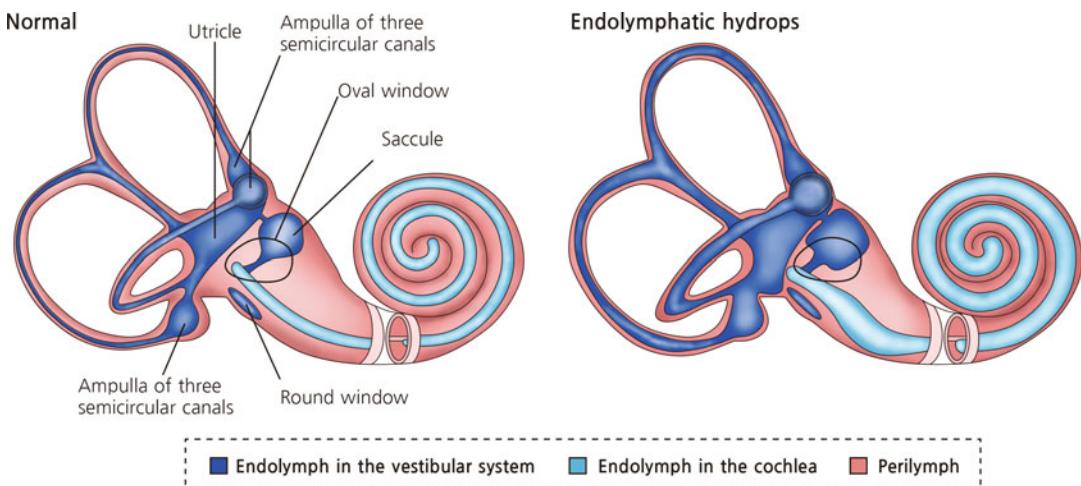

Overview of Ménière's Disease

Ménière's disease (MD) is named after a French doctor, Prosper Ménière (1799–1862), in the middle of the nineteenth century [9]. Recurrent dizziness and fluctuating hearing loss, tinnitus, and ear fullness are typical symptoms. He claimed MD as an inner ear disorder causing dizziness through an autopsy of a patient who complained severe recurrent dizziness during his lifetime. However, he did not provide any clear pathophysiology of MD [10]. It was not until 1938, 70 years later, that the Yamakawa group and the Hallpike and Cairns group almost simultaneously presented the pathophysiological evidence of MD. They found endolymphatic hydrops (EH) in human temporal bone specimens with dilated scala media in the cochlea, which was later considered a histopathological marker of MD (Fig. 1) [1, 11].

The epidemiologic studies on the prevalence of MD vary. This is thought to be due to the uncertainty in the diagnostic criteria and pathophysiological mechanism. The prevalence rate is reported to vary from 17 to 513 per 100,000 people [12]. MD is a complex and heterogeneous disease in which various factors may interact, including genetics, immunity, hydrodynamics in the inner ear, psychological aspect, and cellular and molecular mechanisms [6]. The causes or course of the disease can be diverse, but one of the most important

histopathological hallmarks is the distention of the endolymphatic space in the inner ear. For treatment, lifestyle modifications, such as stress reduction, dietary restrictions, and medical treatments, are mainly used. Surgical treatments including vestibular ablation or sac

decompression are available in medically intractable cases. Patients may experience psychiatric problems along with other symptoms as poor quality of life is expected due to unexpected vertigo attacks and severe hearing loss [13].

The History of Inner Ear MRI to Visualize Endolymphatic Space and Hydrops

In the twentieth century, with the development of imaging technology using MRI, various efforts have been attempted to identify EHendolymphatic hydrops (EH) in vivo. In 2004, Duan et al. succeeded in visualizing EH in vivo for the first time in a guinea pig using 4.7 T MRI [14]. Nakashima et al. succeeded in confirming EH after injecting contrast media through intratympanic (IT) and intravenous (IV) injections into MD patients using 3 T MRI [15]. Recently, many reports have been published regarding the use of MRI to assess EH. In particular, IV gadolinium (Gd)-enhanced inner ear MRI has shown promising results [16, 17]. IV-Gd inner ear MRI is less invasive and is much more efficient because it requires less time after the contrast agent injection compared to the IT method (4 h vs. 24 h) and can evaluate both sides simultaneously [18]. Direct assessment of EH using MRI can be applied in clinical practice using the semiquantification and grading protocol suggested by Naganawa et al., which is currently the most widely used [16]. Several studies have shown a relationship between the severities of EH in MRI and MD patients' symptom correlation, and IV-Gd inner ear MRI is beneficial for diagnosing MD by demonstrating the correlation of hydrops with audio-vestibular results [19]. MD research using MRI is still ongoing in many groups, and although there are various methods in visualizing EH, the most widely used sequence is 3D-FLAIR, which uses an intravenous infusion of a gadolinium-based contrast agent. Recently, several different studies evaluate hydrops either by precisely dividing each area of the cochlea and vestibule or by implementing a 3D model to measure the whole volume of the entire endolymphatic space through MRI [19, 20].

Current Diagnostic Method and Dilemma in Ménière's Disease

The diagnostic criteria for MD proposed by AAO-HNS have been widely used and recently revised in 2015 (Table 1). According to the

diagnostic criteria, the diagnosis is inevitably dependent on the subjective symptoms except for pure tone audiometry, and all other vestibular diseases must be excluded.

Besides pure tone audiometry, electrocochleography (EcoG), vestibular evoked myogenic potential (VEMP) test, caloric test, and video head impulse test (vHIT) test have been used as clinical tests. However, it is challenging to accurately assess EH levels with these tests. Among these tests, EcoG has been used for more than 30 years in the diagnosis of MD [4]. However, EcoG is used only as a reference examination to diagnose MD because it cannot directly show the endolymphatic space. Even the diagnostic value of EcoG is still part of a debate in literature [21]. Regarding cervical VEMP (cVEMP) indicating saccular function, there was no significant correlation between the hydrops level and interaural difference (IAD) ratio. Several studies have shown that cVEMP response was reduced or enhanced in MD patients depending on the duration and stage of MD [22, 23]. Previous literature suggested that enhanced cVEMP response in the affected ear was often associated with the early stage of MD, and as MD progresses, a decrease in amplitude was observed. In patients with MD, canal paresis is sometimes observed in caloric testing. However, even with canal paresis, vHIT often shows normal findings. Suppose the hydroptic expansion of the endolymphatic duct in MD patients allows a local flow within the duct. In that case, this could dissipate the hydrostatic pressure caused by thermally induced density difference and diminish or eliminate the cupula's deflection. Thus, the hydrops of the endolymphatic duct could cause a caloric deficit without compromising the vestibulo-ocular reflex response in vHIT [24]. Therefore, additional tests currently used for MD diagnosis do not reflect the level of EH directly, which is a histologic hallmarker.

Sequence and Analysis of Inner Ear MRI for the Diagnosis of Ménière's Disease

Since the mid-2000s, 3 T MRI using a three-dimensional fluid-attenuated inversion recovery (3D-FLAIR) sequence has been used to detect

EH in MD [15]. These days, 3D-FLAIR and inversion recovery turbo spin echo with real reconstruction (3D real-IR) sequence are used the most as an MRI protocol to identify the signal differences between the perilymph (with contrast) and endolymph (without contrast) [25]. A primary advantage of the 3D real-IR sequence is that it describes the surrounding bone as an intermediate (gray) signal, so perilymph, endolymph, and adjacent bone can be distinguished in a single image [20]. To maximize the signal MR imaging was obtained optimally on a 3 T MRI system with a dedicated head coil and multiple receiver channels (over 32 channels). The basic MRI scan sequence is as follows: (1) heavily T2-weighted (hT2W) MR cisternography (MRC) for anatomical reference of total endolymphatic and perilymphatic fluid, (2) hT2W-3D-FLAIR with inversion time of 2250 ms (positive perilymph image (PPI)) to visualize the perilymph space, and (3) hT2W-3D-IR with inversion time of 2050 ms (positive endolymph image (PEI)) for evaluating the endolymphatic space. The parameters of PEI were the same as that of PPI except that the inversion time was 2050 ms. To facilitate comparison, MR cisternography, PPI, and PEI employed identical FOV, matrix size, and slice thickness. The next step is to subtract PEI from the PPI to create HYDROPS (HYbriD of Reversed image Of Positive endolymph signal and native image of positive perilymph Signal) on the scanner console. Upon completion, it is possible to analyze the extent of the endolymphatic space expansion visually. Clinically, several grading systems have been introduced for reading and diagnosis, but the most widely used grading system was announced in 2009 by T. Nakashima et al. (Table 2) [26]. For an accurate quantitative analysis, additional computer software must be used, and this takes a lot of time and effort.

In order to calculate the ratio, a technique for increasing the contrast is also used. To increase the contrast-to-noise ratio of HYDROPS images, HYDROPS-Mi2 images were generated on a DICOM viewer by multiplication of HYDROPS and MRC images (Fig. 2). Additionally, all cochlear and vestibule boundaries must be drawn manually along the contour on MRI by physicians (Fig. 3). This manual process is very

Table 2 Grading system of endolymphatic hydrops using MRI [26]

Grade of hydrops	Vestibule (area ratio ^a)	Cochlea
None	$\leq 33.3\%$	No displacement of Reissner's membrane
Mild	$> 33.3\%, \leq 50\%$	Displacement of Reissner's membrane area of cochlear duct \leq area of the scala vestibuli
Significant	$> 50\%$	Area of the cochlear duct exceeds the area of the scala vestibuli

^aRatio of the area of the endolymphatic space to that of the fluid space (sum of the endolymphatic and perilymphatic spaces) in the vestibule measured on tracings of images

time-consuming, is cumbersome, and is inefficient for clinical settings. An automated analysis system could be an excellent option to accurately calculate EH ratios in real time without a time-consuming and complicated process.

Development of Artificial Intelligence in the Medical Field: Focusing on Medical Image Analysis

The concept of AI was first introduced in the 1950s, but with its limitations in algorithms, data, and computing resources, it was not until the 2000s when AI re-emerged and gained popularity. In particular, the gradient vanishing problem of backpropagation was solved with a new activation function, and deep neural networks based on big data and computing resources, including a graphics processing unit (GPU), showed excellent performance. Along with this, a lot of research and social interest sparked a period of the revival of AI.

Particularly, radiology is the most important in the medical AI field [27]. This is due to developing a convolutional neural network (CNN), which shows excellent image recognition among various deep neural network algorithms. CNN is a deep neural network that mimics the human visual perception process, originating from the neo-cognition model first proposed by Kunihiko Fukushima in 1979 [28]. CNN supports convolution, which has the advantage of being able to

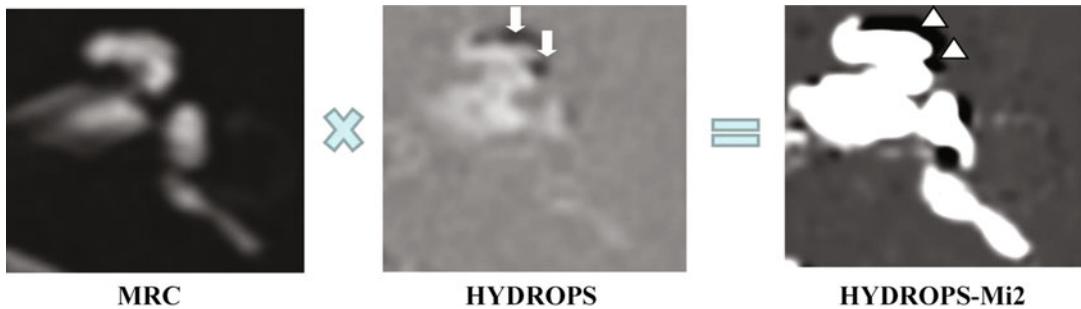

Fig. 2 By multiplying the MRC and the hydrops image, a HYDROPS-Mi2 image with maximized contrast can be created. The endolymphatic space (white arrow) observed

train high-dimensional data with relatively few parameters. This makes it easier to train more than two-dimensional data than general neural networks. Typically, in a conventional artificial neural network (ANN), each neuron in a layer connects to all neurons in the next layer, and each connection is a network parameter [29]. This can result in the creation of a huge number of parameters. Instead of using fully connected layers, CNN is composed of a convolution layer and a pooling layer that extract features of high-dimensional data and a fully connected layer that finally classifies the data. The convolution and pooling layers have the advantage that the number and order of each layer can be arbitrarily adjusted according to the problem the user wants to solve (Fig. 4).

This CNN showed its remarkable progress through the ImageNet Large Scale Visual Recognition Challenge (ILSVRC), which started in 2010. In 2012, Professor Jeffrey Hint's team created an “AlexNet” consisting of 7 hidden layers, 650,000 neurons, 60 million variables, and 630 million network connections at this competition, lowering the error rate to 16%. In 2015, ResNet, which reduced the error rate to 3.57%, appeared, proving that AI outperformed humans (error rate 5%) in the field of image recognition.

Today, these deep neural network models can be used for medical image classification, segmentation, object detection, registration, and other tasks [30]. Chest X-ray, mammography, and computed tomography (CT) in the head area are mainly studied and used most actively [8]. MRI

in the hydrops image is more visible in the Mi2 image (white arrowhead)

is a powerful and noninvasive tool that produces high-quality 3D images of complex brain structures [31]. In addition to the development of algorithms to classify Alzheimer’s or autism, quantification of various brain lesions is also actively studied. Patch-wise CNN architecture is commonly used due to the nature of the complex brain region. This is a simple approach to training a CNN algorithm for segmentation. NxN patches around each pixel are extracted from a given image, and the model is trained on these patches and class-labeled to accurately identify classes, such as normal brain and tumor [32]. Recently, the development of 3D images reconstructed based on MR images or 4D imaging using functional MRI is also accelerating. A CNN architecture with patch-based analysis might be beneficial for the field of medicine when there is a high demand of tools that extract information from large datasets.

The Use of Artificial Intelligence in Ménière’s Disease

Nowadays, many reports have been published regarding the use of MRI to assess EH. To be more specific, IV-Gd-enhanced inner ear MRI has shown good results. The degree of EH correlates well with the severity of symptoms and several audio-vestibular test results that have been used before [33, 34]. Although vestibular migraines and MD are not easily differentiated due to overlapping symptoms, inner ear MRI can

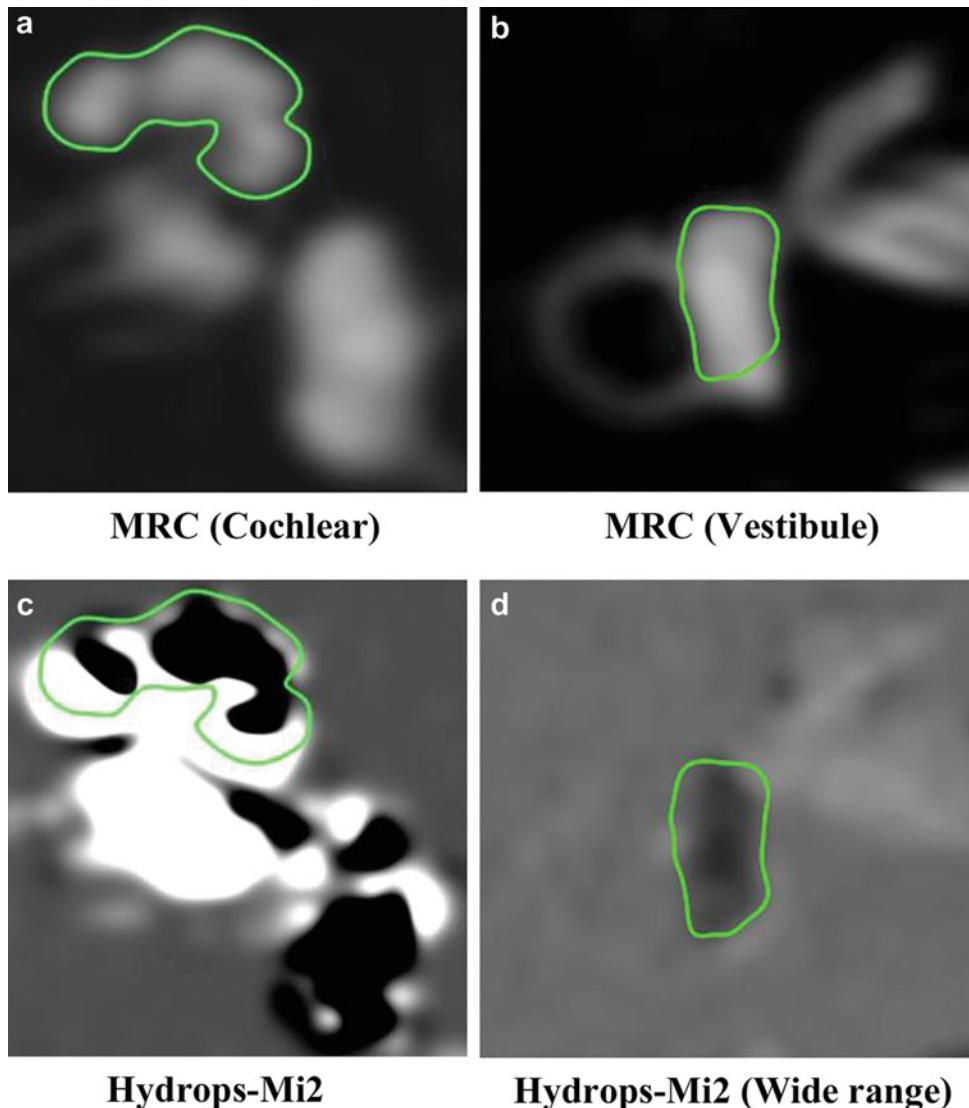

Fig. 3 The process of setting the region of interest (ROI) to calculate the hydrops ratio. **(a)** In the MRC image, the ROI for the cochlear hydrops was drawn along the contour by selecting the slice that best showed the cochlear modiolus. **(b)** For the vestibular ROI, the lowest slice, which the lateral semicircular canal was visualized more than 240°, was selected, and the ampulla was excluded when drawing ROI on MRC. **(c)** A copy of the cochlear

ROI from the MRC image was pasted to the HYDROPS-Mi2 image, and the hydrops ratio was calculated by dividing the number of pixels having negative pixels from the whole pixels. **(d)** A copy of the vestibular ROI from the MRC image was pasted in the HYDROPS-Mi2 (wide range) image. Vestibular hydrops with a negative signal inside is clearly observed

clearly distinguish between the two [35]. Many findings have differentiated inner ear diseases associated with EH (hydropic inner ear disease) using inner ear MRI. For this purpose, it is necessary to accurately and consistently calculate the EH ratio. However, as manual calculations are

required, it is time-consuming to calculate the exact EH ratio.

HYDROPS or HYDROPS-Mi2 images should be created using a specific brand of image viewer software. In addition, all cochlear and vestibule boundaries must be drawn manually along the

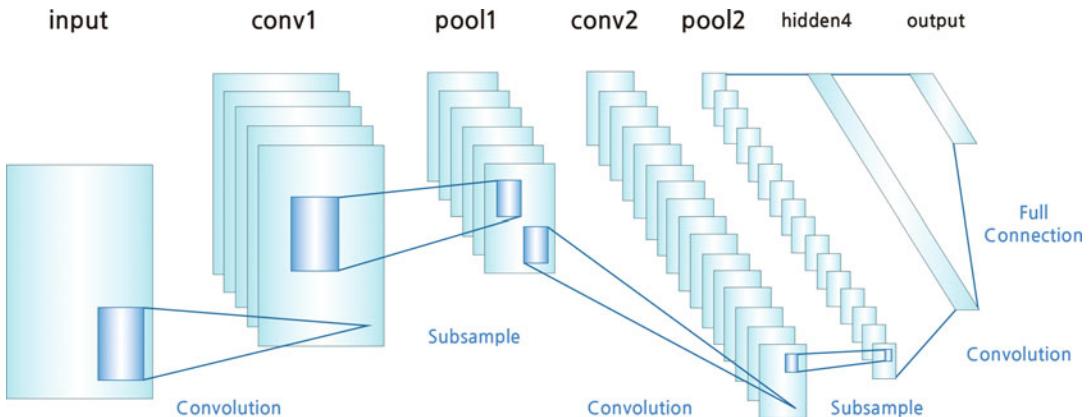

Fig. 4 The architecture of a convolutional neural network

contour on MRI. An automated analysis system could be a good option to accurately calculate the EH ratios in real time. Previous studies have evaluated the automatic segmentation of inner ear organs. For example, one study described semi-automatic CT image segmentation, which combines thresholding techniques and manual segmentation, but experts still needed to localize some points for the segmentation process [36]. Other groups applied a random forest classifier and a Niblack segmentation algorithm to a 3D reconstructed image and measured the endolymph and total fluid space [37]. There is a need for more automated deep learning algorithms for semantic segmentation of individual organs (cochlea and vestibule).

The simplest approach would be to use a fully connected ANN, but this would be highly computationally expensive because every pixel is linked to every neuron. A CNN solves this issue by filtering the connections by proximity (i.e., each neuron accepts inputs from a subsection relative to the receptive field in the image) of the lower layer, making it computationally manageable [38]. Besides, subsection-based processing mimics how individual cortical neurons function (a small portion of the visual field), where components of the CNN operate on local input regions. Accordingly, CNNs have demonstrated good performance in semantic segmentation in natural images as well as medical images [39].

In order to accurately measure EH with CNN, the following steps are required: (1) data preparation for training, (2) accurate segmentation of inner ear organs (cochlea and vestibule) based on the trained images, and (3) accurate and automatic calculation of the EH ratio for the segmented area (Fig. 5).

For accurate segmentation, several factors must be premised. Firstly, as with all CNN-based image analysis, it is necessary to acquire and learn as many datasets as possible to accurately segment the inner ear organ. Due to the specificity of the disease and the characteristics of the MRI protocol, quantitative limitations of the image dataset are inevitable. However, in MR images, it is possible to amplify the original images into the training dataset using flipping, intensity changing, and random shift cropping. The following is an example of a protocol for augmentation of a dataset lacking in the process: (1) low augmentation by flipping and random shifting (144 times); (2) moderate augmentation by flipping, random shifting, and 10 steps of brightness change (1584 times); and (3) high augmentation by flipping, shifting, and 1 step of brightness change (14,544 times). According to this method, it is possible to make a single MR image into more than 14,000 images and train that images. Secondly, since brain MR imaging is more complex and heterogeneous than other organs, a technique that can accurately segment the target inner ear organs is needed. Here, we can use the commonly

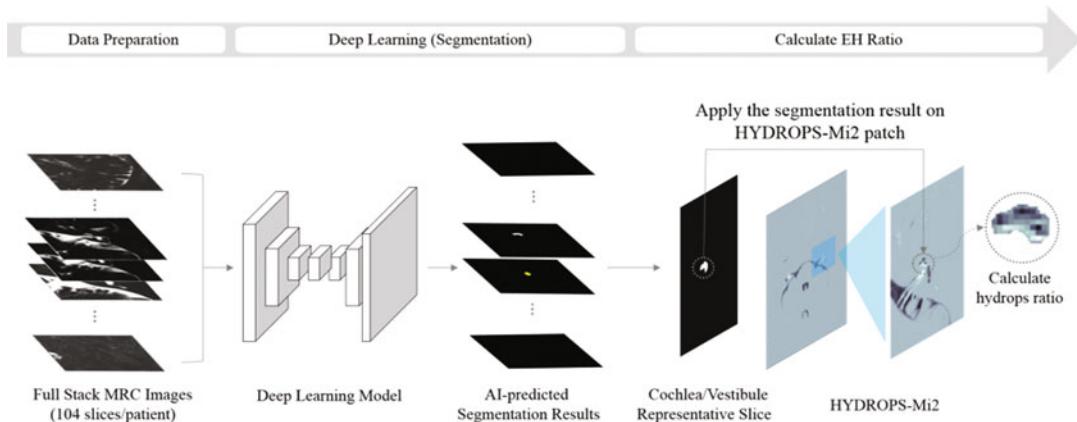

Fig. 5 Process for calculating the endolymphatic hydrops ratio using a convolutional neural network

used learning method of dividing the whole image into small patches. The cochlea and vestibule areas are relatively small according to the original whole MRC images (384×324 pixels). Therefore, the image is cropped 100×100 pixel windows from each side of the inner ear images at the left [215,238] and right [204,92] reference points with the cropping reference points being determined by a radiologist. All the ROIs for the entire dataset resided inside the cropped windows. In addition, the size and location of the inner ear organs are similar regardless of age or sex because they do not grow or change shape after birth,

which is highly beneficial for analysis using CNN [40].

Physicians' annotations on the regions of the cochlea and vestibule using MR cisternography (MRC) images are regarded as the ground truth. The deep learning segmentation model learns from these annotations together with the input MRC images. The results are similar to manual analysis performed by a physician (Fig. 6).

If segmentation is perfectly possible in this way, it is easy to find the area of the endolymphatic space or measure the hydrops ratio. The EH ratio is defined as follows:

$$\text{EH ratio} = \frac{\text{Total number of pixels with negative value in the segmentation area}}{\text{Total number of pixels in the segmentation area}}$$

The negative ratio represents the endolymphatic space area without the perilymph enhanced by a Gd. Recent research shows that the EH ratio is surprisingly consistent between the results measured by the specialist and the results predicted by AI [41]. In this study, the average interclass correlation coefficient (ICC) value for an entire image was 0.971, while the average ICC of the vestibule images (0.980) was higher than the cochlea images (0.952). For accurate calculations, a skilled specialist takes 10 min to calculate the EH ratio through post-processing of images, whereas AI takes only 0.168 s from reading to analysis.

Using this algorithm and framework, we can estimate the EH ratio accurately and quickly. By analyzing hydrops with MRI, the diagnosis of MD could be more accurately made by differentiating MD from other diseases with similar symptoms. In addition, an automatic quantitative analysis of hydrops ratios using inner ear MRI may be applied for assessing the stage of disease and prognosis. Furthermore, it may make the diagnosis of many diseases and symptoms suspected to involve EH much easier. Currently, only the representative section is extracted from the entire MR image, and the EH ratio is calculated. However, it

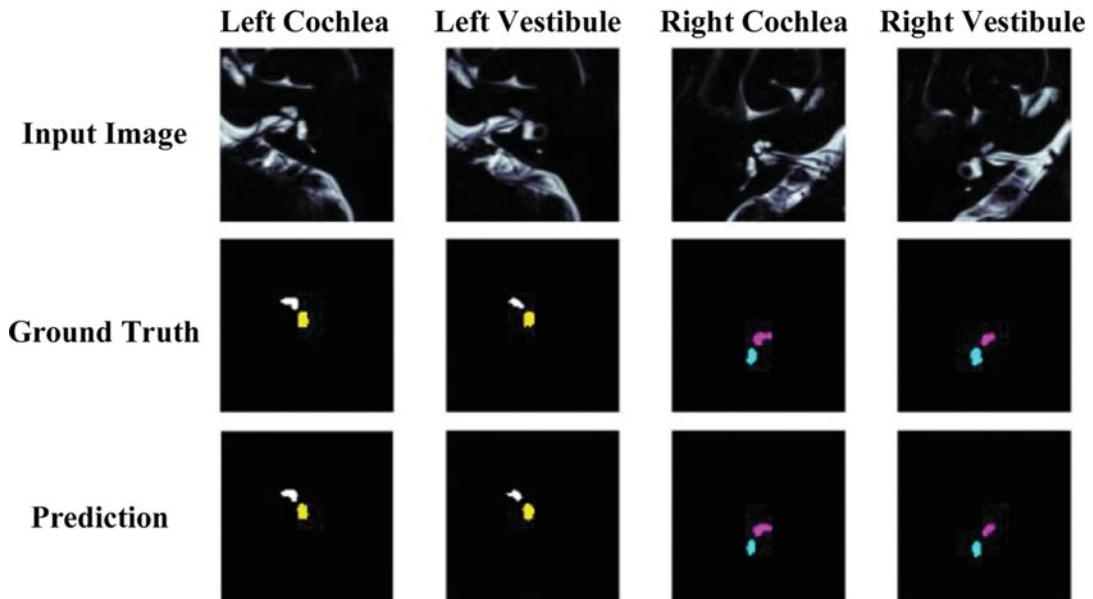

Fig. 6 AI-based segmentation results from a fully annotated dataset. Those examples show that AI-based prediction performs well compared to physicians' annotations (ground truth)

will be more effective if the volume of EH can be predicted quickly in the future.

The Future of Artificial Intelligence in Ménière's Disease

With the development of MRI machines, data and image processing technology, big data, and cloud systems, AI's role in the medical field is bound to increase as time goes by. Until now, algorithms have begun to help clinicians or predict clinical outcomes that are useful in medical systems, but patient-centered algorithms are still lacking [8]. While these technologies can be helpful for diagnosis and treatment of inexperienced physicians, they can lower the barrier to medical knowledge at the same time, making it much easier for patients to have a diagnostic approach to their disease. AI will be used in most of our lives in the future, but we need to be more careful in the medical field. The disease progression of all patients is not always the same, and the fatal errors of generalized algorithms can cause problems that could be more serious than those caused between a single patient and doctors.

Nevertheless, just as evidence-based medicine forms the basis for all medical fields, AI will be an excellent tool to quickly and easily utilize this evidence in the future. Therefore, we can refer to the evidence-based content proposed by AI, but we should still be careful when it comes to utilizing this "evidence-based content" in clinical practice.

Currently, several studies are underway, but the possibility of using inner ear MRI in MD is not yet verified and validated. MRI can confirm the endolymph space and calculate the EH ratio, but the protocol or analysis method differs between researchers. In some studies, symptoms improved through treatment in MD patients, but the pattern of hydrops did not change or rather increased in MRI performed after treatment. Hence, it is necessary to further consider how EH in MD causes symptoms [42, 43].

AI will become important in most medical fields in the future. It seems strongly possible that CNN-based deep learning will be widely used for analysis and reading of medical images. There are still many aspects that need to be improved when it comes to the diagnosis of MD, but AI will be able to perform clustering and

classification by synthesizing patients' symptoms, audio-vestibular tests, and MRI analysis. Healthcare professionals will need to carefully consider and strive for symbiosis between AI and the field of medicine in the future.

Abstract

Brain tumors are among the deadliest human cancers, and despite decades of intensive research the survival for many types of malignant primary brain tumors has not improved significantly. Since we continuously generate enormous amounts of clinical data of various modalities that help clinicians not only diagnose brain tumors, but also monitor, quantify, and assess the treatment process, implementing

data-driven approaches to analyze such complex data automatically is becoming extremely important. In this chapter, we review artificial intelligence (AI)-powered approaches for this task, and discuss how AI can bring value into the clinical setting through automating tedious data analysis tasks, and extracting information from medical data that may directly affect the treatment pathway.

Introduction

The amount of medical data generated every second is rapidly growing, and its effective analysis is key for designing an appropriate – and as personalized as possible – patient’s treatment pathway.

Brain tumors are among the deadliest and feared of all forms of cancer, as more than two-thirds of adults diagnosed with glioblastoma dies within 2 years of diagnosis [3]. Hence, optimizing the clinical workflow and allowing physicians to design the treatment faster and in a reproducible way are critical nowadays – clinical brain tumor imaging plays an integral role in the diagnosis, monitoring, treatment planning, and post-therapy assessment of brain tumors. In this chapter, we discuss how AI helps in the process of tedious analysis of such image data, and ultimately improves the patient care through providing faster, reproducible, and user-independent processing. Additionally, we highlight the most important challenges that have to be faced while designing and implementing the imaging systems benefiting from AI [77].

Magnetic Resonance Imaging of Brain Tumors

Magnetic resonance imaging (MRI) plays a pivotal role in modern brain tumor cancer care because it allows us to non-invasively diagnose a patient, determine the tumor stage, monitor the treatment, assess and quantify its results, and understand its potential side effects. MRI may be exploited to better understand both structural and functional characteristics of the tissue [23]. Such detailed and clinically-relevant analysis of an imaged tumor can ultimately lead to a better patient care. Additionally, MRI does not use the damaging ionizing radiation, and may be utilized to acquire images in different planes and orientations. MRI (with and without contrast) is the investigative tool of choice for neurological cancers – for brain tumors, we acquire multi-modal MRI, including T1-weighted (contrast and non-contrast), T-weighted, Fluid Attenuation Inversion Recovery (FLAIR) sequences, alongside diffusion and perfusion images. For full description of all MRI modalities routinely acquired for brain tumor patients, see an excellent survey by Villanueva-Meyer et al. [89].

An example set of images of various modalities is presented in Fig. 1 (this scan comes from the Multimodal Brain Tumor

Segmentation Challenge [6–9] – we discuss it in detail in section “[Brain Tumor Detection and Segmentation](#)”). We can see that each sequence, rendered in three orientations – axial, coronal, and sagittal – helps evaluate tissue architecture and is captured to manifest its different characteristics:

- **T1** – in pre-contrast sequences, high intensity appears in fat, melanin, blood products, and mineralization, whereas post-contrast T1 is particularly useful in observing the blood-brain barrier and vascular structures. Hence, the post-contrast T1 images may help capture the brain tumor borders, as they become brighter because the contrast agent would accumulate there due to the disruption of the blood-brain barrier in this tumor region [52].
- **T2/FLAIR** – high intensity in T2/FLAIR is seen in peritumoral edema, non-enhancing tumor, as well as gliosis and white matter injury [89].

Automated Analysis of MRI in Brain Tumors: Challenges

Extracting informative features from MRI scans can be represented as a chain of several image analysis and processing tasks (Fig. 2). Importantly, every step directly affects all consecutive blocks in the pipeline. Therefore, any errors or inconsistencies propagate toward the final analysis and interpretation stage. Naturally, each step involves different challenges that need to be faced in order to build a hands-free system that could be deployed in the clinical setting. Here, the segmentation step (i.e., determining different regions of a tumor, e.g., its enhancing part, tumor core, and so forth) is rendered as a dotted block because it may be considered optional – there exist applications in which we are interested in, e.g., quantifying the volume of a whole tumor, not necessarily its specific subparts [65].

The most important challenges concerned with applying AI in brain tumor analysis are summarized in the following bullet points. Note that practically all of them are tightly related to the data availability, quality, and volume:

Fig. 1 Example MRI scan (T2-FLAIR, T2, T1, and post-contrast T1Gd), and the overlaid ground truth (green – peritumoural edema, yellow – enhancing tumor, red – necrotic and non-enhancing tumor core). We can see that different modalities present different tissue characteristics, and the signal intensities captured for the same tumor region substantially vary across them

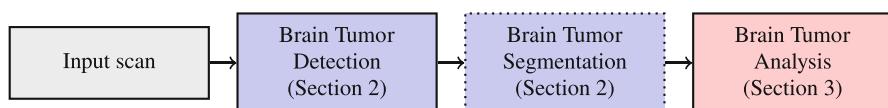

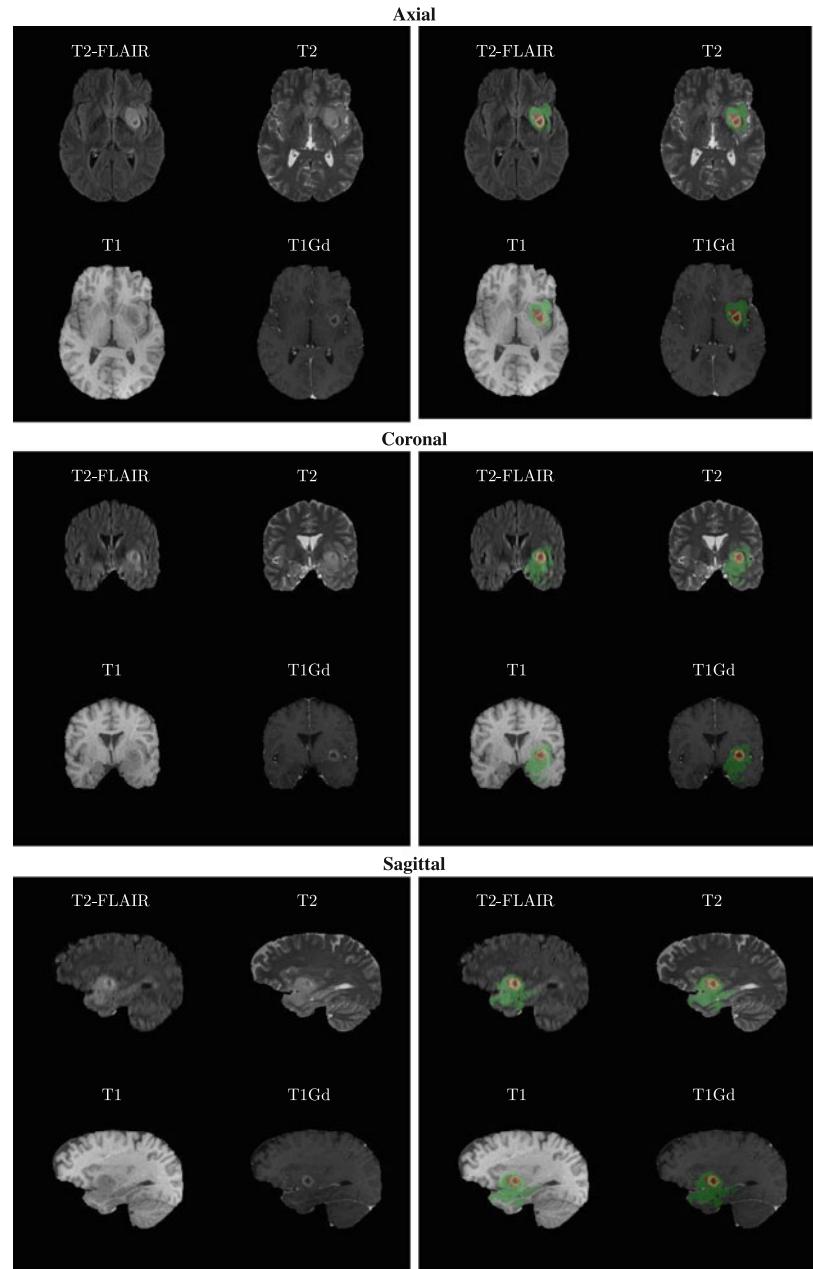

Fig. 2 A high-level flowchart of the automated analysis of brain tumors from MRI. The dotted block presents an optional step of the pipeline that is sometimes omitted in specific use cases

- **The lack of ground-truth data**, being the manually annotated data sets that could be used for training supervised learners. Since

the process of manual contouring of regions of interest in MRI scans is tedious and time-consuming, generating new ground truth is

- often infeasible and cost inefficient. Also, it often involves gathering a group of readers to resolve inter-rater disagreements in the annotation process [65], and to establish “acceptance criteria” for manual delineations.
- **Varying quality of manual delineations in the ground-truth data sets.** Annotating tumor regions is a user-dependent task, and it may be affected not only by a reader’s experience, but also other inter- and intra-operator variability [22]. Therefore, such contouring can easily lead to ground-truth segmentations of questionable quality (hence, it should be manually or semi-automatically improved). Including low-quality image data adversely affects the performance of supervised learners trained over such scans. (However, if the number of such low- or medium-quality examples is small, they could potentially be treated as the data-level regularization [62].)
 - **Very high (often extreme) imbalance of examples** captured in existing ground-truth data sets [46]. It is common that the number of samples (i.e., pixels or voxels) of different classes (e.g., enhancing tumor or necrosis) in a data set is extremely imbalanced, and there exist the majority class(es) dominating the others (called the minority classes). Such data imbalance makes the training process challenging, as it is difficult to capture intrinsic features of the under-represented class(es) from a small number of samples.
 - **Lack of representative ground-truth data sets and the limited representativeness of existing ground truth.** The heterogeneity of healthy brain tissue and brain tumors, alongside the possible locations [72], features, and sizes of tumors make gathering the large and representative training data of brain tumor examples extremely challenging. Also, MRI scans captured using different scanners or acquisition protocols can present significantly different intensity and sequence characteristics – to capture such differences, the ground truth data sets should encompass data acquired using different scanners and protocols [34, 71, 83].
 - **Difficulties in sharing and distributing ground-truth image data across sites (e.g.,**

hospitals). Dealing with medical image data poses new challenges toward its sharing or distributing, especially in the cases where the patient’s information is embedded into the data [91]. Although there exist a plethora of anonymization techniques that help remove “sensitive” information and retain the image data only (without unnecessary metadata), transferring data across sites (and countries) is one of the largest practical challenges nowadays, and there still are situations when it is virtually impossible due to various legal reasons. Therefore, the collaborations between hospitals in the context of building AI-powered systems together may be extremely difficult (or impossible) if they involve data sharing.

Structure of the Chapter

This chapter is structured as follows. In section “[Brain Tumor Detection and Segmentation](#),” we discuss the current advances in the AI-powered brain tumor detection and segmentation, together with the approaches toward dealing with limited ground-truth data, and the ways of assessing the performance of AI models. Section “[Analysis of Segmented Brain Tumors](#)” reviews the most important measures that are typically extracted from brain tumor regions in MRI to quantify the treatment response, perform diagnosis (or prognosis), and better understand the effectiveness of the undertaken treatment pathway. Finally, section “[Conclusion](#)” concludes the chapter.

Brain Tumor Detection and Segmentation

Detection and segmentation of brain tumors from MRI are the critical steps in a process of analyzing an MRI study, as they significantly influence, e.g., extracting quantifiable tumor characteristics. Here, by *detection* we mean the process of determining tumorous pixels (or voxels in 3D) in the input scan, and by *segmentation* – classifying such pixels/voxels into specific tumor subparts (e.g., edema, enhancing part of a tumor, tumor core, and so on).

Incorrect delineation may easily lead to improper interpretation of the captured scan and thus can adversely affect the treatment pathway [59].

A tremendous amount of MRI data generated every day drives the development of machine learning-powered brain-lesion segmentation systems. However, such data is extremely imbalanced (only the minority of all pixels or voxels are tumorous), it is very large (in terms of volume) and heterogeneous. This heterogeneity may be not only due to different scanners and/or protocols utilized to capture MRI data, but may also be a result of various tumor characteristics and intrinsic features captured in the image. Therefore, manual delineation of MRI scans is time-consuming and tedious, and generating high-quality manually-segmented brain lesions (that could be exploited for training) is challenging in practice. It is worth mentioning that there might be discrepancies and disagreements between readers delineating the very same scan (or even between two segmentations provided by the same reader at different time points), and – in general – the quality of manual segmentations vary [90].

Automatic Detection and Segmentation of Brain Tumors

Fully-automated medical-image segmentation pipelines, e.g., exploiting image analysis and machine learning, are of great interest, as they can accelerate diagnosis, ensure reproducibility, and make comparisons much easier (e.g., comparing the manual delineations performed by two readers at two different oncology centers alongside the extracted brain-tumor numerical features is extremely challenging if they did not follow the same acquisition and segmentation protocol). Also, we are aimed at decreasing the overall analysis

time. Finally, we want to reduce false negatives, being the tumorous voxels that were incorrectly classified as healthy by an algorithm or a human.

In Fig. 3, we present a high-level taxonomy of the algorithms for automated detection and segmentation of brain tumors from MRI. In the *atlas-based* techniques, manually segmented images (*atlases*) that model anatomical variability of the brain are exploited to segment unseen scans [66, 70]. Thus, to ensure that such algorithms can be successfully applied to new MRI scans, creating large and representative annotated sets is pivotal yet very costly [4]. Additionally, atlas approaches are dependent on the quality of the underlying image registration process [11]. The *image analysis*-powered algorithms are commonly split into *thresholding-* and *region-based* techniques [40]. The former algorithms extract the threshold values (either single or multiple of them, potentially in an adaptive way) to classify voxels into different classes, whereas the latter utilize the neighborhood pixel information (quantified using a selected criteria) during the segmentation process [21]. Other techniques that benefit from image analysis include active contours (deformable models) [12], region-based active contours [92], and elastic image deformations [63].

The *classical machine learning* brain tumor detection and segmentation algorithms involve feature engineering (i.e., feature extraction, commonly followed by feature selection), whereas *deep learning* techniques allow us to perform automatic representation learning. Both approaches can be further divided into *unsupervised* and *supervised* algorithms. The former operate on the unlabeled data and reveal its hidden structures and characteristics through, e.g., clustering [15, 25, 58, 86]. *Supervised* techniques use manually delineated scans as examples to train a model, and include a plethora of techniques, such as

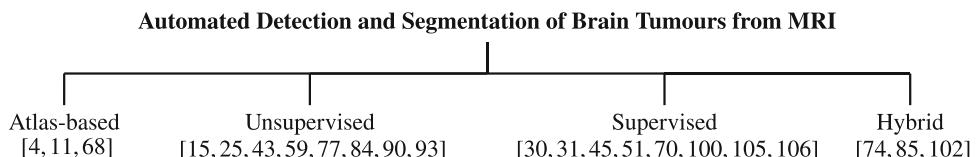

Fig. 3 Automated delineation of brain tumors from MRI – a taxonomy [56]

decision forests [30, 101], conditional random fields [95], extremely randomized forests [69], support vector machines [49], k -nearest neighbors [44, 82], various architectures of artificial neural networks [1], and many more. We have been witnessing the unprecedented success of deep learning in practically all areas of science and industry, and medical image analysis is not an exception here. Deep networks have been applied to process brain scans [31, 37, 61, 100] – they consistently outperform other approaches in the Multimodal Brain Tumor Segmentation Challenge (BraTS) [43]. We can observe that the U-Net-shaped architectures (in both 2D and 3D) are currently the “architecture of choice” in automated brain tumor delineation [41]. Although there exist a multitude of variants of the vanilla U-Net [19, 26, 56, 87], the appropriate pre- and post-processing, alongside the configuration of the basic architecture are key in obtaining very accurate detection and segmentation [42]. Finally, *hybrid* approaches combine methods from other categories [81, 97].

Although multi-modal processing is pivotal for segmenting brain tumors into sub-regions, they can be effectively detected (without dividing them into sub-parts) from a single MRI modality, e.g., T2-FLAIR [54, 65, 89, 96]. This approach is often much easier to implement, train, and deploy, and infers in shorter time, especially due to the lack of the sequence co-registration step required in multi-modal techniques. Additionally, it is common that some modalities are missing in clinical scenarios, hence designing and implementing brain tumor analysis algorithms robust against the absence of a modality (or a set of modalities), and quantifying their influence on the overall segmentation quality are of research interest [80, 98].

Automatic brain tumor detection and segmentation has become a mature and very active research topic – a battery of available approaches allow the practitioners select and implement such methods in clinical settings. Although the progress in the field has been driven by the revolutionizing impact of deep learning, all of the aforementioned techniques have their own advantages and shortcomings, and are often applied in different use cases. For a comprehensive review of the state of the art,

coupled with a detailed analysis of their pros and cons, see [14, 65, 76, 92].

Dealing with Limited Ground-Truth Data Sets

Questionable quality of manually-generated ground-truth information is an important problem in the case of supervised methods, because it directly affects the abilities of a trained model. Additionally, gathering well-represented heterogeneous MRI examples, i.e., scans acquired using a variety of MR scanners and imaging protocols, is extremely costly and time-consuming. In BraTS, the authors publish a set of MRI scans (obtained at 19 institutions) – the T2-FLAIR, T2, T1, and T1c (T1Gd) sequences are co-registered, skull-stripped, and interpolated to the resolution of 1 mm^3 (155 frames of 240×240 size) [6–9]. The scans are coupled with manual annotations generated by one to four experienced readers who followed the same delineation protocol. Afterwards, their annotations were double-checked by neuro-radiologists, and the following classes of voxels were included in the data set: GD-enhancing tumor, the peritumoral edema, and the necrotic and non-enhancing tumor core. In the newest (2020) release of the challenge, the training set contained 293 high-grade glioblastomas and 76 low-grade gliomas with manual annotations, and – to the best of our knowledge – is the largest and the most comprehensive data set that can be used for training supervised learners, and for quantifying the performance of existing and emerging algorithms.

Although the BraTS data set is widely used in the field, the number of patients included in this set is still relatively small and dealing with limited (in terms of the size, heterogeneity or specific-class examples) ground-truth data sets remains a valid real-life challenge. The approaches toward tackling this issue may be divided into:

- **Unsupervised and semi-supervised learning.**
As discussed earlier in this section, unsupervised methods do not require any ground-truth data to uncover “hidden” features of the raw

data. Although such techniques allow us to determine consistent 2D/3D regions that manifest similar characteristics, we miss the class label once the pixels/voxels are grouped. Thus, such pre-processed scans undergo additional analysis to, e.g., manually classify the segmented regions. Importantly, unsupervised learning may accelerate the process of generating ground truth through elaborating pre-segmented areas that are later classified into the classes by a human. On the other hand, semi-supervised algorithms make full use of the unlabeled data (note that a multitude of unlabeled MRI scans are generated daily worldwide), and they estimate the missing labels. Then, these samples can be used together with the labelled data for training a supervised learner [29].

- **Transfer learning and domain adaptation.** In transfer learning (Fig. 4), we exploit existing ground-truth data sets (referred to as the *source data sets* in this context), very often captured in different domains, to train a deep learning algorithm in a supervised way. Then, the feature extractor is transferred to the target domain, and the classification part of the model is further trained over the *target data set* (of a much smaller size). In this scenario,

we still need the target (labelled) data but it may be of a significantly smaller size.

- **Synthesizing artificial training examples through data augmentation.** Data augmentation is a process of generating synthetic samples [62]. Such artificial images can be either included in the training set (in order to increase its size and representativeness) in the *training-time* augmentation, or utilized during the inference to benefit from the ensemble-like approach in the *test-time* augmentation approach. In the latter case, we generate n synthetic samples for each original input sample, classify ($n-1$) samples, and aggregate the classification results (e.g., via the majority voting) into the final label assigned to the original sample. Data augmentation approaches are divided into the techniques that operate on the existing data via applying simple image transforms such as rotation, flipping, shearing, translation and zooming [28, 53], alongside elastic [13, 33, 38, 63] or pixel-level transformations [2, 75], and those that synthesize new examples, using, e.g., generative adversarial networks [99] or various tumor growth models [32] (Fig. 5). The former techniques often generate correlated image samples but can be employed at test time, as they can synthesize

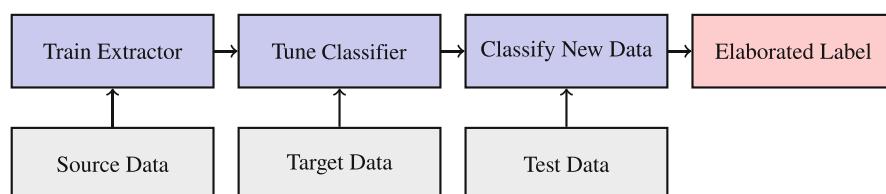

Fig. 4 In transfer learning, we train feature extractors over the source data, and fine-tune the classifier over the target data. This figure is inspired by [64]

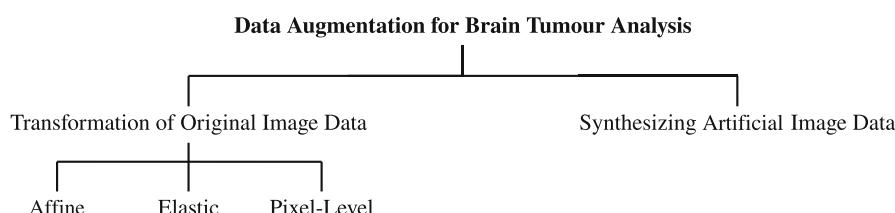

Fig. 5 Data augmentation for brain-tumor detection and segmentation – a taxonomy [62]

artificial images using an incoming test image. On the other hand, the methods that generate image data with the use of generative models can only be deployed before training the models to enhance the training set. Data augmentation is a standard procedure that proved to be pivotal in obtaining well-generalizing models, and it is consistently exploited in the best-performing tumor detection and segmentation systems [62].

- **Federated learning.** Multi-institutional collaborations in the context of medical image analysis are extremely difficult in the scenarios involving centralized data centers, in which data would be shared across sites, due to the issues that are concerned with data anonymization, privacy, and ownership. To leverage the unprecedented amount of data that can be captured at numerous sites (clinics, universities, research centers, and so forth), federated learning – as a new distributed training paradigm – can be utilized [78]. Here, the process of training the models is distributed across the collaborators, and each collaborator trains the model using their data, hence the data privacy is fully maintained. Afterwards, the models are “aggregated” and assessed before the final deployment [79].

Assessing Automatic Detection and Segmentation

Quantifying the performance of automatic brain tumor detection and segmentation methods is critical to fully understand their performance abilities.

In general, we distinguish three ways of assessing the quality of such algorithms that are commonly used to thoroughly analyze emerging techniques:

- **Quantitative analysis.** To quantitatively measure the quality of automatic segmentations, we utilize various metrics extracted from the confusion matrix containing true positives (TP), true negatives (TN), false positives (FP) and false negatives (FN). They commonly include the spatial overlap metrics: DICE coefficient (sometimes coupled with the Jaccard’s index; both metrics range from zero to one, and both should be maximized: ↑ – see an example rendered in Fig. 6), true positive rate (sensitivity, recall; ranging from zero to one, ↑), true negative rate (specificity; ranging from zero to one, ↑), and other related metrics [85]. On the other hand, the spatial distance metrics quantify the quality of the boundary (contour) [27], and encompass the Hausdorff distance (↓), Mahalanobis distance (↓), together with their variants, usually more robust to outlying (low-quality) delineations [39]. It is worth noting that the aforementioned metrics are calculated with respect to the ground-truth segmentations. Therefore, the quality of ground truth directly influences the extracted metrics, and – in extreme scenarios – low values of, e.g., the overlap metrics do not necessarily mean that the automatically contoured regions are of poor quality, but they may indicate the poor quality of reference annotations delivered, e.g., by inexperienced readers. Hence, the quantitative analysis should be coupled with the qualitative analysis that could reduce

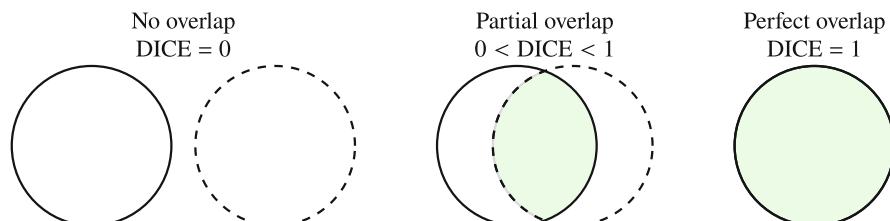

Fig. 6 Example values of the DICE scores obtained for two contours annotated using solid and dashed lines. The larger overlapping areas are reflected in greater DICE values

the impact of “misleading” quantitative metrics obtained for ground truth of questionable or varying quality.

- **Qualitative analysis.** Exploring and investigating the automatic delineations is pivotal not only while developing the algorithms, but also during their verification and validation. In [65], the authors exploited the mean opinion score experiment as a framework for assessing the quality of automatically determined brain tumor contours – a group of readers were asked to investigate the annotations elaborated using a deep model, and score their clinical utility using a simple scale (“very low-quality” and “low-quality” segmentation that map to “I would not use this segmentation to support diagnosis,” and “acceptable” and “high-quality” segmentation that map to “I would use this segmentation to support diagnosis”). Since the readers may easily be biased, the authors analyzed inter-rater agreements and delivered secondary analysis over the results of this experiment. Such qualitative investigation and assessment of image data performed by human practitioners is extremely important, as it can prove the clinical utility of a developed algorithm (or show that the results are not mature enough to be deployed in a clinical setting).
- **Statistical analysis.** To fully understand the statistical relevance of the obtained results (together with the differences between the investigated variants of the segmentation techniques), we commonly execute statistical testing [102]. It may be exploited to, e.g., verify the null hypothesis saying that “applying Algorithm A and Algorithm B leads to segmentations of the same quality, quantified, e.g., using the DICE score.” Also, as already mentioned, investigating the inter-rater agreement is critical to demonstrate consistency among observational ratings provided by multiple readers [48, 90], but – at the same time – incorrect statistical procedures are commonly utilized in this context [35]. Statistical tools are also used to prove the reproducibility of the results delivered by AI algorithms [67, 74].

Analysis of Segmented Brain Tumors

AI algorithms are often utilized to automate brain tumor detection and segmentation, but these are commonly the intermediate steps in a processing chain. In this section, we discuss two important analysis steps that may follow the process of locating the tumors: quantifying tumor characteristics and features (section “[Quantification of Tumor Characteristics](#)”), and classifying delineated tumors into specific classes (section “[Classification of Brain Tumors Using AI](#)”).

Quantification of Tumor Characteristics

Currently, the most widely-used criteria of assessing response to therapy in high-grade brain tumors are based on single- or two-dimensional measurements of an enhancing part of a tumor in computed tomography or MRI [94]. Although they have limitations, as enhancement is non-specific, hence may not always be an appropriate surrogate of tumor response, and some therapies result in transient increase of tumor enhancement (referred to as the pseudo-progression), such criteria are consistently utilized in clinical practice to analyze longitudinal scans. In Table 1, we gather the popular criteria, alongside their basic features, including the image modality, the way of determining target lesions, and the shrinkage required for partial progression [51]. Importantly, these response criteria are the result of the international effort of building a standardized set of measures that allow us for designing the objective assessment of treatment response. Also, they are commonly reported together with other volumetric and bidimensional measurements extracted for the analyzed tumors. Establishing such criteria is a dynamic process, as we gather new underpinnings of primary and metastatic brain tumors, therefore new or updated measures are likely to emerge in the nearest future [18].

Because the response criteria are based on one- or two-dimensional measurements of a tumor, determining such measures involves detecting and segmenting of a lesion in an input scan – see an example of visualized diameters that are used to calculate the Response Assessment in Neuro-

Table 1 The criteria commonly used to assess response to therapy in brain tumor patients, alongside the shrinkage required for partial response. If a patient has multiple

lesions, the enlarging lesions are considered as target lesions. For more details, see [51]

Criterion	Modality	Target lesion	Measurement type	Shrinkage (%)
RECIST 1.0 [88]	MRI or CT	Longest diameter >10 mm	Unidimensional	≥ 30
RECIST 1.1 [24]	MRI or CT	Longest diameter >10 mm	Unidimensional	≥ 30
Macdonald [55]	MRI or CT	Minimal size is not specified	Bidimensional	≥ 50
WHO [60]	–	Minimal size is not specified	Bidimensional	≥ 50
RANO [94]	MRI or CT	Contrast enhancing lesions with two perpendicular diameters (> 10 mm)	Bidimensional	≥ 50

Oncology (RANO) criterion presented in Fig. 7. Thus, AI techniques for these tasks are naturally embedded into the systems that are designed to extract quantifiable tumor measures utilized to track treatment response [16] (note that elaborating, e.g., the perpendicular diameters in RANO does not involve any AI and is a pure image analysis and optimization task). Finally, quantifying the impact of automatic segmentation quality on the biomarkers extracted from MR brain imaging is a vital research topic. In [65], Nalepa et al. implemented a fully-automated deep learning-powered technique for extracting biomarkers from dynamic contrast-enhanced MRI (DCE-MRI) of brain tumors. Once the contrast bolus is injected, DCE-MRI captures the voxel intensity changes within a volume of interest, and it allows for quantifying the dynamic processes within a tissue based on such temporal changes of voxel intensities. Biomarkers extracted from DCE-MRI can be used in patient prognosis, risk assessment and quantification of tumor characteristics and stage – such analysis of the temporal enhancement pattern can benefit from AI for segmenting the tumorous regions as well.

Classification of Brain Tumors Using AI

Many computer-aided diagnosis systems are aimed at not only detecting and segmenting brain tumors from MRI, but also at classifying them into specific classes. Such classes may reflect their

aggressiveness, stage, or type, e.g., benign and malignant; primary and secondary; grade II, III, and IV tumors; glioma, meningioma, and pituitary tumor [45]. Machine learning algorithms for brain tumor classification (both two- and multi-class) include classical techniques that involve feature extraction, selection, and training, alongside deep learning methods that automate feature extraction. Handcrafted features commonly include texture, statistical, shape, and grey-level characteristics of the tumorous part of the brain [36, 73] – such extracted features form feature vectors that are fed into the training process of a supervised learner, e.g., a support vector machine [5] (Fig. 8). On the other hand, deep learning models embed the feature extractor into the network architecture and make it possible to train [84, 93]. As an example, trainable kernels in convolutional neural networks act as such feature extractors. There exist hybrid approaches [47], in which hand-crafted tumor features are coupled with the deep ones to fully exploit both the “expert knowledge” that may be manifested in manually designed extractors, and data-driven feature extractors (e.g., autoencoders or convolutional feature extractors) that may potentially capture features that can be “unknown” for humans [10]. Since the issues concerned with the limited number of training examples are valid in the context of supervised tumor classification, the same approaches are utilized to tackle them [17, 20, 57], as in the segmentation task (see section “Dealing with Limited Ground-Truth Data Sets” for details).

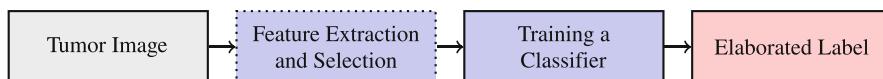

Fig. 8 Classification of brain tumors using classical machine learning (with manually designed feature extractors and selectors, annotated as a dotted block) and deep learning

Conclusion

AI algorithms are being continuously deployed in medical data analysis systems, and can fundamentally affect different levels of the analysis workflow (e.g., enhancing the quality of medical images, improving their interpretation, automating tedious analysis tasks, and extracting mineable high-dimensional data to enhance clinical decision making, just to mention a few workflow steps that could easily benefit from AI). Although it is tempting to think that AI can effectively solve all emerging problems in automated analysis of high-dimensional medical data, there are a

multitude of challenges that have to be tackled before deploying such data-driven techniques in clinical practice [68]. In this chapter, we discussed how AI can improve the brain tumor patients' care through automating pivotal steps of analyzing image data. We identified the most critical obstacles that are faced while designing, verifying, and validating new AI algorithms, and presented the ways of dealing with them.

AI will transform (and it actually *is already transforming*) clinical imaging practice [50]. It is, however, important to realize that AI *is not* to replace clinicians, but to deliver tools that can automate their most tedious, time-consuming,

and user-dependent tasks, and to help them move the focus to the actual interpretation of the results and designing more personalized and even better treatment pathways.

Acknowledgments This chapter is in memory of Dr. Grzegorz Nalepa, an extraordinary scientist and pediatric hematologist/oncologist at Riley Hospital for Children, Indianapolis, USA, who helped countless patients and their families through the most challenging moments of their lives.

The work was supported by the Silesian University of Technology grant for maintaining and developing research potential, and by Rectors Research and Development Grant 02/080/RGJ20/0003. The author thanks Krzysztof Kotowski for implementing the RANO visualization.

Abstract

Artificial Intelligence (AI) is a broad term used to describe the science and engineering of making intelligent machines. AI tools use a range of computer algorithms that learn from experience and allow machines to simulate human intelligence. Management of the stroke patient involves an algorithmic approach. The algorithmic nature of stroke workflow creates an

opportunity for the artificial intelligence (AI)-based tools to increase workflow efficiency. These tools have been implemented in the stroke care and research and include tools for the patient triage, image analysis, decision making with therapeutics and interventions, rehabilitation, and trial design. In this chapter, we describe the critical aspects of the stroke management, clinical contexts where the AI tools have been used, and suggest scientific questions that should be tackled using AI.

Introduction

Stroke is the fifth major cause of mortality in the United States [1]. It is broadly classified into ischemic stroke and hemorrhagic stroke. Ischemic stroke accounts for about 80% of the stroke patients. It is caused by the interruption of blood supply to the brain. Hemorrhagic stroke is caused by the rupture of a blood vessel or of an abnormal vascular structure. The differentiation into ischemic and hemorrhagic stroke is the first critical step in the management of ischemic stroke patients because the treatment approach is different for these two stroke subtypes. For the ischemic stroke patients, the goal is to recanalize the brain vessel feeding into the ischemic territory and thus achieve rapid reperfusion of the hypo perfused but salvageable brain parenchyma. Eligible patients are, therefore, offered intravenous (iv) thrombolytic agents and/or recanalization therapy [2]. In case of intracerebral hemorrhages, the use of iv thrombolytic agents is contraindicated, and the goal is to prevent clinical worsening due to mass effect from the hematoma (Fig. 1) [3].

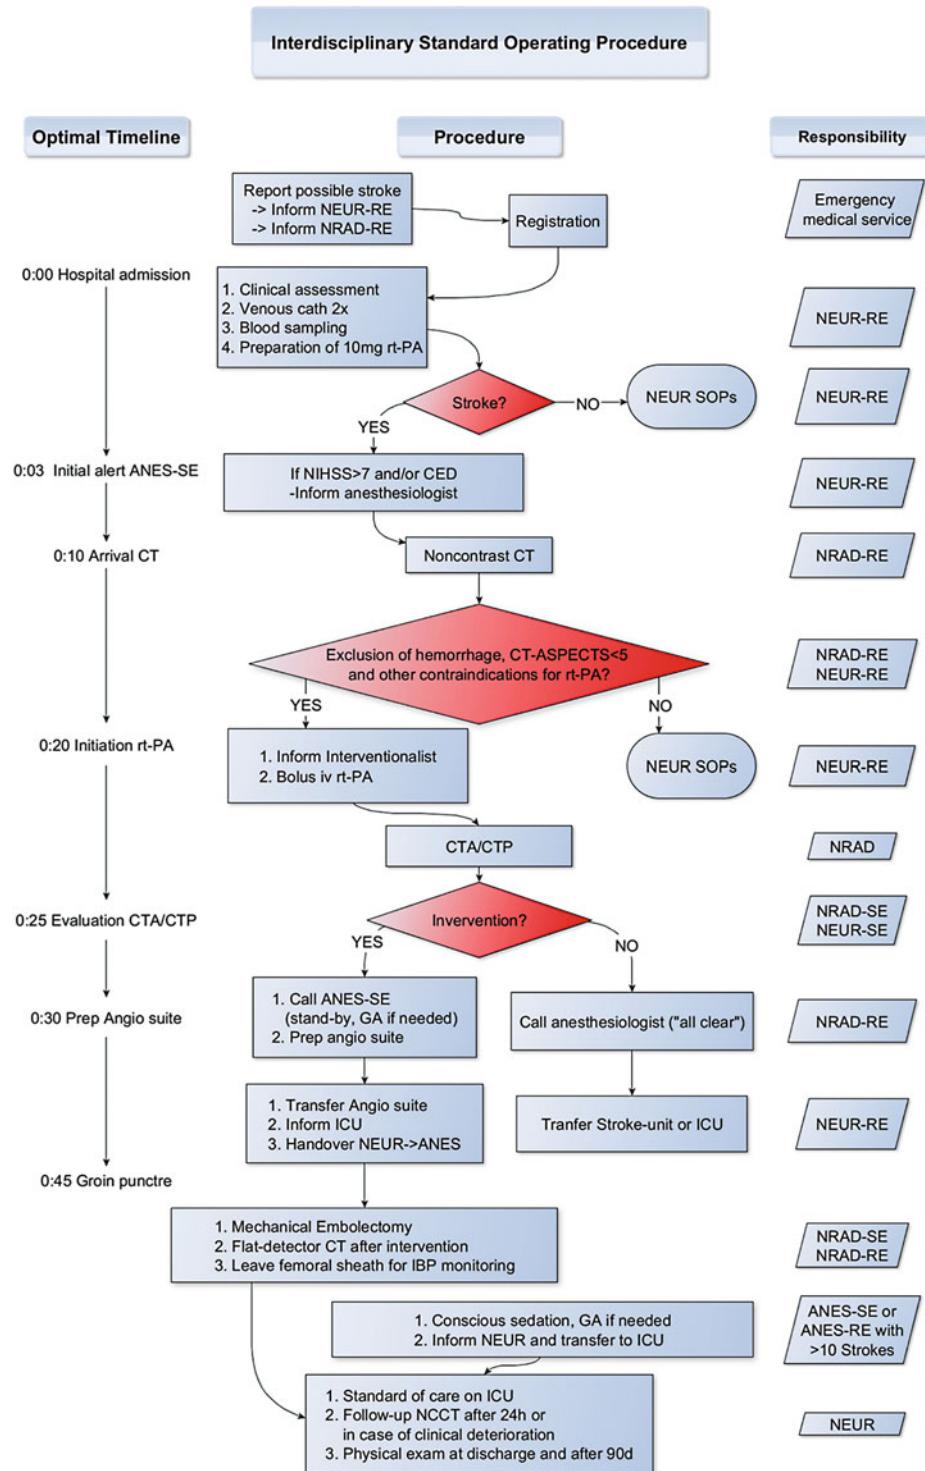

Intravenous alteplase is administered to eligible ischemic stroke patients who present within the prescribed time window (i.e., within 4.5 h of the symptom onset), do not have contraindications to iv alteplase, and do not show intracranial bleed on immediate brain imaging. Two NINDS trials demonstrated the safety and efficacy of iv alteplase in 3 h time window in acute ischemic stroke patients and were reported together in 1995 [5]. A pooled analysis subsequently showed that the odds ratio for the improved outcome declines rapidly after the symptom onset (Fig. 2) [6]. The need to quickly offer iv alteplase to eligible ischemic stroke patients led to the recognition that it was critical to avoid delays. With that objective, Hazinski et al. proposed a “stroke chain of survival and recovery” in 1997 [7]. The stroke chain of survival and recovery involves *seven Ds*: **d**etection (prompt detection of stroke symptoms), **d**ispatch (quick dispatch of the emergency services to a patient’s location), **d**elivery (rapid administration of prehospital care and quick transport of the

patient to an appropriate stroke center), **d**oor (efficient triage of the patient at the emergency department of the stroke center), **d**ata (quick clinical assessment and neuroimaging), **d**ecision (rapid interpretation of the clinical and radiological data and determination regarding which treatment pathway to pursue), and **d**rug therapy (decision to offer reperfusion therapy, or other therapy) [7, 8]. Rehabilitation is the next step in the stroke chain of recovery wherein the goal is to optimize a patient’s functional outcomes and integrate them into the social milieu. The algorithmic nature of stroke workflow creates an opportunity for the artificial intelligence (AI)-based tools to increase workflow efficiency.

AI-based tools have been implemented in the stroke care and research and include tools for the patient triage, image analysis, decision making with therapeutics and interventions, rehabilitation, and trial design. In this chapter, we describe the critical aspects of the stroke management, clinical contexts where the AI tools have been used, and suggest scientific questions that should be tackled using AI tools.

Artificial Intelligence

AI is a broad term used to describe the science and engineering of making intelligent machines. AI tools use a range of computer algorithms that learn from experience and allow machines to simulate human intelligence (chapters that inform technical aspects of AI). Deep learning is a subset of machine learning which in turn is a subset of AI. Machine learning-based imaging tools demonstrate their ability to rapidly perform objective and quantitative inspection of the subtle differences within and between the voxels, and these can be repeatedly performed on a large scale. Artificial Neural Networking (ANN) is an example of supervised machine learning that is inspired by the biological neural units that process the data in a manner similar to the brain neurons, that is, by the activation and inhibition of neurons. It can be used to build prediction models, and its advantage

**Fig. 1** An example of stroke care workflow [4]

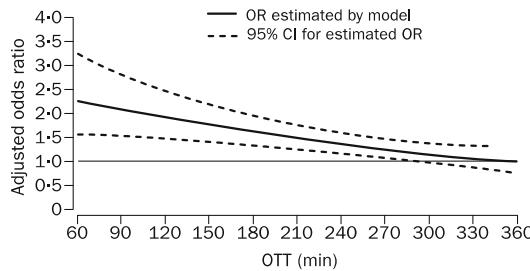

Fig. 2 Pooled individual patient data analysis of the NINDS, ECASS, and ATLANTIS trials showing adjusted odds ratio for favorable outcome at 3 months in ischemic stroke patients treated with iv alteplase [9]

is that it requires less input, less formal statistical training, and can handle nonlinear relationships between the variables.

Early Detection of Stroke Symptoms

The years 1995 and 2008 are the turning point in the history of stroke care when the NINDS trials and the ECASS III trial reported data to support the use of iv alteplase in eligible ischemic stroke patients up to 4.5 h of the symptom onset [5, 10]. Since 2015, several randomized trials have also shown that the patients with large vessel occlusion also benefit from mechanical thrombectomy up to 18 to 24 h of the symptom onset [11–17]. These data have led to major restructuring of the workflow to offer stroke care. The goal is to offer quick delivery of iv thrombolytic agent and/or endovascular recanalization to an eligible patient [18–21].

In the prehospital stage, a paramedic or mobile stroke unit team identifies the stroke symptoms, performs early assessment and information gathering, and in case of mobile stroke unit even administers iv alteplase, and then quickly prompts an appropriate stroke center – primary or comprehensive – with relevant clinical information [22–24]. Comprehensive stroke centers are chosen if the patient is potentially a candidate for endovascular treatment [25–28]. The communication is one way in this prehospital triage, and it is critical that the information sharing is not fragmented, recurrent, or disorganized [21, 29, 30]. The stroke care heavily relies on synchronized flow of information

throughout the stroke care pathway, and delays can occur at various levels during the stroke care pathway (Table 1) [21]. Automated communication system during the prehospital management can better prepare the receiving hospital to allocate resources as soon as the patient enters their facility [21]. An Australian group has reported a python-based electronic communication system to streamline code stroke alert pathway. This communication system has data fields relevant to each stage of the chain of stroke care to which data relevant to a provider's role can be input [21]. At the receiving end, this platform provides a tiered level access to data based on the role of the individual in the stroke care pathway [21]. Within this automated platform, AI-based tools can be integrated at each step to assist with decision making.

When called to evaluate a patient with stroke like symptom(s), the first major step is to ascertain that the patient's symptoms are truly of vascular origin. Missed diagnosis of acute stroke accounts for about 13% of the stroke presentation to an emergency department (ED) [31]. An analysis of ED data revealed that the patients with intracranial hemorrhage who presented with headache and ischemic stroke patients who presented with dizziness and headache were more likely to be missed [31]. Abedi et al. [32] built an artificial neural network (ANN) model that correctly differentiated acute cerebral ischemia from stroke mimic with a 92% precision. They used Neuralnet package of the freely available R software for the model development and applied back propagation-based learning followed by tenfold cross validation [32]. We propose that the ANN models like this can be integrated with in the electronic medical records of hospital networks to quickly analyze patient's data and advise the stroke team about the level of confidence in predicting a vascular cause of the patient's symptoms.

Patients with large vessel occlusion are offered endovascular recanalization and it is desirable to be able to select a patient population with greater likelihood of the presence of large vessel occlusion predominantly based on the clinical data available at prehospital stage. Chen et al. [33] reported an artificial neural network (ANN) algorithm that was associated with a high accuracy

Table 1 Common causes of the delay in reperfusion therapy [21]

Community	EMS	Hospital
Barriers to Timely Reperfusion		
Delayed or mistaken identification of stroke	Delay in arrival or inappropriate triage	Delay in initial assessment or triage
Delay in alerting EMS	Delayed assessment and information gathering	Delay in imaging acquisition or review
	Delayed decision-making	Delayed decision making
	Transport to hospital	Delay in activation of mechanical thrombectomy team
		Delay in transfer from the emergency department to angiography
		Delay in transfer from an ED to another mechanical thrombectomy-capable hospital

(82%), sensitivity (83%), and specificity (82%) for predicting large vessel occlusion (LVO) in the prehospital stage (see Table 2). This algorithm used the data available at the prehospital stage and included a patient's demography, National Institutes of Health Stroke Scale (NIHSS), and the patient's vascular risk factors [33]. The authors included patients who received reperfusion therapy within 8 h from symptom onset and assessed their CT or MR angiogram for the presence of occlusion in the internal carotid occlusion, M1 and M2 branch of the middle cerebral artery, and basilar artery [33]. This was a retrospective analysis and the stroke patients in this study had received reperfusion therapy. A better approach would be to design an AI-based model that uses large data of unselected stroke patients in the prehospital stage and prospectively determines the hidden predictive features to optimally classify patients into LVO and no LVO group.

Acute Stroke Therapy

When a patient with stroke symptoms arrives at a stroke center, patient's cardiorespiratory stability is ascertained and brain imaging is immediately performed; the goal is to determine whether the patient had a hemorrhagic stroke [34–37]. If there is no evidence of intracranial hemorrhage, the patient is a candidate for reperfusion therapy provided he has no additional contraindications [38, 39]. There is a potential to automate the steps leading to the administration of

thrombolytic agents and facilitate the treating physician. The automation would involve automated retrieval of patient's medical history and medication refill history to supplement the information obtained during the stroke code.

NINDS trials and ECASS III trials supported the use of iv alteplase within 3 h and 3–4.5 h of the symptom onset. Time since symptom onset is uncertain in patients with wakeup stroke or unwitnessed stroke. Mismatch between the Diffusion weighted imaging signal and fluid attenuated inversion recovery imaging signal (DWI-FLAIR mismatch paradigm) was proposed to select patients when the time since symptom was uncertain [40]. DWI-FLAIR mismatch is present if the patient's magnetic resonance imaging (MRI) reveals hyperintensity on DWI sequence and no hyperintensity on the FLAIR sequence and indicates that the patient is within the time window for receiving thrombolytic agent [41]. This approach, however, has limitation: this patient selection approach has limited sensitivity (0.78) and specificity (0.62); and interobserver agreement (0.57) is moderate [40]. Because of the limited sensitivity and moderate interrater agreement, DWI-FLAIR mismatch paradigm is not reliable. Deep learning approaches can, however, be applied to learn the “deep” features on DWI and FLAIR sequences; this approach can be used to correctly classify the patients for the patient's time since last seen normal and improve the reliability of DWI-FLAIR mismatch paradigm. Ho et al. [42, 43] used auto-encoder architecture for deep learning and demonstrated that stepwise multilinear regression

The ANN model included age, gender, prior antiplatelet therapy, 15 NIHSS items and nine risk factors, while ANN model^a only included 15 NIHSS items. FAST-ED indicates Field Assessment Stroke for Emergency Destination, 3I-SS indicates 3-item Stroke Scale, CPSSS indicates Cincinnati Prehospital Stroke Severity scale and LAMS indicates Los Angeles Motor Scale, PASS indicates Prehospital Acute Stroke Severity scale.

(SMR), support vector machine (SVM), random forest (RF), and gradient boosted regression tree (GBRT) were able to improve the classification of the stroke patients into a iv alteplase eligible group (time since symptom onset, i.e., <4.5 h) and ineligible group (time of symptom onset $>=4.5$ h) [42]. To be able to determine patient's time since symptom onset based on AI algorithm, and not merely on the family and EMS, will hasten the stroke work flow and also augment a physician's confidence on this key variable which is used to determine whether to administer a thrombolytic agent [42, 43].

Pooled analyses of iv alteplase trials revealed that the odds for improved functional outcomes decline rapidly over time, but stay statistically significant in the first 4.5 h of the symptom onset (Fig. 1) [9, 44]. In the time window 4.5 h to 6 h, the odds for improved outcomes are statistically nonsignificant and associated with a wider confidence interval (CI), that is, 0.9 to 1.5 [6, 9, 44, 45]. (Fig. 1) [44]. This suggests that in the time window beyond 4.5 h, there may still be patients who could benefit from thrombolysis; others may, however, be at an increased risk from delayed reperfusion therapy [46]. In order to select patients in delayed time window, a perfusion and ischemic core mismatch paradigm (PWI/DWI mismatch, for example) was proposed with a goal to identify ischemic stroke patients with persistent salvageable tissue (penumbra) [46, 47]. This model was supported by earlier EEG and PET studies. For example, in humans, the clamping of carotid artery results in flattening of the electroencephalogram (EEG) at the hemispheric blood flow below 0.16–0.17 ml/g/minute [48–50]. Cerebral blood flow below 0.10 ml/g/minute is associated with infarction (ischemic core), cerebral blood flow in the range 0.10 to 0.17 ml/g/minute is associated with ischemic penumbra (hypo perfused but salvageable brain tissue), and cerebral blood flow greater than 0.17 ml/g/minute is associated with the presence of benign oligemia or normal tissue [48–56]. The goal of reperfusion therapy is to prevent the growth of ischemic core into the penumbra. The goal of mismatch paradigm is to be able to distinguish the benign oligemia from true “penumbra.” An ideal approach to make this distinction would be to use

positron emission tomography (PET) imaging. PET can be used to quantify the CBF, regional oxygen extraction fraction, and the regional metabolic rate for oxygen. PET, however, is cumbersome in routine clinical setting; alternative approaches like MR- or CT-based perfusion imaging were therefore proposed. MR and CT perfusion imaging provide the perfusion metrics like time to peak (TTP), mean transit time (MTT), Time to peak (Tmax), cerebral blood volume (CBV), and CBF. These are calculated using the concentration time curve derived from a patient's cerebral artery and/or vein (Fig. 3) [57, 58].

A meta-analysis of the DIAS, DIAS-2, DEDAS, EPITHET, and DEFUSE trials revealed that mismatch-based delayed treatment resulted in the greater odds for recanalization; this, however, did not translate into improved clinical outcome with thrombolysis in 3–6 h time-window [46]. Some of the challenges with the earlier mismatch paradigm were the lack of automation during the postprocessing of the perfusion images (e.g., manual selection of the arterial input function), conservative thresholds of Tmax and mismatch ratio that therefore also included regions with benign oligemia, assumption of linear relationship between the signal change and concentration time curve, and eyeballing of lesion volume [46, 59–62]. Several challenges related to the use of the postprocessing of the perfusion imaging data have now been tackled. For example, contemporary postprocessing soft wares are now able to automatically correct the perfusion images for the errors due to motion and time of each imaging sequence, automatically select the location for measuring concentration time curve, correct for the nonlinear relationships related to the gadolinium in case of MR perfusion, perform deconvolution, compute perfusion maps for coregistration with the ischemic core maps (DWI in case of MR paradigm and rCBF $<30\%$ in case of CT perfusion), and provide mismatch summary maps (Fig. 4). Postprocessing softwares are now available through various vendors like IschemiaView (RAPID), Olea, and VizAI.

Automated postprocessing of perfusion imaging data has been a major advance in the use of

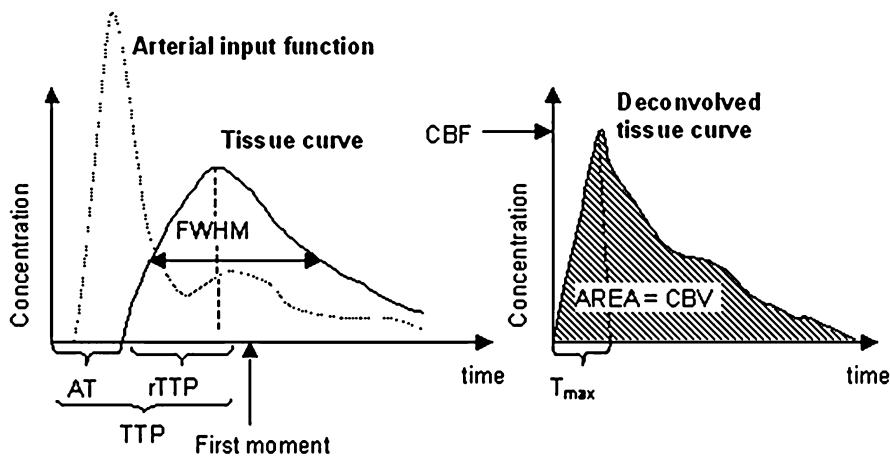

Fig. 3 Concentration time curve (time to peak (TTP), peak time fitted minus arrival time fitted; AT: bolus arrival time; FWHM (full width half maximum): width of the

concentration time curve at the point of halfway to the maximum concentration; 1st Moment: balancing point of the curve; AUC: Area under curve) [57, 58]

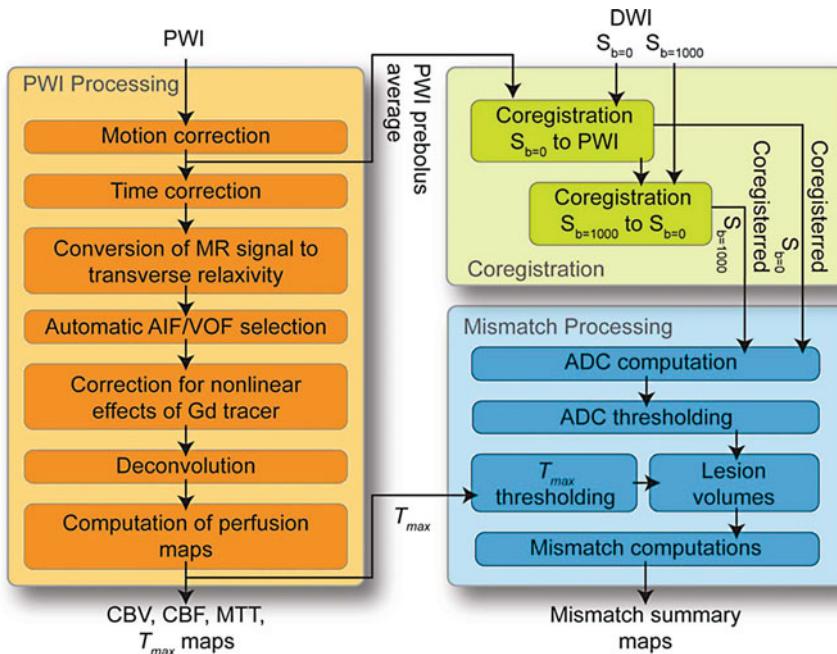

Fig. 4 Steps involved in the postprocessing of MR perfusion data by Stanford's RAPID software [63]

mismatch paradigm to select patients for reperfusion therapy. Automated detection of the concentration time curves, that is, the arterial input function (AIF) and venous output function (VOF), is an example of the use of artificial intelligence in perfusion imaging [63]. The automated, operator independent, selection of concentration

time curves (AIF and VOF) has removed the interrater variability which used to arise from manual selection and thus has given consistency to the calculation of the perfusion metrics [63]. Automation also saves the time in the post-processing of the perfusion data as this was a major challenge that precluded the use of

mismatch paradigm in selecting patients in the trials like EPITHET [46]. Matus Straka and colleagues at Stanford developed a postprocessing software called RAPID which has been used in several perfusion imaging trials. RAPID's algorithm automatically selects an optimal AIF and VOF locations by the following steps: first, it automatically identifies the height, arrival time, and the width of the concentration time signal at several brain locations and determines their average values; then the perfusion algorithm searches for the spatially clustered locations where the concentration time signals have an above average amplitude, below average width, and early bolus arrival time; and finally, the algorithm determines the best fit for these clustered concentration-time curves using the weights determined from the perfusion imaging data [63]. The algorithm ensures that the input function estimates are optimized for anatomically appropriate locations, that is, the large arteries and veins [63]. Thus, the RAPID software determines the location of the final input function over a vessel where the sum of the fit statistic (c) is maximum, and this includes a location with at least three adjacent pixels with the dimensions $1.88 \text{ mm} \times 1.88 \text{ mm}$ and six adjacent pixels with dimensions $0.94 \text{ mm} \times 0.94 \text{ mm}$ [63].

Despite being a major advance in the field of mismatch-based reperfusion therapy, the perfusion imaging algorithms are not without challenges. For example, whereas we use common perfusion thresholds for gray and white matter, there are differences between the two [64]. Relative CBF $<30\%$ best defines core in the gray matter (AUC 0.73) and $<20\%$ best defines the core in the white matter (AUC 0.67) [64]. Similarly, a Tmax delay of $>5 \text{ s}$ best defines a perfusion lesion in gray matter (AUC 0.80) and a delay of $>7 \text{ s}$ best defines a perfusion lesion in white matter (AUC 0.75) [64]. Postprocessing therefore ought to automate methods to select optimal thresholds for gray and white matter and determine core and penumbra threshold specific to the location of the individual brain region being analyzed.

Another challenge is that the postprocessing of the imaging data involves assumptions and

thresholds which are prone to introduce errors. Assumptions are involved in deconvolution of the AIF, the concentration time curve from artery, to generate residue function; and residue function is then used to calculate the perfusion metrics by curve fitting approach, a process which is prone to errors [65–67]. A major challenge is to calculate AIF in a voxel from the small vessel feeding into each voxel; a global AIF from a large vessel like a middle cerebral artery is therefore used. Independent component analysis has been reported to demonstrate how the local AIFs can be selected for postprocessing [68]. The characteristics of the AIF curve depend upon the patient-specific cerebrovascular anatomy and the cardiac function [66]. The variation in the local AIFs and cerebrovascular anatomy, physiologic changes from, for example, cardiac dysfunction, and the use of thresholded perfusion metrics like Tmax and relative CBF contribute to the errors in the measurement of perfusion metrics [69].

A major challenge with the contemporary perfusion imaging softwares is the significant reliance on the use of fixed thresholds of the perfusion metrics (e.g., $\text{Tmax} > 6 \text{ s}$ to define penumbra and $\text{rCBF} < 30\%$ to define core on CT perfusion). The deep convolution neural network-based algorithm can avoid the need for using thresholds by determining the tissue fate by learning the features directly from the concentration time curve thus not requiring the AIFs and the assumption-based curve fitting [69]. For example, Ho et al. applied a convolutional neural network-based AI approach on 4 dimensional (x, y, z, t) perfusion imaging data to predict final infarct volume [69]. They were able to show significantly improved prediction of tissue fate [69]. Deep convolutional neural networking has major strength in its ability to learn the data driven filters to extract complex features linked to tissue infarction. This approach is better than using model derived perfusion metrics like CBF because it does not require the use of error prone AIF or the assumptions used in deconvolution [69].

Regarding the choice of thresholds, a mismatch ratio >1.8 and Tmax delay threshold of $>6 \text{ s}$ is in use to define mismatch profile [70, 71]. These thresholds are not fixed, however.

The earlier perfusion imaging studies used to use a mismatch ratio of 1.2 and Tmax delay threshold of >2 s to define mismatch [46]. The older trials that used these conservative thresholds were found to be negative, and a common element noted for the failure of these trials was that these thresholds included patients with benign oligemia [46]. The variation in the thresholds of the perfusion metrics is due to the significant heterogeneity between the patient cohorts, variations in the postprocessing of the imaging data, and simplistic assumptions regarding the tissue physiology (e.g., the presence of collaterals, tissue type, lesion location, vascular delays, and dispersion effects). Because of the complex nature of these perfusion metric, certain thresholds are sometimes chosen out of trial design considerations. A secondary analysis of the DEFUSE [72] data showed that a mismatch ratio of 2.6 is associated with maximum sensitivity; [71] the DEFUSE trialists, however, selected a mismatch ratio of 1.8 to define the ischemic penumbra in the subsequent DEFUSE 2 [73], CRISP [74], and DEFUSE 3 [17] studies, out of the trial enrolment consideration [17, 73, 74]. The problem of a fixed threshold is greater with CT-based perfusion imaging paradigm where not only the perfusion metric is derived from thresholding, the ischemic core is also determined from an optimized threshold of relative CBF, and a threshold of $<30\%$ is commonly considered to be an optimal value [75]. In the sphere of perfusion imaging, DWI hyperintensity is considered a gold standard to define ischemic core; however, this metric is also not without challenges. For example, diffusion reversal, even though is rare, does occur [76–80]. Automated segmentation of DWI lesions is prone to errors as well [77, 78]. For example, the $b = 1000$ images are preferred by human eyes to visualize the DWI lesions, but these cannot be used to automate segmentation using computing software [63]. RAPID, for example, uses an ADC threshold of $<600 \times 10^{-6} \text{ mm}^2/\text{s}$ to automatically define DWI core arguing that this threshold is more acceptable for computerized segmentation and removes the noise due to the artifacts like T2 shine through, susceptibility pile up, and coil sensitivity field variation [63]. In order to avoid the need for

using fixed thresholds, convolution neural network can be used to yield more reliable volumes and location of ischemic core. Chen et al. [81] have attempted this AI approach: they used the first fully automated deep convolutional neural networks to segment the acute ischemic stroke lesions on DWI. They then validated their approach on a large clinical dataset achieving good dice coefficient (mean: 0.67; small lesion: 0.61; large lesion: 0.83) [81]. Chen et al. also observed that the approach by combining the EDD Net and multiscale convolutional label evaluation (MUSCLE) Net approach gave the best results [81].

Perfusion imaging technology not only can identify mismatch; it can also prognosticate the risk of the ischemic brain regions to develop hemorrhagic transformation, the most feared complication of reperfusion therapy. For example, the brain regions with significant Tmax delays, blood brain barrier disruption, and very low cerebral blood volumes have been shown to be at an increased risk of hemorrhagic transformation and poor outcomes [82–85]. AI tools can be used to learn the deep features of the Tmax delays, low CBV, and permeability changes to determine the risk of hemorrhagic transformation. AI tools should also be designed to provide an easy to interpret metric that informs a physician regarding its “confidence” on the output that the algorithm generates.

It can be argued that the perfusion-diffusion mismatch paradigm is a simplistic dichotomous predictive model of patient outcome [71]. Mismatch ratio has both interindividual and intervoxel variability; a common threshold should therefore not be applied. PET-based selection of mismatch would be more reliable, but it is challenging to use it in an acute stroke setting [57, 58]. It is, however, possible to train the deep learning algorithms like deep convolutional neural network on patients with subacute and chronic ischemia and then apply this model in acute stroke setting for defining optimal volume of mismatch.

MR CLEAN proved that the showing of arterial occlusion at stroke onset was critical to the success of endovascular treatment [11]. The site of arterial obstruction strongly predicts patient

outcomes [86]. Endovascular recanalization relies heavily on the prompt detection of the intracranial large vessel occlusion (LVO). Several vendors have developed automated software for this purpose. The presence of an LVO is associated with nonopacification of the vessel distal to the occlusion and results in reduced vessel density on the side of vessel occlusion [87]. Algorithms built for this purpose look out to detect the hemispheric differences in the vessel densities within the suprasellar cisterns and sylvian cistern [87, 88]. The RAPID applies the following steps in the detection of LVO: perform motion and tilt correction of the CTA raw data; align the human head template with the CTA data; create masks by warping the templates off of the anatomic structures like the bones; use bone mask to remove the skull base and calvarium; dichotomize the intracranial vessels into large and small vessels based on the vessel dimensions; calculate the vessel density and compare the vessels to their contralateral counterpart, first with in suprasellar and proximal sylvian cistern, then distally; build maximum intensity projections (MIPs) of the vasculatures from the bone masked CTA; and apply color code to the vessels depending on the difference in the interhemispheric vessel density on the MIP images [87]. To detect an LVO, vessel density threshold of 75% or less is applied by the RAPID software [87]. Amukotuwa et al. [87] reported 92% sensitivity, 97% negative predictive value, and 81% specificity for the detection of intracranial LVO or M2 segment vessel occlusion using the RAPID's fully automated LVO-detection tool. The study highlighted that the false positives commonly resulted from the vascular asymmetry [87]. RAPID's processing time is $</=5$ min [87]. Automated detection of LVO is particularly useful at the smaller centers where radiology services are not always available, and the findings of LVO by this software can automatically alert the nearest comprehensive stroke center initiating a prompt transfer of the patient to a center equipped with tools and expertise to provide mechanical thrombectomy [87].

Because mechanical thrombectomy is now offered as a standard of care, it is now possible

to investigate the pathologic and radiologic characteristics of the cerebral clots causing stroke [89, 90]. A clot perviousness can be calculated by subtracting the CT attenuation measured using noncontrast CT head and CTA head from the clot location [91]. Both the functional outcome and successful thrombectomy are linked to the perviousness of the clot in the cerebral vasculature [91–94]. The clot perviousness can guide an interventionist regarding whether the clot will lyse from the iv or intra-arterial thrombolytic agent or whether mechanical thrombectomy would be needed. AI-based approach can automate the measurement of clot perviousness and incorporate it in the CT/CTA head protocol for use in routine clinical practice.

Successful recanalization is not an equivalent of successful reperfusion. Despite successful recanalization, patients do not show improved outcomes. The clinical outcomes depend not only on the degree of penumbra salvaged or the degree of vessel recanalized; they also depend on the other clinical variables like the oxidative stress from the interaction of hyperglycemia and ischemia or the activation of inflammatory cascades. Large clinical database linked to patient images should be exploited to better automate AI-based prediction of patient outcomes.

Role of AI in the Subacute Phase and Follow-Ups of the Ischemic Stroke Patients

The goal of stroke management in the subacute phase is to determine the stroke mechanism. This is done regardless of whether a stroke patient received reperfusion therapy or not. It is critical to determine the stroke mechanism because it guides the physician to adopt measures to prevent stroke recurrence. A popular classification of the stroke mechanism is the Trial of Org 10172 in Acute Stroke Treatment (TOAST) criteria and includes the following subtypes: (1) large-artery atherosclerosis (embolus or thrombosis); (2) cardio embolism (high-risk or medium-risk); (3) small-vessel occlusion (e.g., lacune); (4) stroke of other determined etiology; (5) stroke of

undetermined etiology (with either two or more causes identified, negative evaluation, or Incomplete evaluation) [95]. Based on the degree of certainty, these subtypes are referred as possible or probable [95].

Early detection of atrial fibrillation in stroke patients is critical because the showing of atrial fibrillation indicates that the stroke mechanism was cardio embolism and the patient should be started on anticoagulation therapy to prevent stroke recurrence linked to cardioembolism. Early identification of atrial fibrillation is also critical because its management can prevent heart failure and death in these patients. Hence, these patients are started on continuous electrocardiogram (ECG) monitoring during their hospital stay, and if no atrial fibrillation is detected by the time of their discharge, a loop recorder is often applied to remotely monitor cardiac rhythm. An AI algorithm can be used to carefully analyze the hidden ECG patterns to detect the risk of atrial fibrillation much earlier than they are detected in routine ECG monitoring. Attia et al. [96] developed an AI-enabled ECG using convolutional neural network to detect the ECG signature of atrial fibrillation. This analysis was based on a very large database: 180,922 patients with 649,931 normal sinus rhythm ECGs [96]. A single AI-enabled ECG identified atrial fibrillation with 79.4% accuracy, 79% sensitivity, and 79.5% specificity [96]. When the ECGs obtained during the first month after the stroke onset were analyzed, the accuracy increased to 83.3%, sensitivity to 82.3%, and specificity to 83.4% [96]. Kashaou et al. [97] reported a case of a 92-year-old woman with hypertension, diabetes mellitus, and peripheral arterial disease patient who had recurrent cryptogenic strokes (left frontal and five years later a posterior circulation stroke with acute right leg ischemia) but repeat ECGs and cardiac monitoring found sinus rhythm. Her echo at the time of first stroke revealed left atrial enlargement, but because of no evidence of atrial fibrillation on ECG or outpatient Holter monitoring, she was continued on antiplatelet therapy [97]. Her second stroke occurred 5 years later [97]. This time, transesophageal echocardiogram revealed left atrial enlargement with left atrial thrombus, and therefore, she was started on anticoagulation

[97]. The ECG and cardiac monitoring at the second stroke again showed sinus rhythm [97]. A retrospective AI-enabled analysis of her prior ECGs revealed that the earliest detection of atrial fibrillation risk could have occurred 12 years prior to her first thromboembolic event [97]. Despite an elevated CHA₂DS₂Vasc score, this patient could not be started on anticoagulation therapy after her first stroke. It is unclear what exactly the AI enabled ECG sees that human eyes do not; however, validation of this approach in other stroke patient population will potentially pave the way for primary stroke prevention in patients likely to develop cardioembolic stroke from an atrial fibrillation.

Whereas stroke mechanisms linked to large artery atherosclerosis or cardio embolism can relatively easily be determined by the means of vessel imaging and telemetry (or loop recorder at discharge), about 25% of the ischemic stroke patients continue to have an undetermined stroke mechanism; this group has historically been referred as having a cryptogenic stroke [98]. Embolic Stroke of Undetermined Source (ESUS) is a recent construct developed to identify and enroll ESUS patients in anticoagulation clinical trials [99]. ESUS is defined as the stroke subtype in which the patients have a nonlacunar brain infarct, vessel imaging reveals <50% luminal stenosis in the arteries supplying the ischemic region, and thorough work-up is unable to reveal a major risk of cardioembolic source or other specific cause of stroke like arteritis, dissection, vasospasm, or drug abuse. Potential embolic sources in ESUS are (a) atrial cardiopathy (defined on echocardiogram as left atrial dilatation or increased left atrial diameter (>38 mm in women and >40 mm in men); or on ECG as the presence of supraventricular extrasystoles), (b) atrial fibrillation, (c) left ventricular (LV) dysfunction (defined as low LV ejection fraction (<35%), LV hypertrophy, left sided heart failure, or LVH on ECG using Sokolow's index >/=35 mm), (d) cardiac valvular disease (moderate to severe stenosis or regurgitation), (e) patent foramen ovale, and (f) cancer [100, 101]. AI-based algorithms can be used to determine stroke mechanism, including the potential sources of embolism in ESUS. For example, Ntaios et al. [102] applied unsupervised machine learning approach, namely,

hierarchical clustering, on the data from three registries (Acute Stroke Registry and Analysis of Lausanne (ASTRAL), Athens Stroke Registry, and Larissa Stroke Registry), to investigate the potential sources of embolism in ESUS patients. They determined four optimal clusters using data-driven machine learning analysis and identified clusters strongly associated with arterial disease, arterial cardiomyopathy PFO, and left ventricular disease [102]. Kamel et al. [103] used machine learning approach on the patients lodged within the Cornell Acute Stroke Academic Registry (CAESER) to distinguish cardioembolic vs. noncardioembolic etiology. This distinction is critical because of the therapeutic implications. Stroke etiology was determined in 1663 patients (large artery atherosclerosis, $N = 291$; cardiac embolism, $N = 688$; other determined etiology, $N = 104$) and cryptogenic in 580 patients [103]. Kamel et al.'s predictive model distinguished cardioembolic from noncardioembolic with a very high validity (AUC 0.85) among the 1663 patients with determined stroke etiology [103]. They used an ensemble machine learning method known as super learner algorithm to subsequently compute a Bayesian targeted machine learning estimator. This machine learning estimator detected that 44% of the ESUS cases were due to occult cardioembolic source [103]. Among the 580 patients who were classified as ESUS patients, the machine learning estimator found a significantly increased predicted probability of cardioembolic source and eventual detection of atrial fibrillation.

Use of AI in the Management of Transient Ischemic Attack

Transient ischemic attack (TIA) is a major risk factor for stroke [104, 105]. It is critical to rapidly identify it and take measures to reduce the risk of subsequent TIAs and/or stroke. Perfusion imaging, including artificial spin labeling, can play an important role in its detection [106]. Prolonged Tmax or MTT, for example, can support that the presenting semiology is neurovascular (i.e., TIA) even though the clinical symptoms were transient. Approximately one fourth of the TIA patients are also found to have a DWI lesion, and this changes

the diagnosis from TIA to silent stroke [107]. Perfusion imaging-based TIA detection algorithm can be incorporated in stroke workflow for AI-guided automated detection of patients with TIA [106, 108–110]. For example, in a study that use the convolutional neural network to predict the cause of TIA like presentation, the AUC was greatest ($88.3 +/− 3.6$) when the network was given the patient's presenting complaint and MRI report [110].

Role of AI in the Management of Intracerebral Hemorrhage

Spontaneous intracerebral hemorrhage (ICH) accounts for about 20% of the strokes and is associated with very high mortality [111]. Despite significant efforts, there has not been major success in therapeutic management of these patients. A management workflow is shown in Fig. 5.

Hematoma volume is a significant predictor of outcomes. About 30% of the cerebral hematoma expand over time and are associated with further clinical worsening because they worsen the mass effect. It is critical to identify patients who are more likely to develop hematoma expansion. AI approach to detect this patient population would be useful. Liu et al. [113] have reported a support vector machine-based AI algorithm which learns from observing the ICH datasets ($N = 1157$ patients) and intrinsically builds complex models to determine relationships between the covariates and the outcome of interest (i.e., hematoma expansion). Automated stratification of a patient's predicted outcome will not only inform the patient's family with regards to the goal of care discussion but also held design better trials.

Future Directions

Prompt treatment of acute stroke, its cause, and complication is critical to reducing the morbidity and mortality. Futures studies that validate the AI approach are needed to allow for its greater acceptance in the routine clinical practice. The goals of AI in stroke management are to facilitate the physicians and not replace them, and it is expected

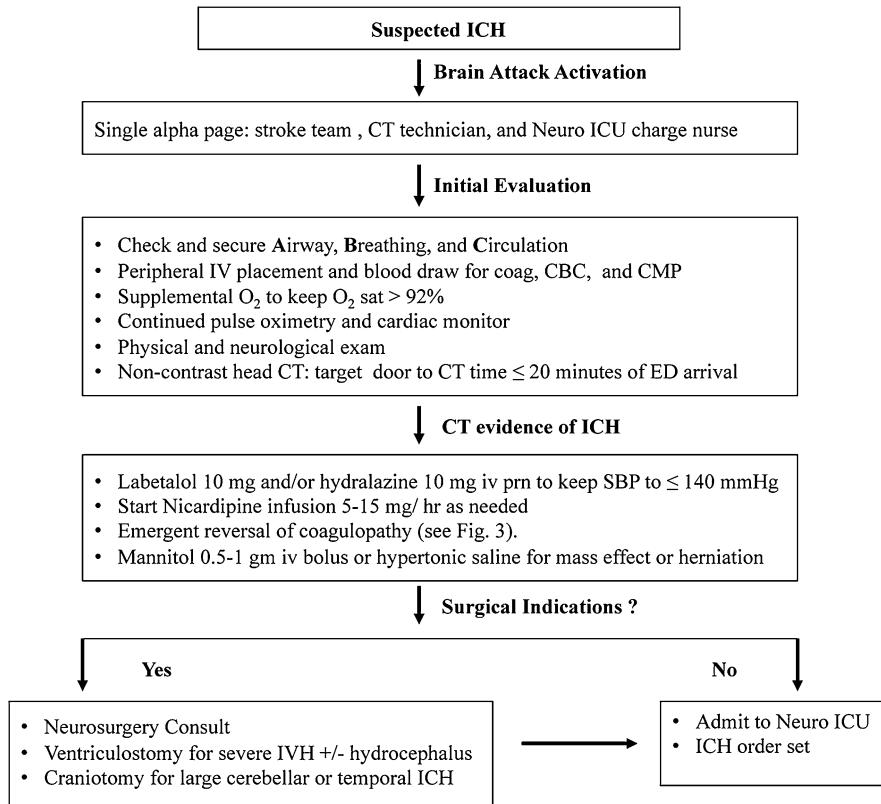

Fig. 5 Work flow for the management of intracerebral hemorrhage [112]

that the AI tools will soon become a valuable partner of the physicians. A physician's decision making would significantly improve if AI tools provide timely information that the physician would otherwise take a while to process himself. Information of the risk of drug interactions or side effects, patient suitability for reperfusion therapy, identification and prediction of stroke mechanism, and integration of wealth of clinical, proteomic, and genomic data to individualize patient care would be a great leap forward in the patient care. As an example, radiologists are confronted with a huge volume of imaging data to sift through. AIDOCs which runs in the background highlights the images (and regions therein) for the radiologist to give greater attention and thus prevent missing clinically important imaging feature.

An AI algorithm engineer needs a clearly defined ground truth based on a clinician's expertise; a clinician needs technical expertise to design algorithm suited to the clinical needs. A symbiotic relationship between the stroke researchers, AI

algorithm engineers, and regulatory bodies would be crucial to advance the use of AI in stroke medicine [114].

Abstract

Artificial intelligence and its facets of machine and deep learning have permeated into the fabric of our society with widespread adoption. However, the medical community is only recently beginning to embrace its potential for applications in various subspecialties. Clinical neurophysiology, neurology, neurosurgery, and the rest of the neurosciences are seeing considerable impacts in how AI is being utilized across these specialties. EEG analysis using deep learning in the field of neuro-pathophysiology is also gaining rapid traction with a myriad of emerging applications suggesting promise. However, although deep learning has shown considerable potential, the lack of transparency about how models make decisions and the barriers to entry curtail acceptability among clinicians. Some have argued that the stakes for erroneous judgments in the diagnostic pathway remain too high to be completely reliant on AI, while others have embraced its potential and are delivering services using AI. This chapter discusses the role of AI in clinical neurophysiology with an extended focus on epilepsy and EEG analysis. We also highlight some of the areas where AI and its applications have been adopted for characterization of other neurophysiological diagnostic modalities, for instance, in migraine, and end with a discussion of model explainability.

Keywords

Introduction

As a subspecialty of clinical neurosciences, neurophysiology provides theranostic avenues for patients with a myriad of neurological diseases ranging from peripheral nervous system disorders, disorders of muscle, and nerve conduction abnormalities to central nervous system disorders such as Parkinson’s disease, spinal cord pathology, and epilepsy.

Traditionally, investigations in clinical neurophysiology have fallen into two facets: (a) the study of brain function using electroencephalography, on the scalp or direct to brain contact electrode recordings of the intrinsic electrical neuronal activity, and (b) the study of peripheral nervous system disorders using electromyography and nerve conduction studies. The latter can provide precise information about neurodegeneration or neuronal dysfunction at the ion channel, neuromuscular junction, or corticospinal tract level. While the former can precisely identify aspects of intracranial neuronal dysfunction at millisecond resolution and correlate it to brain structure, these investigations are still supplementary adjuncts to the patient’s history and examination, which form the basis of all neurological diagnosis.

Over the past 100 years, this subspecialty has also evolved into supporting intraoperative monitoring of neuroanatomical pathways during epilepsy surgery, Parkinson’s disease surgery, spinal cord surgery, and brain tumor excision. Functional monitoring and brain mapping are used to alert or forewarn the surgeon of likely iatrogenic injury to eloquent areas within the central nervous system. Monitoring establishes baseline amplitude, latencies and frequencies, or the presence of discharges to

enable ground truth comparison with abnormal changes in these areas, whereas testing localizes normal functioning eloquent tissue and also differentiates it from dysfunctional tissue for surgical resection [1].

Similarly, over the past 50 years, since Turing and collaborators hinted at intelligent machines within the field of AI, Hinton and others have made important contributions with deep learning [2]. It has seen widespread adoption in various medical specialties, as one can read in the respective chapters. Over the past decade, the field has seen unprecedented growth in applications of AI for neuroscience specialties as well.

The focus of this chapter will primarily be on functional brain monitoring and diagnostics using electroencephalography and the applications of AI and machine learning in this area, with an additional focus on epilepsy. However, we will also briefly identify aspects of brain mapping where progress has also been made using machine learning.

Epilepsy

Epilepsy is defined as a disorder of the brain characterized by an enduring predisposition to generate epileptiform seizures and the neurobiological, cognitive, psychological and social consequences of this condition [3]. Epilepsy is the term used to describe a recurrent seizure disorder.

An epileptic seizure is the transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain [3]. Seizures and epilepsy are common: 1 in 20 people will experience a single seizure at some point in their life and 1 in 50 will have epilepsy [4].

The approach to any patient presenting with epilepsy is to classify it as accurately as possible as this has a significant impact on the approach to treatment. The current approach to diagnosis operates at three levels: seizure type(s), epilepsy type(s), and epilepsy syndrome. Where possible, a diagnosis at all three levels should be

sought as well as the etiology of the individual's epilepsy [5].

The first diagnostic quandary for any patient presenting with seizure(s) is to classify whether the problem is focal or generalized.

The term "focal-onset epilepsy" is best understood in its unifocal variation. Unifocal-onset epilepsy indicates that a person's seizures arise from a focal lesion within the brain matter and then may or may not spread to other brain regions. The epileptogenic lesion can be caused by a wide variety of insults including infection, trauma, tumors, and strokes to name a few. The lesion produces paroxysmal, stereotyped signs and symptoms which can then progress on to a generalized seizure if the abnormal neuronal activity spreads.

The diagnosis of "generalized epilepsy" is made on clinical grounds and a clinician would have to identify that the individual experiences a range of seizure types including absence, myoclonic, atonic, tonic, and tonic-clonic. Importantly, the patient's electroencephalogram (EEG) would typically show generalized spike-wave activity and support the diagnosis [5].

This chapter will focus on the diagnostic challenges that clinicians and patients face at various stages along the patient pathway and the ways in which AI/machine learning could support this.

Artificial Intelligence, Machine Learning, and Deep Learning

Artificial intelligence is an umbrella field encompassing machine learning and deep learning. Machine learning combines statistics and computer science to develop algorithms. These algorithms are used on large meaningful datasets and refine themselves to improve performance. Machine learning paradigms can be divided into supervised, unsupervised, semi-supervised, transfer, and reinforcement learning paradigms. However, the algorithms familiar to most machine learning scientists usually leverage supervised, unsupervised, and reinforcement approaches for their training.

Various aspects of machine/deep learning are described below, but readers are encouraged to also refer to the earlier chapters of the book where we summarize some of these concepts. In the context of neurophysiology, supervised learning involves training an algorithm that maps a function containing an input of neurophysiological datasets to an output space by using, for example, labeled ground truth training data that is provided directly to the algorithm. This labeling is usually performed by an expert clinician or scientist forming the ground truth. Unsupervised learning algorithms, on the other hand, draw inferences from input neurophysiological datasets without any need for labeling. The data can be structured or unstructured and the most common approaches have been clustering and dimensionality reduction methods. We summarize both approaches below. However, general data science best practice principles should also be implemented from the data mining perspective, including clinical neuro-electrophysiological data preprocessing and cleaning, data integration and data transformation, etc.

The steps for a supervised approach vary but usually require the following:

- Acquisition of adequate well-prepared training data based on the preference of the researcher or clinician and based on the question they are trying to answer.
- The training set is sampled using the appropriate sampling methodology that must be representative of the current data universe of interest.
- The input features that are to be represented could either be feature-engineered into an appropriate vector space or in some instances could require dimensionality reduction to enable optimized training and improved model accuracy. Poly-dimensional datasets are common in neuro-electrophysiology.
 - Note that this step of dimensionality reduction is an unsupervised approach, but it is sometimes required for optimal supervised learning in a multidimensional dataset.
- The feature set, which may sometimes also require scaling or normalization as some of

the algorithms may need this for optimal learning.

- Selection from an appropriate class of models and in some cases a universe/an ensemble of models or designing the right learning model architecture that would be optimal for framing the dataset.
- Hyperparameter optimization or tuning of the model where specific hyperparameters are tweaked to optimize the output to a desired level of accuracy and to identify the best bias-variance trade-offs.
- Model accuracy evaluation and metric reporting.
- Production deployment of the model for inference.
- Designing and building a user-friendly dashboard or interface for user interactivity to apply a trained model to solve new problems.

Some of the steps above are in some cases combined into frameworks that abstract away the complexities to the basic steps of data preprocessing, train-test splitting, model selection, model training, and inference reporting.

The unsupervised approach usually requires no labeled data and uses self-organization to identify latent features within the dataset that may not be easily discernible or apparent to the researcher.

The approach nonexclusively includes the following:

- Data acquisition using an appropriate sampling methodology as explained above.
- Principal component analysis, K-best, or other dimensionality reduction analysis on the dataset to limit the “curse of multidimensionality” as mentioned in machine learning parlance.
- Eigenvector decomposition analysis on the covariance matrix of features given to the model.
- Feature vectorization and scaling methods used are also similar to the above supervised model-dependent learning approach.
- Model learning of a new feature space that captures the characterization of the original unlabeled feature matrix.

Table 1 Summarizes some examples of supervised and unsupervised learning algorithms. Some have both regression and classification derivatives

Supervised	Unsupervised
Common regression algorithms Linear Logistic regression Ridge regression	Clustering K-means clustering Hierarchical clustering OPTICS DBScan

Machine Learning and Deep Learning Approaches in Epilepsy

The Role of History-Taking and Where Deep Learning Can Make In-Roads

The foundation of epilepsy and other neurological diagnoses lies in a detailed account of the patient's medical history from the patient or their carer. A thorough profile is required consisting of the patient's demographics, age of onset, family history, seizure semiology, seizure frequency, triggers, risk factors, drug history, driving status, and substance misuse. Before the use of imaging or EEG, a clinician uses these inputs to judge whether a patient's given events and history are suggestive of a seizure/epilepsy. A pretest

diagnosis is generated, which the investigations then support or refute. Often, patient history carries the greatest weight in coming to a final diagnosis. This is because, in many circumstances, imaging and EEG return normal results. In focal epilepsy caused by small lesions, imaging with modern 3-tesla magnetic resonance scanners does not have enough resolution to identify them and EEG is only helpful if a recording is made during a seizure [6]. Thus, many patients with a classical history of seizures are often formally diagnosed and started on medical treatment even though their investigations are normal [7].

This foundational aspect of patient assessment is the one part of the patient journey where deep learning processes have seldom been applied. This is not surprising. In comparison to imaging and EEG, this person-to-person interaction is inherently more difficult to encode into the required datasets necessary for deep learning to be effective. Nevertheless, there may be a role for screening patients using pre-clinic questionnaires.

For example, take a patient who presents to primary healthcare services with transient loss of consciousness. The current method by which patients are referred to First Fit Clinics is time-consuming for primary healthcare practitioners

and results in a heterogenous group of etiologies. Recent studies suggest that 17–35% of patients referred to a First Seizure Clinic do not have epilepsy and could be better served in other specialty clinics [8, 9]. Instead of a non-specialist taking a curtailed history in a time-pressured environment, the general practitioner could point the patient/carer in the direction of an online questionnaire. The responses to the questionnaire would then be fed into a predictive model, which has been trained on a previously encoded dataset. The model could judge from these responses whether the patient's events fall into one of three categories (vasovagal syncope, cardiogenic syncope, or seizure) and advise on the best referral pathway. This could greatly decrease the burden on primary and acute healthcare services and decrease the time taken for patients to see the correct specialist for their complaint.

Deep Learning Approaches for Investigating Epilepsy

As deep learning analyzes large datasets, its utility in interpreting investigative material for epilepsy patients has been of growing interest. The areas of interest include seizure detection, neuroimaging analysis, and EEG analysis.

Seizure detection/prediction is of great interest as it promises to solve multiple problems for clinicians and patients. As mentioned above, a major challenge in diagnosis is the fact that seizures can be infrequent and vast resources are required to constantly record and interpret video-EEG data. Time-locked video-EEG is the gold standard for diagnosing seizures and requires multiple days of scalp EEG and at least one video feed. Currently in the UK, this means admitting a patient to a video telemetry room for 3–5 days and all the costs that this incurs. Automated seizure detection could reduce the need for an expert reviewer and lower diagnostic and treatment costs.

Novel approaches have been used in both adult and pediatric settings. Karayiannis et al. examined limb movements in bedside video recordings, training neural networks to classify recordings as focal clonic seizures, myoclonic seizures, or non-seizure movements [10]. They report seizure

detection sensitivities of 85.5–94.4% and specificities of 92.5–97.9% on a matched testing set. Other groups have added EEG data to video feed with incremental gains on diagnostic accuracy (sensitivity 96.2%, specificity 94.2%) [11]. The former studies are impressive not just because of the accuracy of the algorithm but due to the fact that this could be achieved on video data alone.

While video recording is cheap, accessible, and reliable when recording infants, adults can be a more difficult cohort as they often live lives outside of the camera's view. Accelerometers are cheap and robust and, when paired with a simple surface electromyography electrode, can reach sensitivity of 90.9% and clinical latency of 10.5 s [12]. This promises clear benefits for carers as they could be alerted each time the system detects a possible seizure.

Image analysis constitutes an important aspect of diagnosis and preparation for surgery in focal epilepsies. Machine learning has been deployed in the interpretation of various imaging modalities including magnetic resonance imaging (MRI), fluorodeoxyglucose positron emission tomography (FDG-PET), and diffusion tensor imaging (DTI). Of greatest interest to most healthcare systems are the MRI studies, as they are the most readily available. Of course, one would not require the assistance of advanced neural networks in locating large obvious lesions. The main utility would be in identifying small epileptogenic lesions often missed by human experts. El Azami et al. trained a neural network to identify heterotopias and blurring of the gray-white matter junction as outliers on T1-weighted images from 77 healthy controls. The testing run on 11 patient scans attained a sensitivity of 77% with a mean of 3.2 false-positive detections per patient, compared to a sensitivity of 54% and an average of 6.3 false positives using state-of-the-art gold standard statistical parametric mapping (Wellcome Centre for Human Neuroimaging, London, UK) [13].

Machine Learning for EEG Analysis

EEG records electrical activity of the brain and usually requires specific electrode placement according to international 10–20 electrode

Machine Learning for EEG analysis

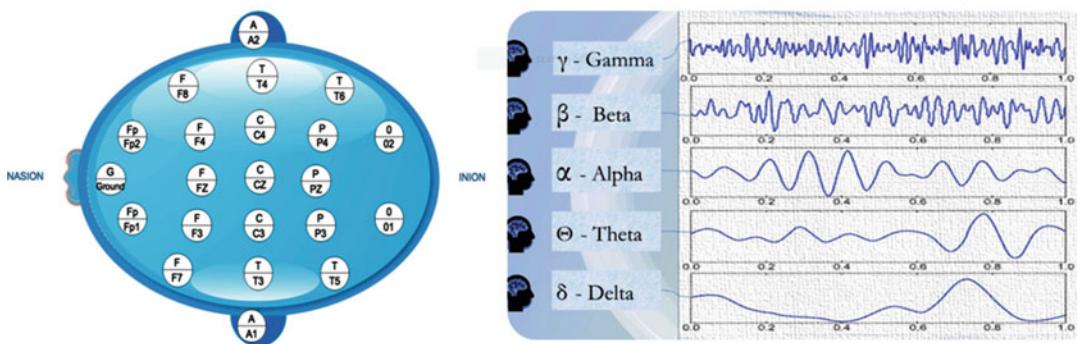

Fig. 1 Diagram of a single plane projection with electroencephalographic electrode placement. Left is the topographical map of a 21 EEG channel subset of international 10–20 placement common in all recordings and included in TUH Abnormal EEG Corpus (v2.0.0) first presented in the 1958 by Jasper [14, 15]. Right is the main characteristic EEG waveforms classified based on

placement criteria (see Fig. 1) [15]. Optimal electrode placement involves identifying landmarks such as the nasion, the inion, and the preauricular points that will provide the best signal-to-noise ratio.

- The electrodes can be placed in various, but specific, regions on the head and must have good contact with the skin of the scalp to limit impedance. Placement usually requires experience.
- Occasionally, sphenoidal electrodes are placed to enable deep structural recordings.
- There is also a routine need to reference the heart's rhythm through an ECG.

Based on placement, the EEG can be monitored using a montage-based system to generate functional outputs.

Montages include the following:

1. Bipolar montage
2. Referential montage
3. Average reference montage
4. Laplacian montage

An in-depth review of these approaches is beyond the scope of this chapter, but readers are referred to Siuly et al. [16]. For a physiologically normal adult, the reported amplitude of an

frequency and morphology. Gamma waveforms predominate during brain concentration and problem-solving. Beta activity reflects high brain activity or anxious states. Alpha arises during restful reflective states. Theta predominates during drowsiness. Delta is the asleep state. F, frontal; Fp, frontopolar; T, temporal; C, central; P, parietal; O, occipital; A, auricular (ear electrode)

EEG signal ranges from 1 to 100 μ V, and it is approximately 10–20 mV. The various detectable waveforms that have been characterized are:

- Delta with a frequency of ≤ 3 Hz
- Theta with a frequency between 3.5 and 7.5 Hz
- Alpha with a frequency between 7.5 and 13 Hz
- Beta with a frequency of ≥ 14 Hz
- Also, gamma oscillations >30 Hz

Machine learning could be used to study the optimal electrode placement when designing the EEG electrode cap and to educate trainees to be familiar with placement. This, together with sampling frequencies and other aspects of EEG recordings, could benefit from optimized and patient-targeted machine learning approaches (Table 2).

Deep Learning in Epilepsy Treatment

Across much of the world, most newly diagnosed patients with epilepsy are treated by primary healthcare practitioners. Some of these patients will respond to the first anti-epileptic drug (AED) they are prescribed, but those that do not are referred to a general neurologist. After the trial of the first drug, we know that further medication

Table 2 Adapted from Gemein et al. summarizing recent approaches in artificial intelligence on pathological EEG data discovery and the accuracies reached from applying various machine learning algorithms. CNN stands for

convolutional neural network and MLP stands for multi-layer perceptron (this is the technical term for artificial neural network); SVM stands for support vector machine [15]

Author	AI architecture	Data used	Accuracy reported [%]	Reference
Lopez de Diego et al. (2017)	CNN + MLP	1387 normal and 1398 abnormal files and an evaluation set of 150 normal and 130 abnormal files	78.8	[17]
Schirrmeyer et al. (2017a)	BD-Deep4	Filter banks common spatial pattern dataset, which underwent bandpass filtering, epoching, CSP computation, spatial filtering, feature construction and classification	85.4	[18]

Amin et al. (2019)	AlexNet + SVM	Temple University Hospital (TUH) EEG Abnormal Corpus v2.0.0. Two classes: normal and abnormal. Evaluation set, the normal class = 148 subjects, and the abnormal class = 105 subjects. Training set, the normal class = 1237 subjects; the abnormal class = 893 subjects.	87.3	[20, 21]
Alhussein et al. (2019)	3 × AlexNet + MLP	EEG signals are made up of many frequency components. Researchers divided the frequency regions into several frequency bands called delta (1–3 Hz), theta (4–7 Hz), alpha (8–12 Hz), beta (12–30 Hz), and gamma (30–100 Hz)	89.1	[22]
Van Leeuwen et al. (2019)	BD-Deep4	Database of 8522 routine EEGs from the Department of Neurology in Massachusetts General Hospital collected over a 4-year period from 2012 to 2016	82.0	[23]

and polypharmacy are unlikely to achieve seizure freedom. It usually takes a trial of 3–4 AEDs before a patient is considered for epilepsy surgery. This sequential process means critical time is lost before drug-resistant patients can be assessed by epilepsy specialists for advanced treatment such as surgery. The associated time delay means such treatments may be less effective [24]. This can often result in years of reduced quality of life, lost productivity, and increased mortality [25].

An et al. compared machine learning algorithms for prediction of drug-resistant epilepsy (defined as requiring more than three medication changes during the study period) utilizing comprehensive US claims data from 2006 to 2015. They found that the best performing algorithm, trained using 635 features (comprising demographic variables, comorbidities, treatment regimens, insurance data, and clinical encounters) from 175,735 records, yielded an AUC of 76.4%

and could identify patients with drug-resistant epilepsy an average of 1.97 years before failing a second medication trial, using data available at the time of the first medication prescription [26].

After the first AED, patients face a trial-and-error-based approach to further medical management. This is often frustrating and time-consuming and carries a risk of hospitalization and mortality. Many studies have demonstrated the possibility of using machine learning algorithms to predict an individual's treatment response [27].

Areas of future development include using AI for drug discovery to control epileptiform discharges, which could be monitored using electroencephalography. There is a putative role of finding “repurposed” medications that can work for epilepsy, e.g., propranolol and candesartan have been found to work for migraine and these discoveries were serendipitous. Given a large

enough dataset, deep learning can alert clinicians to medications that decrease seizure frequency but that have not previously been considered for the treatment of epilepsy.

Machine Learning for Epilepsy Surgery

Barbour and colleagues reported another interesting use-case for machine learning by applying natural language processing to screen for risk factors in sudden unexplained death in epilepsy (SUDEP) so that the clinician can warn the patient and their family of what to look out for in order to reduce the risk of SUDEP occurring and to identify good surgical candidates. In their work, they reviewed 4000 manually coded patient charts and split the text into sentence tokens by the presence of periods, line breaks, three or more white spaces, and headings. A total of 579 (14%) were documented as having GTCS, 464 (12%) had refractory epilepsy, and 163 (4%) were potential or previous epilepsy surgery candidates. There was good interrater reliability for GTCS ($\kappa = 0.64$) and epilepsy surgery (0.72), and it was excellent for refractory epilepsy (0.89). Although varied, promising results were also reported here; for instance, their away test-set performance ranged from low to very high, including for GTCS (sensitivity = 0.94, PPV = 0.72, F-measure = 0.81), refractory epilepsy (0.86, 0.69, 0.76), and epilepsy surgery candidacy (0.74, 0.41, 0.53) [28].

The use of AI and machine learning in anesthetic depth recognition has its origins using EEG activity dated in the mid to late 1990s [29, 30]. Through evolved computational power, epilepsy for surgical anesthetic depth analysis and consciousness calculations using EEG have reached a stage where implementation is within the clinician's reach. Features that have been extracted are wide ranging from fractal and temporo-spectral characteristics to entropy measurements [30]. Others, like Mirsadeghi and colleagues, have employed dimensionality reduction approaches to characterize awake and

anesthetized states. Sun et al. extracted a total of 102 features from six electroencephalography (EEG) channels undergoing routine polysomnography with kappa statistical improvement of the classifier's output with increasing training data but with comparable results to a human scorer [31].

Patients whose seizures are refractory to anti-epileptics can be selected as surgical candidates.

An area of application for deep learning has been in connectomic disease risk factor discovery, surgical selection, and postoperative outcome prediction. Connectivity patterns have clinical phenotypic variations, which means that aberrant connectivity also varies across individuals and in epilepsy these variants occur in limbic and extra-limbic areas. Gleichgerrcht et al. applied deep learning on 50 patients with unilateral temporal lobe epilepsy (TLE) to classify them either as having persistent disabling seizures (SZ) or becoming seizure-free (SZF) at least 1 year after epilepsy surgery. They report a classification accuracy of their trained neural network to show a positive predictive value (PPV; seizure freedom) of $88 \pm 7\%$ and a mean negative predictive value (NPV; seizure refractoriness) of $79 \pm 8\%$ showing the potential of deep learning for postoperative outcome prediction [32].

Successful resection of the epileptogenic focus usually requires the ability to differentiate between normal brain regions and their epileptogenic foci that will enable the delineation of the normal-epileptogenic tissue boundary. The gold standard for monitoring this involves electrocortical stimulation and mapping (ESM) using an invasive grid electrode placement during the intraoperative period allowing functional localization of eloquent tissue. The problem here is that there is a risk of the surgeon provoking after-discharge seizures during the operative process, which consequently led to the introduction of the less risky alternative of electrocorticographic functional language mapping (ECoG-FLM). Deep learning using LSTMs (long short-term memory) has been applied on ECoG-FLM datasets to augment detection of the eloquent

zone with an 83.05% proposed accuracy and a sensitivity of 85%. Their data was from 637 electrode recordings, with 128 electrodes at 1200 samples per second generated millions of samples offer a decent training sample for training [33].

Machine Learning for Electrophysiological Migraine Detection

Migraine remains a highly prevalent and disabling neurological disorder, characterized by recurrent neuralgiform headaches. The diagnosis of migraine is still routinely biased toward clinical interviews, patient diaries, and physical examinations. There are currently no robust adjunct investigations to differentiate between various migraineous syndromes because there is equipoise as to whether there is a detectable electrophysiological substrate associated with migraine. Nevertheless, electrophysiological approaches, such as somatosensory evoked potentials (SSEPs), have shown potential to support identification of clinical fluctuations [34].

Machine learning has recently been applied to electrophysiological migraine detection [34]. The study recruited 42 migraine patients, including 29 interictal and 13 ictal, compared with 15 age-gender-matched healthy volunteers, and performed right median nerve somatosensory evoked potentials. Random forests, extreme gradient-boosting trees, support vector machines, K-nearest neighbors, multilayer perceptron, linear discriminant analysis, and logistic regression were applied to somatosensory evoked potential features in time and frequency domains. Accuracy ranges from 51.2% to 72.4% were achieved for the healthy volunteers-ictal-interictal. However, through appropriate feature selection, an improved accuracy of 89.7% for the healthy volunteers-ictal, 88.7% for healthy volunteers-interictal, 80.2% for ictal-interictal, and 73.3% for healthy volunteers-ictal-interictal classification tasks was achieved.

Other techniques such as therapeutic neuromodulation using electrophysiological transcranial magnetic stimulation are also making

an impact on migraine management. Researchers have also used time series-based algorithms like the line length algorithm used in responsive neurostimulation systems. Transcranial magnetic stimulation leverages intracranial electromagnetic currents to modulate neuronal activity; however its actual mechanism of action remains a black box mystery to us [35]. Applying deep learning to understand this “black box mystery” may open up the opportunity for useful discoveries. However, opponents would also rightfully argue that a deep learning approach is itself a black box which casts further unpredictability.

Deep Learning for Electromyography

Another neuro-electrophysiological method utilized in routine clinical practice for diagnostics is electromyography, which aids neuromuscular junction disease characterizations and records electrical activity produced by the skeletal muscle. Diseases that are easily diagnosed from EMG include the following:

- **Carpal tunnel syndrome (CTS):** A convolutional neural network achieved the best performance with AUC of 0.980, while support vector machines obtained an AUC of 0.943 in a testing dataset to diagnose CTC [36].
- **Cervical spondylosis:** One study was performed on 14 patients and 14 controls that underwent imaging of the cervical spine. Deep artificial neural network models were trained 1) to predict cervical spondylotic myelopathy (CSM) diagnosis and 2) to predict CSM severity. Model 1 was trained to predict a binary outcome and consisted of 6 inputs including 3 common imaging scales for the evaluation of cord compression, alongside 3 objective magnetic resonance imaging measurements. A reported model mean cross-validated accuracy was 86.50% (95% confidence interval, 85.16%–87.83%) with a median accuracy of 90.00% [37]. Wang et al. also applied a convolutional neural network-based multi-channel deep learning algorithm called EasiCSDeep on electromyography data, which

- consists of the feature extraction, spatial relationship representation, and classification [38].
- **Guillain-Barre syndrome:** One study used a dataset with 16 identified features to evaluate and perform a tenfold cross validation (10-FCV) using 15 single classifiers in two scenarios: four subtypes' classification and One versus All (OvA) classification. Their diverse classifiers ranged from decision trees, instance-based learners (k NN: k nearest neighbor), kernel-based learning (SVM, support vector machines), neural networks (SLP, MLP, and RBF-DDA), and rule induction learners (OneR, JRip) [39].
 - **Lou Gehrig's disease or amyotrophic lateral sclerosis (ALS):** Combination of three surface EMG markers achieved 90% diagnostic sensitivity and 100% diagnostic specificity, which were higher than solely using a single surface EMG marker [40].
 - Others include Lambert-Eaton syndrome, muscular dystrophy, myasthenia gravis, peripheral neuropathy, polymyositis, radial nerve dysfunction, and sciatica nerve dysfunction all of which will continue to benefit from the AI and machine learning revolution. In fact, Tapadar and George demonstrated a very practical machine learning implementation for myasthenia gravis diagnostics for starter clinicians interested in this area [41].

Electromyography can now be employed to facilitate gesture-based platforms for disabled patients using training datasets from able-bodied individuals. For example, one study using deep learning was used in the classification of these electromyography signals. Cote-Allard and colleagues reported the use of three different deep learning networks that used three different electromyographic modalities to train. Their inputs, (raw EMG, spectrograms, and continuous wavelet transform (CWT)) were trained on two datasets gathered from able-bodied individuals. Transfer learning methodology was used to enhance the performance for all three networks on two datasets. An offline accuracy of 68.98% for 18 gestures over 10 participants for the raw EMG-based ConvNet and 98.31% for 7 gestures

over 17 participants for the CWT-based convolutional neural network (ConvNet) was achieved [42].

Practical Machine Learning for EEG Analysis

Although texts may usually omit sections on how to find and curate datasets as well as where to start, we believe this to be important to facilitate knowledge dissemination and new discoveries for machine learning within the field. Various repositories have been created for those interested in practical approaches for EEG analysis using deep learning. Libraries available include Google's TensorFlow (<https://github.com/SuperBruceJia/EEG-DL>) which does have a steep learning curve if you have not programmed before.

Moreover, raw open-source EEG datasets can be downloaded for deep learning and other machine learning models, but data provenance and integrity must be verified. It will usually require the clinician partnering with an engineer or computer scientist to achieve this and to help develop the models. However, if one wants to brave it independently, we include a linked list of publicly available EEG datasets that can also be found at <https://github.com/meagmohit/EEG-Datasets>. Another resource that provides a starting point for most neurophysiological data visualizations can be found at <https://github.com/mne-tools/mne-python>. Tapadar and George also demonstrated a very practical machine learning implementation in the Python programming language for myasthenia gravis diagnostics for starter clinicians interested in this area discussed above [41].

If one is interested in the practical aspects, take note of the following:

1. Download Anaconda Python client, which offers you a visual interface and IPython framework, Jupyter Notebook, Spyder, etc.
2. Create a folder on your desktop and clone/download either of the above repositories EEG-DL (link and instructions provided above) into the folder where you intend to

- perform your electrophysiology or EEG analysis.
3. Follow the instructions on the EEG-DL link above, which are self-explanatory and involve interaction with either a Unix terminal or windows command line prompt.

Concluding Remarks

Highlighting the Tension Between Progress and “Model Explainability”

Although deep learning has considerable potential and we are seeing growing adoption and applications for clinical neurophysiology and EEG analysis, the lack of transparency about how models make decisions and the barriers to entry for AI education make it challenging to achieve acceptability among clinicians. For everyday life-changing decisions affecting patients, it is critical to see each step along the decision-making pathway as it could provide insights into the management of pathology and alert the medical establishment to patterns that have been missed. Clinicians are suspicious of and express concerns regarding black box decision-making as they hold both a duty of care and a duty of candor to patients. Consequently, there exists a clinical need to both identify what went wrong and be able to conduct a full risk and root cause analysis. Black box systems affect this diagnostic process. How then can one safeguard a patient from a clearly erroneous decision made by a neural network and where does the duty of candor lie? Questions have also been posed as to the ethical implications of who is responsible if the erroneous decision was made by an algorithm, as opposed to an error made by a human. These are subject areas that are being actively researched. In fact, Stephen Grossberg and others have proposed techniques such as adaptive resonance learning to enable model explainability [43]. In the coming years, we will be better equipped to understand these areas and appreciate model ingenuity, which will open the door to research and additional clinical discoveries. It is ironic that in our quest to understand the brain, we have made in-roads into the building of models of the brain that are now

transferable to solving other problems outside the brain. We are now modeling its function, behaviors, and pathology and designing extrinsic constructs to understanding but a small portion of its inherent frameworks, and yet we are still only scratching the surface to its potential. The evolution of AI promises to help us answer some of these ongoing puzzles of the brain, which will be beneficial for clinical neurophysiology as a whole.

Abstract

Forensic medicine lies at the crossroads between medicine and justice, with a particular connection to criminal law. This field can be

broken down into two major areas: clinical forensic medicine, which focuses on the living, and forensic pathology, which focuses on the dead. The use of data, and in particular artificial intelligence (AI), in this context faces two distinct challenges. First, there needs to be a discussion about the concept of evidence both upstream and downstream. A distinction must be made between scientific evidence, which is used to train algorithms and to support forensic reasoning in order to produce valid and robust information and legal evidence, which can include scientific data from investigations and

interviews, as well as data produced by algorithms. The second challenge is individualization. One of the problems found in medicine, namely the application to a particular patient and situation of statistical knowledge established based on homogeneous groups whose study characteristics do not necessarily correspond to those of the patient, is only exacerbated in the field of forensic medicine. Not only must scientific knowledge be individualized, ensuring the validity of the algorithm to the specific case, without any learning or inclusion bias, but legal reasoning and the sentences handed down must be individualized too. AI can be used to support doctors' decision-making in forensic medicine, and it can also be used to structure research necessary for the evolution of scientific knowledge in forensic medicine. To date, the AIs used to support decision-making remain fairly immature.

Introduction

Forensic medicine lies at the crossroads between medicine and justice, with a specific connection to criminal law [1]. The scope of this field and the prerogatives of medical examiners depend in part on each country's criminal law and on the respective roles of the actors involved: the role of the medical examiner in continental Western Europe is not the same as that of the coroner in English-speaking countries. Doctors, technical and scientific police, investigators, judges, and sometimes even anthropologists, dentists, and criminologists are just some of the many specialists called upon to help complete certain missions, organized according to the established procedure and the direction of the investigation. In this chapter, we will focus primarily on the medical dimension of forensic medicine and on the primary responsibilities of the medical

examiner. We will also discuss how this field intersects with others.

Forensic medicine can be broken down into two major areas, separated by death: clinical forensic medicine, which focuses on the living, and forensic pathology, which focuses on the dead [1]. Depending on the country, the first area may include:

- Crime scene forensics: estimating the functional impact on victims of intentional violence (interpersonal, physical, psychological, and sexual violence, as well as abuse) or unintentional violence (road traffic accidents), which may help to qualify what kind of offence has been committed or what kind of compensation victims are entitled to.
- Medical treatment for those held in custody: examining and treating those in prison or in police custody.
- Estimating the age of adolescent migrants: depending on the laws of each country, the legal provisions for migrants differ depending on whether the person is a minor or not.

The second area, forensic pathology, primarily includes:

- Determining the cause and mechanism of death, especially in cases of violent, suspicious, or unexpected death, which may have legal repercussions for a third party
- Initial observations and *in situ* sampling, in places where bodies or human remains are found
- Conducting external examinations: these may be carried out when removing a body or in special examination rooms. Investigating and making observations of any traumatic injuries and of any distinctive or identifying signs
- Conducting autopsies, including a macroscopic examination of the body and organs. This may also include further analyses, such as microscopic examinations (anatomical pathology), toxicological and genetic testing, etc.
- Postmortem identification: when a person's identity cannot be easily determined (due to decomposition, mutilation, only finding partial remains, etc.) or is unknown when the body is discovered

We will now review several opportunities for using AI in these different areas, without discussing them from too practical a point of view or in too much detail, since they will be covered in ► Chap. 127, “AI in Forensic Medicine for the Practicing Doctor.”

There are many complicated issues bound up in these two areas: health law, ethics, medical expertise (in the assessment of injuries and bodily harm for the compensation of victims), and psychiatric expertise (in the evaluation of the criminal responsibility of the accused and the assessment of a person’s dangerousness or risk of recidivism [2]).

There are two kinds of evidence that are central to forensic medicine: scientific evidence and legal evidence. As well as the question of evidence, there is the question of individualization: How can knowledge that has been established “generally” be applied with any certainty and suitability to specific cases or people? Artificial intelligence, much like P4 medicine (personalized, participatory, preventative, and predictive) [3], may be able to contribute significantly to answering these questions.

Before it can become accepted and used on an everyday basis by the various actors involved in forensic medicine, more research must be done on and with AI. On the one hand, we need a better understanding of what can be expected from AI, of how much it can be trusted in different usage contexts. On the other hand, research needs to be more rigorous, using more scattered and varied data. AI can be used in the collection, federation, and formatting of the data needed for research, and later for practice.

Ethical issues are often closely related to legal issues: in forensic medicine, the ethics of AI and of its practical use raise several specific problems.

Evidence and Individualization in Forensic Medicine

Since the rise of evidence-based medicine (EBM), medicine and clinical practice have been based on knowledge produced within a well-defined methodological framework and have referred to a well-established hierarchy of levels of evidence [4]. The classic case is the use of randomized controlled trials to try to define the causality between an

intervention and an observed event, for example, to help prove the effectiveness of a treatment for a given pathology. The methodological quality, reproducibility, and reproduction of these studies help to establish a range of arguments for or against the effectiveness of the treatment, that is, to determine its effectiveness. These trials are carried out under so-called experimental conditions, which do not reflect real life and are more similar to a laboratory experiment. Both EBM and randomized controlled trials have faced criticism, particularly for the fact that the patients included in these trials are themselves so highly “selected,” not only by the trial’s recruitment parameters, but also by the various inclusion and exclusion criteria, that they barely resemble the wider body of patients who will ultimately receive the treatment under trial [5]. Statistical methods are used to establish the reality of an observed difference between the treatment group and the control group and to account for sampling fluctuations due to chance or inter-individual variability. Patients are organized into homogeneous groups based on a certain number of criteria. This assumes the existence of an “average patient,” who is represented n times (where n is the number of patients included in the group), rather than n unique individuals. The results are therefore statistical and not individual, due to how they were produced. These two limitations make it more difficult to validly apply the results of a trial to a specific patient who comes into a doctor’s office. This is the individualization problem for which n of 1 trial has, for example, been suggested as a potential solution [6]. The same problem arises in prevention, when risk factors are used: these are established and statistically “true,” but they cannot be applied with certainty or be fully adapted to a specific individual.

Patient treatment requires scientifically established and “proven” knowledge, but it also requires the ability to individualize this knowledge, to apply it specifically to one person.

This is also true in forensic medicine and in justice: evidence must be arrived at through a set of arguments, and this evidence must be as specific as possible to the case in question, that is, individualized. When someone goes on trial, they are not judged as if they were an “average” person from a homogeneous group of “similar people.”

Data, Information, and Evidence in Medicine and in Law: AI at Every Step in the Process

Evidence is therefore the result of an entire production process, which ensures quality and reliability using a range of different criteria. That is what makes it so valuable. Evidence is established based on a larger mass of different pieces of information, which, when brought together, solidify into evidence [7]. Today more than ever, this information may come from data collection, processing, and analysis. There are some authors in both science and medicine who have even abandoned the term evidence-based medicine, preferring to talk about data-based or data-driven medicine or decision-making [8]. According to some extreme positions, the entire process of producing evidence by bringing to light causal relationships has run its course, and only data, seen as a “pure” way of observing the world, is necessary and sufficient, at least when analyzed by the correct algorithms. The process of establishing evidence would thus be backed up by the “objectivity” of data and its analysis by algorithms that are supposedly more reliable than humans [9]. Reasoning would be replaced by algorithms, and decision-making would be at least partially delegated to them. Of course, AI is not only used in the analysis of data; today, it is mostly used in the collection, federation, and extraction of data. This is the case in law, for example, where it is sometimes necessary to review entire bodies of case law around a specific issue [10]. AI may be used to identify rules for deciding cases or simply to provide lawyers or judges with summary documents. In such instances, the text analysis and data structuring are done using AI algorithms.

Personalized Medicine, Individualized Sentences: A Shift from the Group to the Individual in Society

By definition, the statistical methods used in randomized controlled trials produce statistical results. It is not easy to make the shift from these collective results to individual cases [6]. One of the promises, or rather one of the hopes placed in

AI, is that it will solve this problem of the individualization of knowledge. How can such information, based on evidence produced for homogeneous groups, but also on individual data on thousands or millions of people and the opinions of experts, be used to arrive at an understanding that will apply to a given individual? This is the idea behind personalized medicine [3–6], and it is what is expected in criminal law too, where people and their situations are judged on a unique basis: Based on the unique characteristics of this person and this situation, how can we reach a valid and similarly unique outcome? Some see AI as a tool for using these different data sources to reach a valid decision for the person in question. The assumption is that all possible combinations have already, in one way or another, been observed and recorded and that all AI needs to do is to find the right combination to determine the right decision [9]. Of course, the reality is more complicated than that [11]: algorithms operate by finding similarities, and they are also based on the creation of homogeneous groups – though these groups are certainly more numerous and granular than those used in traditional statistics or when extrapolating results from a linear regression. In all cases, one critical requirement is that data collection be as exhaustive as possible within the area of interest. This means that all of the relevant data about situations that may be encountered in forensic medicine (traumatic injuries, injury mechanisms, injury dates and timelines, psychological and physical functional impacts of violence on victims, etc.) and in the legal sphere (context of the offence, social context, etc.) would need to be identified, recorded, digitized, and perhaps even shared and standardized. Even at this point, we can begin to trace out two main regimes: Most offences are relatively minor (theft, minor acts of violence, breaking the speed limit, drink driving, etc.), so most of the data and situations encountered will concern these offences. Here, individualization is less critical, because the repercussions are less severe for the individual and for society. Only a minority of offences are major crimes such as homicide, rape, or terrorist acts. In these instances, it might be useful to have some kind of tool to support decision-making, which would help to individualize the decision while

remaining limited in its role and respectful of the collective rules inscribed in law. However, in such situations, AI is much less likely to seem reliable or relevant.

Forensic Reasoning

Over the last decade or so, forensic medicine has seen the publication of several studies, by researchers such as Biedermann and Taroni, that have attempted to establish a general framework for the individualization of results [12]. The framework used is Bayesian, in that it creates representations of knowledge based as much on data as on expert opinions or scientifically established data. Even the parameters can be estimated using the available data. These models make it possible to calculate conditional probabilities and to account for (quantify) the uncertainty related to an event or decision. This means that it is possible to calculate the probability that a certain DNA sample will match the DNA of a certain individual, given that certain characteristics, specific to the person and the context, have been observed. Of course, when specific combinations of characteristics are poorly represented in the data, the level of uncertainty will be higher. This approach could serve as a formal and well-established framework for the use of AI in courts, with the advantage that this kind of AI is more easily explained than other AI models, such as deep learning, or models with large numbers of parameters and hyperparameters, which are impossible to discuss easily with nonspecialists. Bayesian models are basically a graphic representation of the interdependencies between variables (directed graph), which can be used in explanations or to stimulate discussion. To our knowledge, however, this framework has not been used extensively in courts or by forensic doctors in their day-to-day practice. It also has its own shortcomings, such as problems with estimating a priori probabilities, which are central to the Bayesian framework, or probability interpretations (frequentist vs. subjectivist, for example) [13, 14].

Beyond individualization, AI can also be used to help with decision-making.

Artificial Intelligence and Assisted Decision-Making in Forensic Medicine

In this section, we will assume that the AIs in question use algorithmic methods known for their effectiveness in AI and machine learning. We will not discuss specific uses in detail, since they are the subject of their own separate chapter (see ► Chap. 127, “AI in Forensic Medicine for the Practicing Doctor”).

AI and Clinical Forensic Medicine

To date, there has been little, if any, research done on the possible uses of AI in clinical forensic medicine. There have been some multivariate models for estimating the ages of adolescent migrants [15], but they all share the same major flaw, namely that they were not designed based on the populations they are meant to assess [16]. The performance of these models is difficult to measure because the studies themselves do not follow the existing recommendations for AI model reporting (CHARMS or TRIPOD, for example [17]). Some authors have shown an interest in using AI to “diagnose” rape [18]. From an ethical and scientific standpoint, this use of AI should be viewed with caution, since rape is a legal classification and not a medical diagnosis (and therefore not a medical prerogative), and because there is no medical way to prove rape, only indicators that there has been sexual contact. In law, what characterizes rape is whether or not the act was consensual.

Some studies have been done or are currently under way on the possible use of AI to assess the functional impacts of violence on victims [19]. This would help doctors to quantify the duration of such impacts. They could also add the level of uncertainty of this estimate when communicating it to judges, knowing that different practices are employed in different medical centers and by different doctors. The acceptability and potential adoption of AI in this context have been studied using mixed (epidemiological and anthropological) methods, revealing significant fears among judges (fear of doctors being replaced by AI, then of being replaced themselves), but also

opportunities for them to integrate AI into their reasoning and to support their decisions [20]. A systematic review is currently under way, focusing on the role of AI in predicting PTSD among victims of sexual violence during their first consultation with a forensic medical professional [21]. While a handful of studies have already been published on AI and PTSD, none has yet focused on sexual violence specifically.

To date, there have been around ten studies published in clinical forensic medicine journals.

AI and Forensic Pathology

Here, we will not discuss all of the existing examples from forensic pathology, which are discussed more exhaustively in ► Chap. 127, “AI in Forensic Medicine for the Practicing Doctor.” We will, however, look at several representative examples: postmortem identification, estimation of time since death, and determining the cause and mechanism of death.

AI is used to help medical examiners identify bodies and remains by estimating several important characteristics of the body: age at death, sex, and morphology (height, weight, and body mass index). These AI draw most of their input data from medical imagery [22, 23].

Time since death estimates is generally based on observations made during external examinations of the body. These observations are not limited to clinical observations, but also include taking measurements (body temperature) and samples of various kinds, from sampling body fluids for biochemical analyses to sampling insects to collect forensic entomological information [24]. Photography is also used, for example, to estimate the time since death based on corneal clouding [25].

Determining the causes and mechanisms of death is a central part of thanatology and the primary goal of the autopsy. There are several AIs that can help medical examiners to determine the cause of death, which use natural language processing to consider different kinds of documents, such as autopsy reports, death certificates, or electronic health records (EHRs) [26]. These AIs also use postmortem imaging data, something

that is becoming more and more common with virtual autopsies (virtopsy [27]). They can detect internal hemorrhaging and potentially lethal injuries [28], as well as traces such as certain algae (diatoms) in body tissue to suggest – or rule out – the possibility of drowning [29].

These applications remain somewhat immature, with most arising from more or less completed research projects. They are rarely approved (external validation) for certified clinical use. The progress of these AIs is discussed in ► Chap. 127, “AI in Forensic Medicine for the Practicing Doctor.”

AI and Medical Expertise in the Legal Context

In the field of forensic expertise, AI is mostly used in relation to psychiatry. These approaches aim to improve or replace actuarial methods for evaluating psychiatric dangerousness or the risk of recidivism or suicide [2, 30]. They can also be used to help determine criminal responsibility if the accused cites impaired judgment, either at the time of the event or on an ongoing basis, perhaps due to some psychiatric pathology. They mostly use data from neuroimaging.

Generally speaking, any forensic situation that uses scales is likely to benefit from AI, as it appears to be a fairly natural extension of the use of scores and collective and individual data. This is already the case for calculating insurance estimates for personal injuries and damages [10], where the goal is to quantify both the damages and the corresponding compensation. These situations are encountered routinely, which may justify the use of AI.

AI on the Borders of Forensic Medicine

The direct practice of forensic medicine is supported by a range of other professions, techniques, and actions that may all be required in the forensic context. A nonexhaustive list of examples would include the growing interest in AI in ballistics (for identifying weapon or projectile types [31]); in fingerprint searching and comparison for

identification purposes [32]; in genetic analyses, especially for DNA identification based on different types of traces or samples [33]; and in the examination of potentially forged documents, with the knowledge that modern forgers often use AI themselves to create false documents [34].

Artificial Intelligence for Forensic Medicine Research

Well before it is used to support decision-making, AI can be used upstream to help structure research and the data needed to create new AIs for forensic medicine. As mentioned above, access to the necessary data is critical, as most data is divided between different information systems, which may also belong to different actors (e.g., several different hospitals, courts [35]). Even if the proper authorizations are obtained, most of the relevant databases are not interoperable, and it is often the case that some of the documents have not been digitized or are simple scans. Significant work must therefore be done to federate and analyze all of these different data sources to give them some kind of structure. One relevant example is the ORFéAD network, which connects 12 forensic medicine centers across France and federates the data from routinely produced medical documents, extracting the data and structuring a multicenter search database [20]. This database has already made it possible to create a family of algorithms to support decision-making when evaluating functional impacts on victims of violence [36]. This kind of approach is likely to catch on, in some variation, both because of the diversification of data sources and types and because of the cost involved in this kind of research, which requires ever-increasing volumes of data, but which faces increasing challenges in terms of securing the human resources to conduct this kind of research.

Potential Trends and Future Challenges

As in most medical fields, the development of AI and its routine use have yet to find their place in forensic medicine. This task is complicated by the

fact that the acceptance, relevance, and use of AI in forensic medicine is not just up to doctors, but also judges and, depending on the case, lawyers, victims, and those who have committed offences too [36]. AI can be used as part of the toolbox available to these actors to shore up the set of arguments that are ultimately used to establish evidence. Any such tool must be questioned, systematically investigated, and must prove its relevance and robustness in the face of doubt. These algorithms must also be unimpeachable from an ethical standpoint. For example, there can be no suspicion of gender or ethnic bias in these algorithms [37], or else they will be disqualified as nonapplicable. That is not to say that the algorithms used in a legal context must be somehow more “unimpeachable” than those used in other medical fields – all such algorithms should be similarly free of suspicion. In the legal context, however, algorithms are naturally more likely to be the target of criticism and doubt.

Until now, the primary role of AI in forensic medicine has been to support research methods and peripheral tasks: it is mostly used in technical matters, at the interface of medical practice. AI must overcome significant challenges if it is to have a more central, more specific role in medical practice. It is not only medical examiners who need convincing, but other nonmedical actors too, including judges.

Abstract

Forensic medicine is a specialized medicine domain which aims at providing medical expertise in justice courts. In practice, forensic physicians or forensic pathologists can be requested by magistrates or police officers to

contribute solving an investigation, assessing and delivering forensically relevant elements requiring a thanatological or clinical expertise. Since the last decade, applications based on artificial intelligence have emerged in order to help forensic medical doctors in their daily practice. Most applications are developed from recent developments in AI, such as machine learning techniques.

This chapter proposes to describe such applications with a special attention to the current practices in forensic medicine. A use case from the forensic medical doctor's point of view is presented and analyzed for each expertise field. Finally, the applicability and usefulness of artificial intelligence in the routine tasks of forensic medical doctors are discussed in order to analyze the possible impacts in the practices of current and future forensic medicine.

Supplementary Information: The online version of this chapter (https://doi.org/10.1007/978-3-030-64573-1_221) contains supplementary material, which is available to authorized users.

Artificial intelligence · Forensic medicine · Forensic medical doctor · Forensic physician · Forensic pathologist

Introduction

Forensic medicine is a specialized medicine domain which aims at providing medical expertise in justice courts. In practice, forensic medical doctors can be requested by magistrates or police officers to contribute solving an investigation, assessing and delivering forensically relevant elements requiring a thanatological or clinical expertise. In thanatology (as defined in Fig. 1), the main roles of the forensic pathologist are postmortem identification, the determination of the causes of death, and the estimation of the postmortem interval (PMI) or the time elapsed between the death of a person and the finding of the body or the remains. In clinical forensic medicine, forensic physicians mainly perform clinical assessments, carry out treatments on living persons such as people victim of crimes or detainees in police custody, and may give an expert opinion in justice institutions [1].

Since the last decade, applications based on artificial intelligence (AI) have emerged in order to help forensic medical doctors in their daily practice. Those applications are developed from public research and by private companies. Therefore, they may not necessarily be mentioned by any scientific paper or patent for business purposes. For this reason, it is hard to acquire exhaustive knowledge of the AI approaches or technologies in the forensic medicine practices. Hence, an exhaustive systematic review of those technologies is not feasible to date.

In consequence, the expertise fields of forensic medicine in which AI-based approaches are identified or identifiable are presented in this chapter. First, AI-based applications developed to support, augment, or replace the forensic medical doctor in routine tasks are described. The applications that could enhance or create new tasks in daily practice are also considered. However, some may not be

mature enough to date to be used in real conditions due to a lack of validation experiments. That is why the maturity level of the identified AI applications should be taken into account to visualize the future implications of the forensic medicine practice. To do so, this maturity level is estimated by using the technology readiness level (TRL) scale defined in [2]. Briefly stated, the initial TRL values range from 0 (the basic principles of the application are observed) to 9 (the application is validated and its final form is used in real conditions). In this chapter, the TRL scale is reduced to three values corresponding to three main stages of maturity of an application, as described in Table 1. The higher the TRL value, the mature the application is for a use in real conditions. It is thus possible to categorize the advances of AI in each expertise field of forensic medicine. Second, a special attention is paid to the applications with the highest or closest TRL value for a routine use by forensic medical doctors. Indeed, they are the most prone to be used in daily practice. Finally, the applicability and usefulness of AI in the daily tasks of forensic medical doctors are discussed in order to analyze the possible impacts of AI in the practices of current and future forensic medicine.

AI Applications for the Forensic Medicine Practice

Part A: Description of AI Applications for the Forensic Medical Doctor

In this part, AI applications are described by forensic medicine expertise field, as given in the first paragraph of the introduction. For each expertise field, a use case, real or elaborated for illustration purpose, is described from the point of view of the forensic medical doctor.

Thanatology

Postmortem Identification

Postmortem identification aims at finding elements of identification to associate a body or its remains to an identity. To do so, forensic

Forensics-related terms

Term	Definition
Thanatology	Scientific study of death and its associated practices. For instance, external examination of dead bodies and autopsy (or internal examination) are part of thanatology practices in forensic medicine
External examination	Non-intrusive examination of a body. The forensic medical doctor looks for the presence of traumatic wounds, the signs of death and of cadaveric processes such as putrefaction. The forensic pathologist may also take samples for toxicology or identification purposes.
Forensic entomology	Scientific study of arthropods in a forensic context, for example for rough time of death estimation
Diatoms	Unicellular algae composed of a silica shell visible under microscope. During vital submersion, diatoms penetrate into tissues, such as brain, liver or kidney, so that they may be used as elements in favour of a positive diagnosis of drowning.

Data/AI-related terms

Term	Definition
Machine learning	Field of AI that aims at giving computer systems the ability to draw inferences from data without being explicitly programmed.
Deep learning	Field of machine learning in which computer systems may use one or several variants of neural networks to draw inferences from data.
Neural network	Set of mathematical functions (artificial neurons) organized as a network. The layout of neurons and the links between them enable to perform complex tasks, such as object classification and detection.
Data reconciliation	Comparison of data to validate an action or an hypothesis. For instance, in post-mortem identification, data reconciliation consists in comparing post-mortem data against antemortem data to identify a body.

Fig. 1 Definition of terms related to forensics or data sciences

Table 1 Technology readiness level (TRL) values adapted to assess the maturity of AI-based applications in the practice of forensic medicine. The aTRL value represents a range of successive initial TRL values

Initial TRL range	Adapted TRL or aTRL value (used in this chapter)	Designation	Example
1–2	1	Formulation of the concept of the application	The concept of developing an application to estimate the age of an individual from wrist and hand radiograph is formulated
3–7	2	Application in research and development stages	One or several AI models are being developed and validated for a use by forensic medical doctors
8–9	3	Application used or almost ready to be used by forensic medical doctors in real conditions	Forensic medical doctors use the application to estimate the age of an individual at the request of justice authorities

pathologists currently use non-comparative or comparative approaches. The non-comparative approaches consist in inferring or determining individual characteristics to establish the identity of a subject, whereas the comparative approaches aim at comparing antemortem and postmortem data to search or confirm its identity [3].

For both approaches, several AI applications have already been developed. In non-comparative approaches, AI is mainly used to estimate personal characteristics such as age, gender [4], stature [5], height, weight, and body mass index [6].

Most of AI applications designed for that kind of approaches are designed to determine age or

gender of an individual from imaging techniques used in traditional forensic medicine. Indeed, age and gender are mainly determined from radiographs, and new developments take advantage of magnetic resonance imaging techniques for gender determination from brain features [7]. Some AI applications are also developed for facial reconstruction purposes from odontology data [8].

In comparative approaches, AI applications are used to label data or to perform data reconciliation between antemortem and postmortem data. To do so, applied AI research in forensic anthropology and odontology are currently carried out. A plethora of AI applications are also emerging in genetics to help the experts analyzing complex genetic profiles. However, this domain is not really relevant in this chapter since the samples of genetic material are mostly analyzed by genetic experts who are not necessarily and even rarely forensic medical doctors. That is why it was decided not to describe the applications of AI in genetics in this section.

In forensic anthropology, AI is applied for craniofacial superimposition, especially during the skull-face overlay stage, that is the superimposition of skull models to face photographs to identify an individual [9]. In forensic odontology, AI is mainly used to classify dental restorations [10] and dental cusps [11] or for features extraction [12] that are used as elements of comparison between antemortem and postmortem data.

To date, it is not currently possible to assert with certainty that all of those applications are used by forensic medical doctors in daily practice. Although most of applications are proofs of concept validated on real data (average aTRL 2 as shown in Table 2), few are actually reported

to be used in daily or occasional practice in forensic medicine. However, some are already used by forensic pathologists, especially during disaster victim identification (DVI) missions. Indeed, AI was used in the identification process of several disasters such as the MH17 plane crash in Ukraine in 2014, the air crash in Tripoli in 2010, and the tsunami event in Thailand in 2004 [13]. According to the 2018 INTERPOL DVI guide, DVI processes should include four steps defined as scene examination, postmortem data acquisition, antemortem data acquisition, and data reconciliation between antemortem and postmortem data [14]. In practice, AI is mainly applied in the latter. For example, the forensic pathologist may deal with hundreds of victims. In this case, one may imagine that identity documents, such as passports, are present on the disaster site. Therefore, facial recognition may be used to identify a victim from those passports. However, if the victim's face is too damaged, it becomes difficult to compare the victim's face with the photograph given on the passport. Therefore, the forensic pathologist may struggle to identify one victim by using traditional facial recognition methods.

Nevertheless, with the recent development of AI, the forensic pathologist could use an AI-based software that extracts relevant features from a face image. Then the software would perform data reconciliation (as defined in Fig. 1) from the extracted features against a database of identified faces and would output a match probability of the best candidate. The results of the matching process would be taken into account in the final decision handled by the forensic pathologist. The identification process would thus be faster than using

Table 2 Overview of AI application details found in the expertise domains of forensic medical doctors. The average aTRL represents the average of the technology readiness

value (TRL) based on the adapted TRL scale, as defined in Table 1, regarding the number of papers found/tools developed for an expertise domain

Expertise domain	Number of papers found/tools developed	Year of the oldest publication found	Average aTRL
Identification	>70	2012	2
PMI estimation	<20	2010	2
Determination of the causes of death	<30	2012	2
Clinical forensic medicine	<10	2018	2

traditional facial recognition methods, and the medical doctor can identify other victims that require other identification methods such as anthropology-based methods.

Some applications are also developed to anticipate future DVI cases. For instance, a software including AI components would be used in Japan for the automated analysis of panoramic X-ray radiographs in dental records to aid the identification of dead individuals [15]. Besides, since 2018, panoramic X-ray radiographs converted into a standardized format have already been stored within a database on a network shared by several medical institutions. It is worth mentioning that identifying individuals by AI in large-scale disaster from electronic records suggests that a relevant database of antemortem identification records exists and is accessible, all the data stored in the database are standardized to a given format for information sharing, and AI is able to use that database to retrieve relevant data for identification purposes.

Postmortem Interval (PMI) Estimation

PMI is mostly estimated by forensic medical doctors during the external examination of the body. Indeed the succession of features that appear on the body after the death enables to date approximately the death of a person. It is worth mentioning that external examination is not the only way used to estimate the PMI. Forensic medical doctors who are experts on forensic entomology and forensic biochemistry may use other skills to estimate the PMI with more accuracy than the methods used during classic external examination. In forensic entomology, PMI is estimated by identifying the successive waves of arthropods that appear after the death on the body and in the area where the body is found. In forensic biochemistry, the concentration of electrolytes in the eyeball (vitreous humour) may be used to estimate the PMI. Complementary methods based on body and ambient temperature measures may also be explored by using Henssge's nomogram [3].

In scientific literature, AI applications are appearing to estimate the PMI by using data from the external examination, as well as from

forensic entomology, forensic biochemistry observations, and temperature-based methods.

For instance, applied AI research is carried out to estimate the PMI from eye opacity features extracted from postmortem images [16]. In forensic entomology research, AI is mainly used to determine the age or the species of forensically relevant blowflies from spectrograms [17] or photographs [18], respectively. In forensic biochemistry, AI takes measured chemical compound concentrations as input data to estimate the PMI [19]. Recent papers suggest the use of AI to extract features from mass spectrometry profiles for PMI estimation [20]. However, this approach may not be used in daily practice since it is not validated on human cadavers to date.

Other papers also describe applications relying on AI to estimate the PMI from microbiome data [21].

Moreover, indirect approaches relying on AI are explored. For example, the authors in [22] have developed an AI model to determine the ambient temperature of a site in the past in order to calculate the accumulated degree days, an estimate of PMI, more accurately than the traditional methods.

However, none of the AI-based applications mentioned above are currently used in practice by forensic medical doctors. Nevertheless, it would be easy to imagine a use case in which a software analyzes an eye photograph to estimate PMI during the external examination of the body. In this case, the forensic pathologist would first take a picture of an eye during external examination. Then, the software would output the PMI estimate with a confidence interval corresponding to the accuracy of the AI model. Therefore, this application may avoid additional biochemical analysis for PMI estimation purposes and would enable to save the time spent on analyses processes and administrative procedures.

Determination of the Causes of Death

One of the main goals of forensic pathologists is to determine the causes of death from the observations reported during the autopsy (as defined in Fig. 1) and eventually from the results of additional analyses.

Several AI applications in this expertise field are based on textual data, such as autopsy reports, death certificates, and clinical bulletins [23]. Those applications aim mainly at determining the underlying cause of the death among the possible causes listed by the medical doctor.

Some research is also carried out to determine the cause of death from analytical data [24]. However, the resulting application is only limited to assess specific causes of death. Besides, most of AI applications designed to directly determine the cause of the death are specific to one or some causes of death.

Other AI applications may provide elements to determine the causes of death, such as the detection of hemorrhages [25], the identification of fatal injuries [26], or the detection of diatoms (as defined in Fig. 1) for the diagnosis of drowning [27], from postmortem imaging data.

To date, the diagnosis of drowning cases by AI is one of the most mature AI-based applications (aTRL 2; see Table 1) in research and development. Indeed, the presence of diatoms in specific tissues is a good indicator of drowning cases [28]. However, the search of diatoms in tissue samples may be a very time-consuming task since only one diatom may be present in one tissue sample. The comparison between diatoms from tissue and water samples may help confirm the location where the drowning occurred. Hence, the current AI approaches in this field mainly consist in diatom detection and/or classification.

Currently, AI is not reported to help forensic medical doctors in daily practice for the determination of the causes of death. However, one may imagine a use case in which a drowning case is suspected. In that case, the forensic pathologist would proceed to a diatom search on microscope slides of tissue and/or water samples. Instead of scanning manually a slide through a microscope, an AI application may be used to detect and classify automatically the diatoms present in a microscope whole-slide image. The forensic pathologist would then analyze the diatoms found to provide elements in favor or not of a positive diagnosis of drowning. To do so, the applications designed for those purpose should be able to identify at least the common diatom species in water samples as

well as tissue samples with high precision and accuracy. Those applications should also be able to learn to detect and classify diatom species for which they have never been trained with. Indeed, an AI algorithm is specific to the categories of data it was trained with. For example, if the algorithm was trained with 20 different diatoms, it would not be able to identify more than those 20 diatoms as is. Therefore, the AI algorithm should be flexible enough to enable the recognition of other diatom species. Hence, when encountering new species, the AI algorithm must be trained again with data including the new species to be able to recognize them in the future.

Clinical Forensic Medicine

In clinical forensic medicine, the forensic physician may be asked to perform clinical analyses on living persons and interpret the results to answer a given issue such as determining the age of a living individual [3] such as unaccompanied adolescent migrants or determining the mental state of a person or assess bodily injuries [1]. However, to the best of the authors' knowledge, AI is not currently used by medical doctor in clinical forensic medicine. Nevertheless, studies involving AI approaches are performed in clinical forensic medicine, especially in forensic psychiatry. In this field, AI applications are mainly designed to assess the risk or recidivism of an offender [29] or the risk of suicide of an individual [30]. Those studies are mostly based on neuroimaging data or electronic health reports. In both approaches, AI aims at extracting features used to assess a risk.

However, AI is currently not used by psychiatrists due to several reasons. First, the existing tools to assess the risk of violence are not widely adopted by forensic psychiatrists [29]. Therefore, an AI application may fail at the validation stages due to the use of nonrelevant data. Second, forensic physicians may have some reservations about using AI in forensic psychiatry due to law and ethical issues [31]. That is why forensic psychiatry is a field in which AI is currently hard to implement for a use in real cases.

Other AI applications are developed in order to help the forensic physician in the examination of individuals alleging to have been raped. One of

the most advanced AI applications (aTRL 2; see Table 1) is the automated classification of colposcopy images for forensic evaluation purposes of sexual assault [32]. Currently, this application is not developed enough to be used in daily practice for rape investigation. Nevertheless, it is relatively easy to imagine a use case from this application. For instance, the forensic physician could examine a victim through a digital colposcope associated to a computer which includes an AI-based application. Each time a photo is taken, the AI application would detect and point out wounds on the image. The forensic medical doctor would then decide if the highlighted elements are relevant enough in the diagnosis of sexual assault and proceed to first-line treatments. Therefore, AI could act as an assistant for the physician in this case. However, the application developed by [32] is not accurate enough to be used in real conditions.

Part B: Applicability and Usefulness of AI in Current and Future Practices in Forensic Medicine

Since the last decade, more and more AI applications in forensic medicine have been developed mainly, thanks to the developments in information technology, the increase of data volume, and computational power [33]. Currently, AI is mainly used for machine learning purposes, in other words the learning of patterns or representations in given data to answer a specific issue. To date, AI is able to learn from different data types, such as numerical values, images, reports, videos, and graphs. Hence, the diversity of data types an AI may learn from enables to explore AI-based approaches for many goals in forensic medicine, such as the detection of anomalies in postmortem computed tomography (PMCT) scans [34], for instance. However, AI is not able to model new purposes without human intervention. Therefore, AI applications are currently designed for specific tasks only. For example, an AI model only trained to determine the age of an individual will not be able to determine the gender of a person or use other data types than one or ones used during the

learning process, if the AI is not modified by a human. Besides, all the AI applications mentioned in this chapter are trained for a sole task.

Nevertheless, AI is useful in forensic medicine, especially for detection and classification tasks. For instance, as described in section “[Determination of the Causes of Death](#),” AI may be used to detect and classify automatically diatoms from whole-slide images. Therefore, the search of diatoms would be handled by an AI application, which would thus aid not to miss any diatom present on a slide. AI applications may also be designed in order to optimize time-consuming tasks, such as data reconciliation in DVI cases, as mentioned in section “[Postmortem Identification](#).”

Although many research studies deal with AI-based approaches for forensic medicine (see Table 2), the AI applications developed for DVI purposes seem to be the only ones which are reported in the literature of the current practices. From this observation, one may infer that AI is not used in daily practice by forensic medical doctors. However, the difference between the number of AI-related research papers in forensic medicine (see Table 2) and the number of applications used in daily practice by forensic medical doctors may be due to several reasons. First, not all AI applications designed from research projects are implemented in real and operational environments. Indeed, they may only contribute to improve the knowledge and the literature of applied AI in forensic medicine. Second, most of research studies in AI applied to forensic medicine are derived from recent developments in AI, such as deep learning approaches (as defined in Fig. 1). Therefore, due to a lack of validation studies, it may be too early to use the resulting AI applications in practice. For instance, PMCT imaging is a relatively recent technique implemented in forensic medicine practices; thus, AI models developed to process PMCT data often lack reliable data to be implemented in real environments. Third, medical doctors may be reluctant to the use of AI in forensic medicine.

Indeed, forensic medical doctors must be trained to use AI models and interpret their results. However, some AI applications, especially those relying on dense neural networks, are considered as “black box” models. In other words, the

rationale or the explainability of an AI model for a specific task is not known or not clear enough to figure out how the model interprets data. For instance, if an AI model based on dense neural network is trained in order to determine the height of an individual from anthropometric measures, it would be hard to understand how the model interprets the data to output the height of an individual. This is due to the architecture of the model. Indeed, dense neural networks are composed of several layers of individual operations also called neurons, such as the layers of neurons that process electric signals in the brain. A neuron of a layer is connected to all the neurons of the previous layer, except for the first layer which contains input data. With few neurons, it is relatively easy to understand the meaning of operations. For example, with two neurons, one may be dedicated to the detection of spine curvatures, another one to the correlation between height and the length of the spine. However, the more the neurons and layers, the more difficult the explanation since layers are densely connected. Some interpretation methods have already been studied [35]; however, it is currently hard to clarify the AI interpretation processes for models based on dense neural networks. Nevertheless, it is worth mentioning that research projects in explainable or interpretable AI are currently thriving, so that one may expect in the future that more explicit interpretation methods would emerge.

Forensic medical doctors may also be reluctant to use AI in daily practice due to bias-related issues. Indeed, current AI applications in healthcare medicine may correlate the ethnic group an individual belongs to with a given issue. For instance, AI might discriminate against Black people with regard to the additional care provision in complex cases [36]. Therefore, an AI model may be biased by unwanted correlations. Hence, justice decisions that would partially result from biased elements provided by an AI could be unfair due to rationales based on non-admissible elements, such as the race of the defendant. Moreover, AI models may also be biased by data. Indeed, when AI models are trained on too little data, they may be prone to overfitting. In other words, the model fits so well the data it is trained

on that it is unable to generalize on new data, which leads to overrate the performance of the model. Nevertheless, bias identification and removal in AI models are subject to active research studies. To be applied in real conditions, AI models should thus be transparent and fair in order to prevent any misinterpretation based on spurious correlations. That is the reason why validation studies are prominent to prevent such biases in the lifecycle of an AI application.

In addition, the use of AI in justice procedures raises other ethical issues such as liberty or privacy violation [31]. For example, in a fictitious case, if an AI algorithm erroneously points out a person with a high risk of violence, that person could be placed in police custody or in hospital to receive psychiatric care, which is a case of liberty violation. This fictitious example may remind some science fiction movies, like Minority Report, which explore that kind of speculative and preventive punishment. However, no current legal system can condemn an individual on the sole basis of an estimated risk, without a well-characterized offense. Privacy may also be affected since the data used to train AI should originate from real cases. Nevertheless, regulations like the General Data Protection Regulations or the Health Insurance Portability and Accountability Act are emerging to supervise the storing and sharing of such data.

Forensic medical doctors may also be worried about being replaced by AI in the future. Actually, current AI technologies do not allow replacing forensic examiners. Although AI models may provide correct and accurate suggestions, the final decision remains entrusted to the forensic medical doctor since models may make mistakes. Indeed, as mentioned above, AI models are mostly designed to answer a given issue. Even though data-driven algorithms may be able to handle several tasks, they are not able to understand the meaning of data. The interpretation of data by AI is only based on correlations, patterns, or explicit rules given by a human being. Therefore, forensic medical doctors have a more complete understanding than AI, so that they are more skilled to detect and explain outliers in data than AI. In addition, forensic medical doctors should

be vigilant about the use of AI to determine or assess elements that cannot be defined on a clinical or physical basis. For instance, in the use case presented in section “[Clinical Forensic Medicine](#),” the definition of rape relies on the notion of nonconsensual intercourse that cannot be assessed nor proven through an AI or other methods. Hence, using an AI algorithm that proposes to determine the consensual nature of an intercourse based on physical observations is not relevant since there is no certain causal relationship between both. Therefore, forensic medical doctors should first assess the relevancy of an AI algorithm before using it in daily practice.

As a consequence, AI models may currently be regarded more like an assistant for forensic medical doctors than fully skilled experts.

Moreover, AI might be applied to enhance forensic medical doctors in their practices instead of replacing them. Indeed, the applicability of AI in several domains of forensic sciences, like ballistics and forensic medicine, enables transdisciplinary approaches to address a given issue. For example, the determination of a bullet trajectory from postmortem data is currently a research project that may be used in the future by forensic pathologists [37]. In that case, the forensic pathologist may request an analysis of PMCT scans by AI to determine the vital parts a bullet may have damaged in order to investigate fatal damages caused by the bullet.

However, AI models should not be transferable from one application to another without expertise in both applications. For example, AI applications used for postmortem purposes may not be relevant for antemortem purposes. Indeed, missing elements of the body, decomposition processes or predation marks that could alter the tissues, are limiting factors in postmortem identification. Therefore, clinical and postmortem identification by AI would require either an AI model trained on postmortem and antemortem data or two AI models, one specific to postmortem data and the other one specific to antemortem data. As a consequence, forensic medical doctors should be trained to select the right AI model to use by taking into account the advantages and the limitations inherent to the model.

Nonetheless, a positive opinion from forensic medical doctors about the use of AI in forensic medicine does not mean a successful implementation of AI in daily practice. Indeed, the expertise of forensic medical doctors enables to produce conclusions and evidence elements that should be admissible by all the justice, especially magistrates and advocates [38]. Moreover, in forensic medicine, the medical doctor deals with unique cases that should be subject to unique and personalized justice decisions. Therefore, it is hard to rely on algorithms based on statistical groups. Hence, in justice court, it could be relatively easy to argue against the use of statistical AI by explaining that each case is unique and must be considered with all its specificities, which are not included in any statistical rationale. Some authors have proposed a Bayesian approach to individualize results in forensic medicine; however, this is still limited for a daily practice [39].

Therefore, the applicability of AI in forensic medicine depends on the adoption of AI by forensic medical doctors as well as magistrates and barristers.

Conclusion

Finally, few applications based on AI approaches are reported to be used by forensic medical doctors to date. In practice, the applications which are really used by medical doctors are mostly developed for identification purposes and applied in DVI cases. However, hundreds of research projects involving AI have been conducted in forensic medicine, and research studies are still in progress. Currently, most of those studies and projects from research and development departments of public institutions or private organisms show promising results. The performance of AI models in forensic medicine ranges from approximately 30% for the less accurate model to approximately 99% for the best one depending on the application and the forensic expertise field. Although most of current AI applications are more than 75% accurate, many are trained on too little data, so that such models are subject to overfitting and their performance is overrated.

Indeed, this overfitting phenomenon produces models which are not able to generalize to other data than those that were used during the development of the models. Therefore, such models cannot be applied in daily practice. Moreover, the implementation of AI in forensic medicine is not a trivial process. Indeed, the AI-based applications produced during research stages require further validation studies with more real data to be implemented in real and operational environments. Moreover, forensic medical doctors may be reluctant to use AI in daily practice due to ethical, professional, and AI-inherent issues, such as the presence of biases and the lack of elements of AI interpretability in specific kinds of application.

Nevertheless, AI is a thriving field in which techniques are constantly improved, so that the potential of AI in forensic medicine purposes is not fully exploited to date. Therefore, AI applications in forensic medicine are promising data-driven tools that could enhance the forensic medical doctor in daily tasks.

Abstract

Physiotherapy is a natural component of modern clinical medicine, and frequently the most efficient remedy to a wide range of medical conditions. Physiotherapists are an integral part of the medical team of professionals. After surgeries or accidents, especially those involving bones and joints, and against osteoarthritis and other conditions involving pain, the physiotherapeutic treatment is commonly used in clinical practice. It is often the sole curing ingredient. At other times patients usually present to physiotherapists with backpain that have sinister underlying pathologies such as cancer or cauda equina syndromes. Therefore, this chapter aims to delve into how this remedy could be augmented with artificial intelligence (AI). It will show how AI can increase the supportive frameworks of physiotherapy in the era of digitizing medicine, through a plethora of new applications, ranging from in real time video instructions in combination with pose and joint angle detections to give optimal feedback, to motivational and psychotherapeutic components to increase exercise precision and discipline. AI will contribute to making physiotherapy even more personalized, enduring, and further integrate cognitive behavioral therapy and virtual reality into the precise treatment regimens. It will also increase the frequency of exercise, since the patient can work out in several places, with the use of telemedicine for physiotherapy too.

Introduction

Physiotherapy is a specialty that involves guiding patients who have been affected by a pathological process, such as a neurological or traumatic insult leading to a disability, to help restore their function. It encompasses a group of skilled individuals working in tandem with a multidisciplinary team of occupational therapists, speech and language therapists, cognitive behavioral therapists, neuromuscular physiologists, specialist rehabilitation nurses, etc. Physiotherapists utilize integrative approaches adopting a holistic psycho-physico-biosocial approach to achieve this goal by allowing the patient to either directly regain their level of independence or reach a desired level of reduced carer dependence and improve their quality of life. The functional restoration is necessary to also limit the risk of further injury or relapse. It requires the right psychological, emotional, and physical support as well as direct and (as we will subsequently cover) indirect physical input to support the patient's needs. Patients and their carers usually require a significant amount of funding for (often long-term) packages of care post-discharge from the hospital to support their rehabilitation and subsequent recovery. There is also a need for an optimal interface between community physiotherapy and hospital physiotherapy to facilitate continuity of care, and to support quality improvement and feedback systems that

would later benefit patients going through a similar predicament. Additionally, an auditable trail and follow-up of patients that are discharged is also required to subsequently monitor progress and rehabilitation compliance. This all requires a significant proportion of funding and healthcare investment and is a socio-economic challenge for healthcare providers and policy makers.

These aforementioned areas are increasingly gaining recognition as key to a patient's recovery and are where machine learning can serve as significant adjuncts to physiotherapy service provision. Machine learning has been extensively covered in this book and so its introduction will not be heavily labored on here. However, as a sub-facet of artificial intelligence, machine learning algorithms are mathematical instructions allowing a computer or any electronic device to be programmed and learn to independently carry out an automated objective without the presence of human supervision. It has been applied to multiple fields with tremendous success and is touted to also impact physiotherapy. The extent of this impact continues to be a topic of considerable debate across multiple fields. Several chapters in this book have covered some of these applications and challenges as well as approaches to optimal machine learning methodology. A summary of the machine learning pipeline is presented in Fig. 1.

In physiotherapy, the re-training and rehabilitation of patients could benefit from artificially intelligent robotics or wearable and smart apps, and simulation for workforce education [1–10]. Indeed, progress has been made over the past decade where artificial intelligence has entered all aspects of healthcare delivery. However, ML also promises to help augment, but not yet replace the physiotherapist, whose role remains paramount to the pre and post-discharge recovery of a patients' cognitive and physical function.

AI in Physiotherapy and Physical Rehabilitation of Patients

This section discusses the use of artificial intelligence in physical therapy of patients. Physiotherapy for physical patient training is required for those who have had diseases that affect multi-

organ systems or undergone procedures to treat them. These diseases include [1, 3–6, 9–13]:

1. Rheumatological diseases, sports injuries resulting in back, neck and shoulder pain.
2. Diseases of the central nervous system such as age-related, developmental and movement disorders associated with Parkinson's disease, multiple sclerosis, Alzheimer's disease, amyotrophic lateral sclerosis, Huntington's disease, stroke syndromes, hydrocephalus, and brain tumors affecting the motor homunculus, etc. [11, 12].
3. Diseases of the cardiovascular system such as myocardial infarction and peripheral vascular disease necessitating rehabilitation [14].
4. Respiratory diseases such as infective exacerbations of chronic obstructive pulmonary disease, acute respiratory distress syndromes requiring intensive care support, and cystic fibrosis, which usually also requires breathing retraining to optimize tissue oxygenation and perfusion [15, 16].

Physical rehabilitation in these circumstances is usually performed by experienced specialist physiotherapists. About 50% of stroke survivors develop disabilities of motor function, which requires continuous rehabilitation including gait-based retraining [3, 12]. In this regard, machine learning algorithms have been developed for stroke recovery aiming to predict the scope of recovery based upon features such as duration of in-hospital stay, duration of stroke, and patients' Bartels index score [9, 12]. The intention is to enable a functional recovery estimate to be identified [12].

Another area utilizing AI for physical rehabilitation is the use of the OpenPose platform for posture detection, hand gesture detection and in sports physiotherapy for predicting how an individual can handle and throw a basketball [5]. It offers a cost-effective alternative to other methods that are resource-intensive and require expensive equipment. The OpenPose platform can be incorporated into a mobile app using an individual's phone camera to take photos and send images to the algorithm for automated posture assessment and classification. This becomes useful in patients

rehabilitating from lesions of the brain and spine that affect posture and sensori-motor function as is evident in brain and spinal tumours requiring surgical excision.

Since the physical side of rehabilitation is usually not completely effective without the psychological rehabilitation component as well, an additional extension to platforms like OpenPose system would be the use of natural language processing algorithms to build a chatbot that can then guide the patient through rehabilitation and pose training [4]. As such, chatbot systems can also be designed to offer further psychological and cognitive support to patients looking for additional training time after their physio sessions are completed for the day to augment healing, maintain routines, and stimulate compliance. Chatbots can also offer remote physiotherapeutic support by referring patients who require out-of-hours physiotherapy input within the community so that distressed patients can better engage with their physiotherapist and referred for the right service. It could also be applied to help follow-up patients for needs assessment, track their progress with their prescribed rehabilitation plan or determine whether there is non-compliance.

The above platforms facilitate a scenario where considerable amounts of information are captured to gain a complete picture of the patient's continuous psychological and emotional needs, which could in turn affect a patient's physical recovery. The need to engage other teams to order the right equipment and provide the care plans that the patient needs to rehabilitate is centered on the data available to the physiotherapist. Discussion with physiotherapists revealed that a considerable amount of time is spent processing this data and identifying missing data often from different disjointed sources. Most of these data sources are not electronic and even when they are, these systems poorly communicate with one another, making effective decision support challenging. As the data for patients significantly grows in scope and volume, especially for chronically ill patients, machine learning algorithms become necessary to derive insights that would aid the physiotherapists' decision making, assessment of patients for the optimal physical therapy regimen, etc. These

insights could support the selection of the right equipment needed for the patient to physically rehabilitate, the right companies with the required tools and the creation of advanced care plans to facilitate physical rehabilitation.

Microsoft invented the Kinect system for motion tracking, and it became popular for hands-free gaming. Kinect-based physical rehabilitation is another area demonstrating significant potential to change patient lives and physical needs due to its level of flexibility and low cost for human action capture [1, 3, 6, 13, 17]. It is marker-less which means that the patient does not need to be attached to wires. It also offers patient continuity from hospital rehabilitation into the home environment. There is also scope for physical feedback monitoring and a platform of external mentorship and interactivity with friends or others. In a study, the authors acquired multiple features from the patient including their skeleton joints and depth map features to assemble multiple classifiers. The areas that were analyzed and example of exercises that were developed to support patients included [3]:

- Range of motion exercises, which help patients with the mobility of their joints.
- Muscle strengthening exercises to gain better balance, mobility and ability to enjoy a normal lifestyle include squats, arm rowing exercises and modified push-ups, shoulder presses, etc.
- Balance exercises enable stroke and Parkinson's disease patients to improve their balance, or those with mobility-limiting muscle weakness to build strength and improve their balance.
- Flexibility exercises to support patients with upper motor neuron-related contractures associated with stroke and neurological disease, those experiencing back pain or those with Parkinson's disease as well as those with herniated disc conditions. Others also benefit from chest, hamstring, back and shoulder stretches. Although the degree of muscle stretch is difficult to objectively quantify and would benefit from AI-augmented measuring methods.
- Following surgery, physical rehabilitation is usually necessary to reduce post-operative pain and muscle stiffness, and to improve the patient's conditioning or to prepare them for

discharge to the community, where potential physical rehabilitation continues until full recovery.

AI in Exergames and Serious Games for Early- Stage Physical Rehabilitation

The process involves the patient performing rehabilitation exercises, such as stretching, captured by the Kinect sensor, which detects the person in the frame, analyzes the pose, recognizes the movement, and classifies the human action, the degree of difficulty and the activity performed [3, 18]. A reward-based system can be implemented to provide a psychological feedback incentive to engage patients.

Algorithms that have been discussed in the literature for human detection include Histogram of Gradient for low level feature identifier, Wavelet and Principal Component Analysis Shift, together with shape contexts [3, 19–24]. To improve detection speed, other authors have also proposed rejection cascades, but this can be computationally intensive and other low-cost algorithms have been proposed [3, 23].

Other algorithms include scale invariant feature transforms (SIFT) which are highly accurate with low computation time and have been used for hand-gesture-recognition [3, 25].

The Kinect sensor can be used to evaluate gait and postural changes in these patients to facilitate powerful physical rehabilitation for the gait impaired stroke patients. The concept of exergames also adopts machine learning and game AI to support the integration of natural human motion and exercise for the elderly. This patient demographic may require continuous physiotherapy but may not necessarily have prescriptions for these in the community unless they are coming home from the hospital setting. Exergames can be set-up for the home environment coupled with tele-mentoring platforms whereas serious games can facilitate the remote monitoring via AI-supported platforms with alerting systems to enable remote mentoring/monitoring and feedback.

A limitation of these games is that they are restricted to the analysis of only impairment-

level-assessments that focus on non-occluding movements, and are unable to diagnose deficits of gross and fine movement in the hand and foot [3]. The games are not usually suitable for all ages, however machine learning algorithms could be trained and programmed to ensure patient-age-targeted games are developed.

The Kinect system as a forebearer to the current Microsoft HoloLens 1 and 2 augmented reality platform also enables registration and joint detection algorithms for the recognition of the shoulder, neck and arm joints. This allows for a multidimensional analysis of shapes, sizes, postures, and other motions to be characterized. Such a high dimensionality of datasets benefits from principal component analysis to determine torso joint position and pose estimation together with Fourier transforms for temporal dynamic changes [3].

Others have also proposed the naïve Bayesian nearest neighbor algorithms such as the Eigen-joint to combine multiple information to aid classification [26]. Others also introduced novel approaches for human action recognition, termed the histogram of 3D joint locations, which extracts spherical coordinates of the position of joints as histograms [27].

Depth image extraction of the 3D position of joints has been achieved using Gaussian kernels to compute confidence scores. Kinect skeleton joint features have also benefitted from algorithms such as support vector machines, K-nearest neighbors, NITE algorithms, etc. [3, 28] These algorithms have been used to model diseases where movement is impaired and to facilitate exercises for physical rehabilitation including motion such as helping patients with performing jumping jacks, arm circles, arm curls, motion of limbs and hips in ways that minimize strain on their joints [3].

Others have also employed kinematic filtering, point cloud segmentation, cylinder model fitting, hierarchical coordinate systems, Z-score normalization, Kalman filters, fuzzy logic, skeleton normalization, and dynamic time warping as well as trajectory recognition to characterize diseased motion for machine learning [3, 29–33]. Furthermore, deep neural networks were also leveraged by Han and colleagues to identify recovery states

and postural correction [33]. Other methods such as zero-velocity crossing to locate starting and ending points for human motion segmentation have also been discussed in the literature [31, 34].

The ability to judge depth by an algorithm is a challenging area that has taken decades of research to develop [1, 3, 17]. Local Ternary Directional Pattern feature descriptors have enabled encoding of depth maps [35]. These feature descriptors can be fed into support vector machine classifiers. This highly performant ML approach outperforms existing descriptors such as HOG, PHOG and CENTRIST, reducing the non-linear feature dependency of classification on the depth map by a support vector machine [3]. Others have proposed HOG-based depth motion maps computing the difference between two frames captured by the Kinect sensor and aggregating the difference over time [36]. Diseases where depth data have proven useful for physio rehabilitation include multiple sclerosis, stroke, wrist and hand injury, and cerebral palsy [37–39]. Machine learning algorithms that have been implemented include K-means, neural networks, fuzzy logic, PCA, decision forest and Histogram of Oriented 4D Normal among others [3, 31, 36, 38, 39].

Estimating pose from the exact body contours of an individual has also been achieved by Xia et al. [27] These and many other areas will continue to evolve over the coming decades to provide robust methods of supporting physical rehabilitation. However, what must also be addressed is the emotional and psychological aspects of physical rehabilitation that can limit patients' compliance, and this is an area in which machine learning feedback systems must evolve to support.

In a gamification setting, there is a need to also provide psychological support when the patient does not successfully complete a task to the desired level or reach their goal. Encouragement is imperative and is one of the crucial roles that a human physiotherapist can provide, together with empathy and motivation. The response to a patient's perceived failure must be measured, but also objectively analyzed so that an appropriate level of support can be adjusted to limit

psychological stress. Machine learning algorithms using natural language processing like the Amazon Alexa, Kinect and others could facilitate this encouragement dynamic to support patients in settings when in-person physiotherapists are not readily available. Physiotherapists cannot be available 24/7 and patient access to services may also be limited due to lack of funding or during situations such as the SARS-COV-2 pandemic, which require social distancing measures.

For exercise assessments, Capecci and colleagues used Histogram Semi-Markov models (HSMM) to monitor and evaluate the conduct of the rehabilitation exercises comparing it to Dynamic Time Warping and reporting superior performance in favor of HSMM to correlate better with clinical scores [31].

Companies in this space are summarized in Table 1 and include SWORD Health, a Portuguese-based start-up that has designed an evidence-backed solution using wireless trackers to obtain biofeedback from the patients' movements [40, 41]. An AI-based physical therapist guides the patient through a few exercises. In an insurance-powered global healthcare system, the physiotherapist together with a remote team of human clinicians could be based in any country and could be incentivized to check in periodically with the patient. This tele-platform approach ensures 24 h support for the patient taking into consideration the different time-zones for both patients and physiotherapists [40, 41].

Other companies such as Physera have an online application and eHealth facilities aiming to facilitate face-to-face physiotherapy between patients and therapists [5]. Physitrack is another company that uses video-platform based methods for orthopedics and neurology patients to enable them to consume several hours of video and learn from various exercises [5]. VeraHealth provides a platform that enables community physiotherapy services to be achieved [5].

Another is the OpenPose platform and library, which is an open-source digital library for musculoskeletal physiotherapy [5, 6]. The OpenPose system enables a computer-aided rehabilitation platform created in C++ for posture detection. It facilitates an online platform for physio-based

Table 1 A summary of some of the companies that are involved in AI for physiotherapy

Apps/ Companies	Purpose	Machine learning technologies behind it.	Clinical examples	Future	Evidenced based medicine	Reference

training of patients. It integrates with computer vision frameworks such as OpenCV, OpenCL, and Caffe for image-based training and live image rendering, where a recorded video can be analyzed and feedback can be provided to the patient [5].

AI in Physiotherapy Education and Use of Simulation for Educating Physiotherapists

The role of physiotherapists has continued to evolve over many decades and provides specially trained and regulated subspecialists in most medical institutions. Physiotherapists often work as part of a multidisciplinary team in various hospital settings ranging from medicine to surgery, outpatient clinics as well as the community health centers and clinics, general practitioners' surgeries, and sports and exercise clubs. There is an unmet need for the education of physiotherapists and their continuous professional development to cater for any subsequent knowledge gaps [4, 42].

Correspondingly, in-situ simulation settings enable senior physiotherapy supervisors to train junior therapists in a safe, controlled environment that mimics the actual clinical situation of interest. This equips them with the necessary practical skills to manage often very complex patients needing a multi-system and multi-disciplinary approach to physiotherapy, occupational therapy, speech and language therapy, to support areas such as breathing training as well as mobilization.

Many algorithms have been developed that are finding their way into high fidelity simulators to heighten the learning experience of physiotherapists. Algorithms that facilitate the recognition and classification of human activities in video sequences, which segment out background distractions, etc. can be used for human action recognition to train physiotherapists to solve a particular problem [5].

Convolutional neural networks, recurrent neural networks and other deep neural networks, and computer vision together with support vector machines are also commonly used to analyze pose and motion recognition. Moreover, random

forests have also been employed for action recognition and can be incorporated to break down specific tasks to enable the learner to make improvements, analyze complications, and improve patient safety [3, 4, 10, 11].

The delivery of physiotherapy education can be achieved remotely. The objective of one study was to assess the effect of simulated learning environments (SLE) on educators' self-efficacy in student supervision skills [43]. Significant improvements in clinical supervision and self-efficacy change scores were seen in SLE participants compared to control participants in three domains of self-efficacy: (1) talking to students about supervision and learning styles ($p = 0.01$); (2) adapting teaching styles for students' individual needs ($p = 0.02$); and (3) identifying strategies for future practice while supervising students ($p = 0.02$) [43]. A facilitated debrief, where most of the learning occurs, can also be augmented by artificial intelligence. For an in-depth treatment of AI in medical education please see the relevant chapter in this compendium of works.

Another intriguing area of physiotherapy education is in advanced gaming immersion utilizing augmented reality and virtual reality settings. In one study, the authors mention that advanced AR/VR and gaming technologies can authenticate simulated learning experiences that are close to real-life conditions, problems, and applications, something that could revolutionize training [42]. The GAMEPHARM platform was described where researchers targeted and consolidated the findings from three distinct pillars to produce a prototype and blueprint for physiotherapists looking to design systems and platforms for rehabilitation education using games. These pillars included: (a) the requirements of the application area in question; (b) the current state-of-the-art and emerging directions in game-based professional education and training; and (c) existing applications of game-based learning in the field of healthcare [42]. Their team proposed an idea and design of augmented reality modules embedded alongside the game simulation and virtual world environment. This is aimed at providing participants with an authentic immersive simulated game scenario. As ML algorithms continue

to evolve, an additional pillar would be to investigate the progression of game AI to support educational physiotherapy-based rehabilitation.

AI and Physiotherapy Education

Physiotherapy education also involves the troubleshooting of problems presented by other less experienced members of the team by a more experienced team leader and educator who provides support for the process of physiotherapeutic diagnostics [44]. The approach is to streamline the number of physical tests that the trainee physiotherapist will perform to reach a clinical diagnosis, as multiple tests can be considerably uncomfortable for the patient and an inefficient use of the therapist's time. In one study, the researchers compiled the anatomy of the neuromuscular system and developed an AI-based tool (called PhysIt), which creates an interactive visualization and diagnostic system to assist the trainee physiotherapist [45]. The efficacy of their diagnostic and visualization tool was successfully evaluated and significantly decreased the number of imprecise candidate diagnoses of patients with physiotherapeutic needs [44, 45].

AI for Robotic Assisted Physiotherapy

Another area with potential for growth is AI-based robotic physiotherapy to support patient rehabilitation. Over recent decades there has been a keen interest in robotic-assisted physiotherapy to improve patient mobility. Either the robots behave in an assistive way or they completely take away the added joint stress that the patient undergoing early rehabilitation is being placed under. According to some physiotherapists who oppose this approach, one disadvantage may be that having the robot take away the added joint stress means that the patient fails to learn how to use that joint correctly, which can inevitably delay their recovery. However, in one study, the team retrospectively identified 107 cases of new cerebral stroke who were allocated into 2 groups. A robotic physiotherapy group where 36 patients

underwent 30 sessions of robotic physiotherapy twice a week using the Lokomat, compared with 71 patients undergoing a 5 times per week conventional physiotherapy program [46]. The Modified Ashworth Spasticity Scale (MASS), Brunnstrom Recovery Scale (BRS), Functional Independence Measure (FIM), and Functional Ambulation Categories (FAC), as well as the Berg Balance Scale (BBS) were used as evaluation parameters. Cognitive evaluators included the Mini Mental State Examination and Short Form Health surveys. The percentage of parameters at discharge relative to pre-treatment values demonstrated superior improvements in FIM, MMSE, in the RT group ($P < 0.05$), suggesting that robotics could be incorporated into current approaches for physical rehabilitation to aid cognitive augmentation of human-guided physiotherapy [46]. The authors did not report on the combination of both human and robotic methods.

Another aspect of robotic physiotherapy is the layer of education that is not available in traditional physiotherapy curricular. Twenty-first-century healthcare will continue to incorporate machine learning methods and the physiotherapy-educator is uniquely positioned to have these skills in their armamentarium to unlock approaches that decades ago would have been considered infeasible. It may be that the future physiotherapist will program to delegate all the repetitive reasoning tasks to an AI agent, such as a robot, to facilitate interpersonal patient-physiotherapy educational development. They may therefore need to educate themselves and learn about how the AI powered robot will interact with the patient and ways to augment its behavior to provide the right support for the patient.

AI for Physio-assisted Activity of Daily Living Monitoring

In one publication, the ATHENA smart process management system aims to bring in advanced planning to improve daily activity and cognitive impairment in patients requiring complex physiotherapy such as for stroke and dementia conditions [2]. The platform leverages AI-based

planning and scheduling to design timed sequences of activities that solve a problem in each environment. Their web-based framework also analyzes and facilitates ambient assisted living for decision support and for the daily care of patients, which enables the design of patient-specific personalized activities of daily living. Technical staff can be organized and coordinated for patients needing a multi-disciplinary input from the entire medical team such as nurses, physicians and physiotherapists as well as the presence of the infrastructure required for their rehabilitation, such as monitors, the need for laboratory support, etc.

AI and Virtual Reality for Physiotherapy and Rehabilitation

Recently others have developed off-the-shelf video game and virtual reality platforms for rehabilitation [47–49]. One such work describes an avenue for integrating virtual reality and AI-based game tracking methods to improve the effectiveness of hand rehabilitation. Prototyped using the LEAP motion sensor as the input device, the tracking cameras leverage the Oculus virtual reality headset for interactive gaming developed on the Unity Game Engine [47]. Their preliminary studies reported good efficiencies in implementation for human subjects in terms of hand physical therapy [48]. Others have also described a similar approach for leveraging virtual reality for upper limb rehabilitation in patients with neurological disease and another termed VirtualPT for home care and elderly patient rehabilitation [49].

AI for Physiotherapy-assisted Sensory and Balance Training

Falls are a common problem affecting about 35% of all community-based individuals aged 65 or older with increasing risk the older the individual becomes [1, 3, 9–11]. Physiotherapists also help patients with their balance and one such platform to train patients with vestibular pathologies to improve their ability to sense their surroundings

and reduce their risk of falling has been discussed by Condron and colleagues [50]. They developed a dual task programmable platform called the Chattecx Balance System (CBS), a computerized force platform that is aimed at facilitating both balance performance and cognition. They looked at twenty healthy elderly patients with a mild increase in fall risk. Artificial intelligence through wearables can be used to support patients who are losing their balance [50].

In a randomized controlled trial the effectiveness of Ai Chi was compared with conventional water-based exercise to improve balance [9]. The researchers used balance performance measures in areas such as the excursion and movement velocity and balance control assessments such as the limit of stability test as well as the Berg Balance Scale(BBS). They reported a significant increase in the anteroposterior direction of motion after receiving Ai Chi ($p = 0.005$ for excursion, $p = 0.013$ for velocity) but not in conventional water-based exercise. The Ai Chi group demonstrated significantly better results than the control group ($p = 0.025$).

AI for Assisted Wheelchair Users and Assisted Mobility Support

A significant proportion of the global population are wheelchair users and in the developed world they receive significant support and advocacy to make their lives easier in terms of mobility. The need for a wheelchair may arise due to a variety of neurological and trauma-related conditions such as spinal cord injury and stroke leading to quadriplegia or paraplegia, multiple sclerosis, and cerebral palsy. These individuals with disability could benefit from AI. Over recent decades, artificial intelligence has been considered for allowing physiotherapy management and mobility support for wheelchair users [1, 7, 10]. Novel engineering approaches have enabled the development of the smart wheelchair, which has evolved since George Westinghouse's 1914 invention of the manually controlled electric wheelchair into a power-driven automated innovation that enables physiotherapy treatment compatibility [7]. Current

innovations include autonomous AI-based advanced speech/voice recognition powered by the Android operating platform that have been incorporated into the design of the smart wheelchair [7, 10]. This now allows the patient to move freely in a highly secured environment using embedded flex sensors to create an awareness of the wheelchair's surroundings. It has the capability to navigate and reduce any strain on an individual and the design can facilitate the needed physical therapy.

Other assistive mobility devices include alternative and autonomous systems as well as augmentative mobility training devices, those that make use of human machine interfaces and brain computer interfaces and electromyography signal processing as well as those for biped station positioning(the ability to support the accomplishment of certain tasks on two legs) [10].

AI for Inattention and Hemi-neglect Training

Inattention monitoring and rehabilitation after a stroke requires advanced physiotherapy and constant patient prompting. This enables an individual who has hemi-neglect and hence restricted use of one side of their body to learn to either slowly improve, recover or gain the ability to compensate using the other side [12]. Inattention mechanisms are poorly understood, but has been studied in motor vehicle drivers and usually include distraction and fatigue but in some patients such as those with stroke the issues are organic in nature leading to hemi-neglect. [51] Currently Constraint-Induced Movement Therapy has shown some promise, but in a systematic review none of the tools designed for managing neglect had evaluated physical performance [12]. One possible area where AI could augment and supplement inattention retraining involves the constant prompting required for the patient to re-learn how to use the other side. A combination of natural language processing, robotics and computer vision can facilitate supplementary prompting with tools such as Amazon Alexa and video cameras helping with the monitoring of the patient's state

especially in scenarios where physiotherapists may not be available on a 24/7 basis.

Despite the growing recent interest in the utility of robotics for autonomous logistical support to aid physiotherapy and rehabilitation, we are yet to have widespread use of fully dedicated humanoid robots to support patient physiotherapy [52]. Inattention retraining could be an area that benefits from the robotic space where robots can be trained to help prompt and guide patients who are not using one side of their bodies.

Another area where AI can benefit inattention retraining involves the use of wearables and smart apps to induce stimuli that could prompt the patient to use the side that they are neglecting. Given the shortage of physiotherapists, as described by several different countries due to the economic landscape, out-of-hours physiotherapy support for conditions such as stroke patients with inattention would perhaps benefit from emerging AI-based technological support.

AI for Respiratory Physiotherapy Management

Clinical disease support systems can improve patient outcomes and decision-making processes. Current approaches are leveraging Internet of Things devices that can collect and stream a vast amount of physiological data from ventilators and other medical devices [53]. Machine learning models offer the unique potential and capability to model these datasets and derive insights into how ventilator-dependent patients can benefit from improved clinical processes and outcomes [15, 16, 53]. Physiotherapists specializing in respiratory and ventilator support can benefit from automated and advanced data analytics for decision support to provide them with insights on managing acute respiratory distress syndromes as illustrated in the recent SARS-COV-2 pandemic. Occasionally neurological diseases that affect the respiratory system like Guillain-Barré syndrome can also need respiratory physiotherapy support.

In one study authors looked at the respiration rate (RR), a vital observation and marker of respiratory disease, and the most widely adopted

techniques used to monitor it. Their work highlighted the many drawbacks clinicians' face when analyzing this marker. They used non-invasive contactless infrared thermography to predict respiratory rate [54]. Their system utilized a thermal camera to monitor variations in nasal temperature during continuous respiration, tracking regions of interest like the nostrils and head motion. Machine learning and computer vision algorithms made use of "Histogram of oriented gradients" and "Support vector machines" (SVM) to build a Breath Detection Algorithm (BDA). Algorithmic performance of this BDA was validated on 150 breathing signals through its precision, sensitivity, spurious cycle rate, and missed cycle rate value. Reported accuracies were 98.6%, 97.2%, 1.4%, and 2.8% respectively. The parameters obtained from the BDA were then passed into the k-Nearest Neighbor (k-NN) and SVM classifiers to determine whether the human test participants had abnormal or normal respiration, which they classified as bradypnoea or tachypnoea. The patterns were visualized using t-stochastic neighbor embedding (t-SNE). Reported validation accuracies were stated as 96.25% and 99.5% with training accuracies 97.75% and 99.4% for SVM and k-NN classifiers, respectively [54].

AI for Community Physiotherapy and Care

In many parts of the world, with a specific example being Bangladesh where 415 physiotherapists have been deployed over a 35-year period to support a 150 million population, practices are concentrated in the cities with limited access of services for the rural communities [55]. A 2005 World Bank report revealed that a significant number of up to 77% of the impoverished can only access local pharmacists or medicine sellers for their ailments due to poor accessibility to healthcare facilities and high consultation fees [55]. The shortage of community physiotherapists means innovative approaches combined with culturally viable physiotherapy services could improve the quality of life of individuals with

physical and emotional disabilities needing rehabilitation.

Machine learning, robotics and most of the previously discussed technologies could be employed to support community physiotherapy services in countries where there is an economic shortage of physiotherapists to supplement the deficits in services.

AI for Cognitive Impaired Patients Needing Physiotherapy and Rehabilitation

In many patients, especially those with neurological diseases such stroke, Parkinson's disease, multiple sclerosis, Alzheimer's disease, traumatic brain injury, etc., there is a clear need to support and manage cognitive deficits. However, these cognitive deficits also affect the patient's ability to be compliant with the physiotherapy rehabilitation regimens that could improve their quality of life and functional capacity.

Authors have discussed the use of symbiotic neuroprosthetics and myoelectric control as well as the use of brain machine interface technologies for perioperative medicine to augment cognition [56]. The use of an artificially cognitive machine developed for cognitive rehabilitative exercise was based on the machine's indications of when cognitive function was impaired [56]. The challenge though is that cognitive dysfunction is very dynamic and requires constant reassessment. Such algorithms must be trained to dynamically monitor the patient's state and alter their response to adjust the rehabilitation regimen or know when to involve or alert a physiotherapist to improve the patient's rehabilitation needs.

AI for Functional and Feedback Systems in Physiotherapy

In one study aiming to help with home-based physiotherapy, the identification of the patient's pose was assessed using the PoseNet. [6] In their study, the system used seven exercises with two sides for more variety, identifying posture and

pose, and generated a scoring function on the analyzed input image. The main idea of their desktop application system using a 3D Avatar is based on the ability to detect the body's key points using pose estimation techniques by extracting key points from different exercises and building a database file that stores the information. This was then compared with the patient's key points and a minimum accuracy of 80% was reported [6].

AI in Smart Watches and Wearables for Physiotherapy

Physiotherapy is recommended in patients experiencing arthritic shoulder pathology, as conservative management approaches are often initially recommended over immediate surgery [3, 5, 6, 8]. However post-surgical rehabilitation also requires physiotherapeutic regimens implemented over a period of weeks to months to ensure that the patient regains optimal function. Current limitations mean that there are no objective measures for unsupervised home physiotherapeutic regimens and exercise programs that allow adherence monitoring. In one proof of concept study aiming to resolve this disparity, a commercial smartwatch was utilized for a home physiotherapy study [8]. Using an evidence-based rotator cuff protocol, data from a six-axis inertial sensor were gathered from the active extremity. A framework called the activity recognition chain formed the base upon which four supervised learning algorithms, K-nearest neighbors, Random Forest, Support Vector Machine Classifiers, and Convolutional Neural Networks, were trained and optimized for classification of the exercises. Algorithmic performance was evaluated using a fivefold by-subject and temporally stratified cross-validation with a categorical classification accuracy of 94%. The convolutional neural network achieved the greatest performance in accuracy reported as 99.4%, but a lower accuracy score of 88.9% was observed when the algorithm was applied to an algorithmically naïve/unseen dataset [8]. Others like McGirr and collaborators have reported similar accuracies using 3-axis gyroscopes on shoulder exercise data in

classification problems and have reported accuracies of 86–91% [57]. Another study by Pan and colleagues used multiple synchronized inertial sensors mounted to the chest, upper arm and one wrist for a classification accuracy of 96.9 on five different shoulder exercises [58].

Future of AI in Physiotherapy

Physiotherapy and rehabilitation are an expensive service needing considerable financial resources that appear well suited to a private insurance-based healthcare system. However, the evolution of AI hopes to reduce costs and support physiotherapists with emerging technologies that will help improve the service delivery and make physiotherapy widely assessable to poorer communities. Technologies like robotic physiotherapy and tele-platform-based physiotherapy, with the right financial incentive and government backing, could support global service delivery of therapies for a large population of individuals. Other challenges that need to be overcome will be the mentality and fear of AI taking over jobs. As pragmatists one can appreciate that the technology has potential, however at such an early stage of development, an AI's role must seek to augment and supplement rather than completely replace the patient-clinician/physiotherapist relationship that has been established over several centuries. Although, as realists we should welcome the use of AI in areas where repetitiveness diminishes the efficiency of a therapist including record keeping, which can be automated using AI. But we must then seek avenues to educate in areas where physiotherapists can also gain the essential skills necessary to be at the forefront of this wave of innovation for better patient outcomes. It is here that we see potential for going forward in the future. Research areas that have evolved include Kinect-based gamification approaches for physiotherapy and the use of augmented reality for patient monitoring. Areas in physiotherapy education also show promise in terms of knowledge-based service delivery and provision of diagnostics as well as feedback for patients receiving physiotherapy across the

community. Wearables, smart sensors, and natural language processing platforms have also gained prominence in patient rehabilitation and will continue to evolve. An area where we see a confluence of technologies between application of natural language processing systems such as the Amazon Alexa with computer vision and robotics is in the cognitive aspects of physiotherapeutic rehabilitation, training, and feedback for patients with pathological deficits such as stroke, gait abnormalities and movement disorders. More robust machine learning algorithms will continue to evolve to help manage the more complex cognitively impaired patients that require continuous physiotherapeutic support.

Abstract

Technological advancements in the past decade, especially in the field of Artificial Intelligence (AI), have influenced almost every industry, and the field of medicine is not an exception. From robots taking care of time-consuming, repetitive tasks in hospitals to

rapid cancer diagnosis methodologies developing every day, it is visible that AI has potential to help further the medical discipline.

AI in rehabilitation has broad usability, such as assisting in the rehabilitation session, evaluating the treatment progress (decision support), and providing prognosis regarding risk of complications or success of the treatment.

In this chapter, firstly rehabilitation and its specialties will be explained followed by a thorough explanation of why AI can be helpful in rehabilitation. Furthermore, different applications of AI in this field will be discussed. The

Introduction

Advancements in technology, especially in the field of AI and robotics, have influenced almost every industry. Looking at a broad field like medicine, the impacts of AI is visible in various shapes and forms. From robots taking care of time-consuming, repetitive tasks in hospitals to rapid cancer diagnosis methodologies developing every day [1], it is visible that AI has potential to help further the medical discipline. In some fields this effect is already visible, while in others it is yet to be proven.

Rehabilitation is an inseparable part of most medical procedures and treatment plans. Therefore, it is vital to look for solutions to automate the tedious processes in the field and instead utilize the regained power on tasks that require the most attention. The need of a powerful processing and analyzing tool results in reaching out for machine learning algorithms in rehabilitation as well. ML algorithms are great tools to be used with large amounts of multiparameter data. This data can be used to personalize care services for individuals and help medical staff in decision making [2].

There are a variety of subjects in AI that can be integrated with rehabilitation. Diagnosis and accurate classification of types of disorders with similar symptoms, unifying medical records in medical databases, decision support systems for therapists, assisting them in rehabilitation session, and prediction of treatment outcome are part of the accomplishments in this field. Examples of such applications are further mentioned in this chapter.

Definition of Rehabilitation

The concept of rehabilitation is generally referred to as a series of tasks and actions which aims for a better physical and social life for the patient. According to the WHO, rehabilitation is defined

as: “a set of interventions designed to optimize functioning and reduce disability in individuals with health conditions in interaction with their environment” [3].

The aim of rehabilitation is to help a patient with a disability or injury to overcome the pressure and be able to adapt to a new life routine as much as possible. In the ideal way, the patient will be able get back to their normal life routines. This goal includes all different aspects of an individual’s life [4].

Benefits of Rehabilitation

Rehabilitation can help with decreasing the burden of a wide range of health issues. This includes chronic or acute diseases, injuries, traumas, or other illnesses. It can also have a tremendous role when it comes to controlling symptoms or severeness of a disease or it can be widely used as a step after surgeries so that patients gain back muscle strength or prevent complications after surgery. A vast number of patients do not only need physical support but also need to consult with a psychologist and receive advice on how to bear with certain inevitable life situations, such as accepting that the patient might not get back pre accident levels of performance.

One of the specialties in rehabilitation in medicine is physical medicine. This specialty focuses on quality-of-life enhancement of patients with a health-related disability and how to provide the maximum level of social integrity for the patient.

Phases of Rehabilitation

Despite a general misunderstanding, rehabilitation is not limited to one single phase in the care procedure. Usually, the plan and execution of a rehabilitation process is spread into separate periods [4]:

1. Acute period of illness or injury
2. Early rehabilitation (intensive care in clinic or hospital)
3. Treatment and rehabilitation phase, in collaboration with the patient

4. Shifting focus more towards rehabilitation and decreasing direct care
5. Focus on vocational rehabilitation with prevention of secondary complications
6. Patient's state support with a long-term mindset

Generally, the efforts in rehabilitation are put forward toward two major goals. The process is done either toward improving a certain deficiency or reducing the effects of a certain deficiency.

According to statistics [4], one-third of patients do not require any rehabilitation after they face an injury or illness, and they are able to go back to their normal life routines after receiving clinical treatment. However, the rest of the patients will need assistance to gain full recovery and be able to adapt again to their life routine, both physically and socially.

Areas of Rehabilitation Medicine

When it comes to rehabilitation, often only the physical regards come to mind, although a full concept includes several different aspects to consider. There are several ways to define rehabilitation, and therefore, there can be different views on how to categorize areas in rehabilitation medicine [4].

In order to reach the ideal outcome in the rehabilitation process, there are several subsections that rehabilitation is divided into. These subsections are physical therapy, speech therapy, neuropsychology, and occupational therapy.

Although in an actual medical case it is not feasible to separate physical medicine into subgroups, but for an ideal and optimal outcome for a patient, all four aspects must be taken into account.

For instance, a patient with an injury from an accident needs different kinds of support. They require physical therapy to help them attain the physical function they may have lost because of the injury. They may also require psychological support as well to recover from the mental distress.

Physical Therapy

The World Confederation for Physical Therapy (WCPT) has defined physical therapy as: "providing services to people and populations to develop,

maintain and restore maximum movement and functional ability throughout the life-span. Physiotherapy includes the provisions of services in circumstances where movement and function are threatened by the process of ageing or that of injury to disease" [5].

Physical therapy is divided into two different general approaches, diagnostic and therapeutic. The diagnostic approach is used to distinguish different sorts of disorders based on their specific symptoms while a therapeutic view strives to improve the physical symptoms of the disorders which affects the patient's life [6].

Speech Therapy

A speech disorder is defined as any sort of problem a person can have with fluency, voice, or sound while they speak. There are many different disorders that can be categorized as a speech disorder or have speech difficulties as a symptom of other illnesses [7].

Speech and language therapy consists of a series of methods and approaches such as verbal, behavioral, and natural language baselines. These therapy sessions may also include behavioral therapy and response training. In this area, the effort is made to help the person to use their speech capabilities more productively and try to improve the ways of communication. Moreover, therapists in this field work on strengthening the patient's ability to produce the correct sounds in speech and make the conversation more understandable and less tiresome for the speaker [7].

Neuropsychology

Neuropsychological disorders are characterized as issues with increased deficits in behavioral, cognitive, or psychological matters. These issues are mostly caused by a trauma or injury occurred to the brain [8]. Part of neuropsychological illnesses can also occur due to natural aging, such as Alzheimer's or dementia [9]. The science of neuropsychology aims for helping the patients to improve their psychological state and retrieve their social skills to blend in better in society [10].

One of the main challenges that is part of neuropsychologists' work is the uniqueness of most cases. No two brains function the same, and no two personalities are identical. In addition, the therapy session is timely and often has to be done physically in a clinical environment [9].

Therefore, it can be quite demanding to tailor, personalize, and follow the goals and treatment planning for each individual patient [11]. In section "[AI in Rehabilitation Prognosis](#)" some examples of AI aids in this field will be discussed.

Occupational Rehabilitation

Occupational injuries and disorders are generally any abnormal condition that has happened related to a person's employment or because of certain exposures linked to work environment. An extensive number of occupational disorders are in musculoskeletal injuries category, and that is the reason why the initial rehabilitation programs were designed for this group. Currently, this area has broadened to different perspectives in health conditions, such as mental and neurological disorders [12].

The British Society of Rehabilitation Medicine (BSRM) describes occupational rehabilitation as "A process whereby those disadvantaged by illness or disability can be enabled to access, return to, or remain in, employment, or other useful occupation" [13].

General Applications of AI in Rehabilitation

After giving a good perspective of rehabilitation and its specialties, it is important to explain why and in which form artificial intelligence comes into the world of rehabilitation. In general, AI algorithms can be used in forms of supervised learning (learning with labels), semi-supervised learning (a mix of data with and without labels), unsupervised learning (learning without labels), and reinforcement learning (reward-based learning). Apart from the logic behind AI models, data is the most important component in AI. In fact,

data is the main resource used to build the models and make assumptions about them.

The methods and models defined in ML can be utilized in several areas of rehabilitation, such as classification, clustering, and prediction. For instance, recent research studies have worked on the application of machine learning algorithms in classification and recognition of human movements. In [14] Li et al. use support vector machines (SVMs) and K-nearest neighbors to classify hand postures in different exercises related to rehabilitation. Related to the same field, there have been cooperative studies done on the power of different classifiers when it comes to differentiating between functional upper limb movements and walking patterns [15]. Moreover, there are models used for prediction of patients' prognosis which can be a great asset in treatment planning as well. SVMs and K-nearest neighbors have also shown promising results in prediction of patients' recovery. This method has been compared to the common practices currently used in the field which is Activities of Daily Living Clinical Assessment Protocol (ADLCAP) to identify patients with potential for improvement and earlier home discharge. The proposed method has shown a better performance than ADLCAP [16].

But the applications of AI do not end there. Recent advancements have shown that AI algorithms can not only learn actions and tasks performed by therapists but they can also then adjust the difficulty level of the tasks to suit every individual patient's needs [17]. As an example, Shirzad et al. [18] have demonstrated an assessment between K-nearest neighbors, neural networks, and discriminant analysis methods. In this study the mentioned algorithms have been compared based on their ability to adjust the difficulty level of tasks to the patients' motor performance and physiological features accordingly.

Robotics in Rehabilitation

Previously, the main application of robots in rehabilitation was limited to assistive purposes, meaning that robots were involved in the process to

ease some daily routines for the patient. The first rehabilitation robot was designed in the 1980s and it was defined as “Any automatically operated machine that is designed to improve movement in persons with impaired physical functioning” [19, 20].

In the past four decades, the means of using a robot in rehabilitation tasks have improved significantly. Tasks in physical rehabilitation can be repetitive for a therapist but a robot is not prone to fatigue and can handle intense, repetitive tasks for a longer period of time than a human. This factor by itself makes robots a great resource in occupational rehabilitation [17].

The main source of input for these human-made systems is the data that they receive through sensors. The decision taken based on this data can be both fully automated and operated by another person [21]. The capabilities of robots are very much determined by the level of complexity of the learning algorithms used and also the number of sensors used to capture data from the environment [17]. For instance, a simple sensor-based system to capture room temperature can be elevated to a complex system by adding humidity sensors or air pressure sensors. In the new setting, there is more available data to process, and thus more distinct predictions can be made based on more detailed data.

In the world of rehabilitation, robots can have an exceptional effect when it comes to assistive help to care givers, or to the patients both in physical and cognitive aspects.

According to [21], robotic applications can be found in different tasks nowadays. For instance, robots can help a patient gain strength in their muscles after an injury or assist them to have smoother movements.

Learning from Demonstration

Learning from Demonstration (LfD) is a set of machine learning techniques that makes a robot able to learn certain tasks by imitating an expert [22]. Then, the robot would be able to reproduce the learned tasks based on the patterns and rules learned from the demonstrator. The demonstrator in this case would be the therapist and the AI model would be the imitator. This technique is

the most useful in settings such as therapy clinics and patients’ houses where there can be lack of enough resources such as computers and therapists [23]. One of the main benefits of LfD techniques is that, thanks to the advanced AI and sensors, the system can assess the patients’ physical performance and tailor the tasks suitable for their readiness level. LfD systems can be both semi-autonomous and fully autonomous, where the therapist can be present as an overseer to the performance of the robot and interrupt if errors are made. This feedback can then be used by the robot to learn from.

One area that LfD has been applied in is cases such as cerebral palsy and stroke. These conditions can have symptoms such as loss of motor function and reduced mobility. According to [24] in patients with Cerebral Palsy (CP), at least one CP symptom can cause issues in cognitive and linguistic development especially in children under the age of 18 and affect their life expectancy. The study suggests a semiautonomous assistance robot which first uses Gaussian mixture model (GMM) to copy the performed trajectory, and later uses Gaussian mixture regression (GMR) to produce a statistically similar process. Meanwhile, patient’s motion will be controlled with a PID (proportional-integral-derivative) controller.

Gait Rehabilitation

One of the areas in which robotics has been a big aid to therapists is gait rehabilitation. Usually, the methodology in this subject involves the application of exoskeletons for paralyzed patients in need of gait rehabilitation.

While the traditional rehabilitation methods are still common, there are various studies reporting considerable improvements in results of gait rehabilitation done by robots [25]. This is a good example to show the effectiveness of assistive robots, but it is important to emphasize that there are also practical differences between the generations of the mentioned robots.

The initial generation of robotic exoskeletons in this field uses predetermined, fixed patterns to train gaits, which means the patient do not have an active role in the process and therefore the process of recovery will take much more time.

Although the recent studies suggest a multimodal human-robot interaction system (HRI) [26] which offers interactions with the patient both cognitively (cHRI) and physically (pHRI), these methods are applied by adapting the treatment process to each patient's current state.

There are also rehabilitation robots that use artificial intelligence as a model to personalize treatment for maximum outcome [27]. One study suggests using a training robot that uses two exoskeletons for the lower limb area, in combination with an adaptive admittance model. The model is adaptive which means that its law is defined based on a sigmoid function and reinforcement learning algorithms. In this approach both passive and active training have been experimented where the active training focuses on personalizing the movements and the passive part verifies the control strategy in the model [27].

AI in Assessment and Decision Support Systems

As it was mentioned in the introduction, assessment of a patient's state plays a big role in determining further steps of the treatment plan. The current practice includes therapists making an assessment based on their experience and mostly empirical knowledge and intuition. They must infer diagnosis based on symptoms and patient's self-reporting which does not include any explicit numbers or quantitative data. The factors taken into account are mostly descriptive and unmeasurable. Also, there is great risk that therapists are not always available to give an assessment periodically. The mentioned issues are why AI can play an important role in medical assessment since it can be accessible without limitations, offers a measurable, numerical system, and therefore provides an intelligent decision support system based on a more precise assessment [28].

Rapid developments in the field of data processing are some of the reasons behind huge success of artificial intelligence in different knowledge areas. In case of medical information systems, a model requires sufficient, reliable sources to accurately organize and represent

patient data. There are also different approaches when it comes to decision-making models [29].

AI in Rehabilitation Prognosis

Since a great number of treatments planning in rehabilitation depend on the outcome of the previous treatment stage, one of the factors that can play an important role in helping therapists is the accurate prediction and analysis of so far applied treatment or prognosis or chronic diseases. Also, such outcome can assist therapists to foresee the patient's assistive needs.

There are an extensive number of prediction models in ML that can be implemented either with supervised or unsupervised learning. Some of the most common ones in nonmedical studies are regression models, decision trees, and random forests (prediction models) [30].

In [30] the subject of memory dysfunction of patients with Alzheimer's disease, the performance of ML algorithms regarding prediction of cognitive health status classification has been examined. In this study, KNNs, decision trees, Logistic Regressions (LR), Multilayer Perceptrons (MLP), Naive Bayes (NB), two varieties of Random Forest (RF100 and RF500), Radial Basis Functional Networks (RBF), and Support Vector Machines (SVM) were utilized for a binary classification of yes/no answers in a health status questionnaire. Results demonstrated an overall better performance for LR in this case.

Unlike Alzheimer, some illnesses have symptoms in early childhood such as CP. Although there is no permanent cure for CP, studies on the treatment of this neurological disorder have never stopped. Nonsurgical approaches such as visual therapy have shown encouraging improvements in CP patients which works on specific visual dysfunctions. In the previous studies, AI has been an aid to detecting and diagnosing different diseases. But when it comes to evaluation of visual improvement in CP children, there have not been much computational advancements.

The suggested methodology in [31] uses ML techniques in both diagnostic and prognostic aspects. By capturing images of the CP patients'

eyes and taking advantage of image processing methods, they have been able to not only classify the eye images into four different eye abnormalities but also to extract quantified information from the images for prognosis evaluation. The calculated percentage of improvement is also used to analyze the effectiveness of the visual therapy in general.

AI Wearable Monitoring Devices

Since AI is built upon data, the availability of resources to provide data for AI models is one of the most important tasks in any field where AI is involved. Wearable devices and intelligent systems such as mobile phones are some of the best examples when it comes to data sources. Almost every person owns a smart device which is supplied with several sensors and processors to gather data. One benefit is that smart watches are available in different price ranges and tech specifications for purchase. Also, smart watches or wristbands are carried by the patient for an extended amount of time and the data collection does not require any specific interaction between the patient and the device. Meaning that patient does not need to input data manually. This continuous process of collecting data is a great source of information especially health-related, physiologic, and behavioral material. In general, these factors can help therapists get a better understanding of ongoing rehabilitation therapy. Wearable devices can be used by elderly people, patients with a history of stroke, or patients under supervision for an extended period of time. Athletes and many other groups of people can also gain from this.

Fall Detection

One of the common uses of wearable devices is their build-in fall detection system which has a simple but important purpose of notifying care takers in case the patient loses balance or falls for any reason [32]. The logic in some of these systems is designed in a way to distinguish between other types of movements and an actual fall with the aid of machine learning algorithms. These algorithms learn the behavioral patterns

while they do normal daily tasks and use the information to lower the number of false positive alarms in this case.

Monitoring Purposes

Another example is the practicality of wearable monitoring devices for patients with cardiovascular problems. Studies [2] have proven that cardiac rehabilitation programs are the second highest effective prevention method that has shown promising results when it comes to treatment approaches. The program requires participants to complete the monitoring and data collection over a period of time which often is demanding and results in participants dropping out or not completing the program successfully. The idea of changing the programs setting to a home-based approach and collecting data via wearable devices has been a proper solution to this matter. As it was mentioned before, the biggest benefit of using wearable devices is the constant data collection which gives the caretaker a thorough view of the patient's status and makes the choice of AI advantageous over questionnaires and reports filled by patients.

AI in Virtual Reality and Serious Games

There are many types of exercise in physical therapy which are advised to be done after an injury, and they do not require a supervision of a therapist at all times. However, it is important for a smooth recovery and lower risk of complications that patients follow the instructions and executes the tasks correctly. Therefore, application of virtual reality and gamification was introduced in the world of rehabilitation. One of the benefits of this technology is the ease of usage and the fact it does not need supervision of a therapist at all times.

The setup can vary in different available products. Some can have a display with instructions, images, or a simulated environment, while there are products that use VR headsets for visual purposes. Based on its purpose some systems have a controller stick that users can hold, and the sensors can capture motion and movements. In [33] such a system is used for hand therapy, one of the most common types of rehabilitation before or

after a surgery. The suggested setup in [33] consists of capturing data from the sensors on a headband and the controller in the user's hand. The data will then be applied in a machine learning model to improve the hand's gestures and analyze the effectiveness of the therapy. The final purpose of this project is not only to help the patient complete their tasks but also to provide some entertainment with games.

The most interesting part of this study is how they have used both passive and real time classification in the system [33]. When the patient completes one task, an SVM algorithm will choose the next suitable exercise based on their performance score. Additionally, the patient is provided with a feedback message where it is explained how accurate their grip was compared to the desired outcome. A KNN algorithm has been implemented to take care of this process [33]. The outcome of this research can be applied for other rehabilitation purposes or to design more exercises using the same setup.

Summary

In this chapter, the definition of rehabilitation medicine, rehabilitation medicine's necessity in medical practice, and the different aspects of rehabilitation through AI have been discussed. There are numerous benefits of using AI in other industries which have helped them become more autonomous and at the same time apply their manpower in a smarter way. The same approach has been applied in rehabilitation with AI and it has had great achievements according to numerous studies in the field. The state-of-the-art algorithms and considerable amounts of data are two important factors behind the success of AI. A variety of examples about the influence of AI in rehabilitation are also mentioned in this chapter.

Abstract

The potential of AI for Sports Medicine has been highlighted in the literature. However, few results are found when the command line

(“artificial intelligence”) AND (“sports medicine”) was applied in three of the main databases. These findings show how much we still have to improve in this area of knowledge and this chapter is going to start this process by presenting advances, potential trends, and future challenges of AI in Sports Medicine.

Introduction

One of the main outcomes of the 4th Industrial Revolution, also known as Industry 4.0 is the large amount of data produced. Industry 4.0 is characterized by “cyber-physical systems” – systems that integrate computing, networking, and physical processes, as well a multitude of

technologies (e.g., internet of things, smart sensors) that generated large datasets and leveraged the artificial intelligence (AI) algorithms [1–6].

Recent manuscripts have highlighted the potential of AI for the Sports Medicine area [7, 8]. On the other hand, when applying the command line (“artificial intelligence”) AND (“sports medicine”) in 3 of the main databases, 47 results are found (at January/2021: Pubmed = 14; Web of Science = 04; Scopus = 29). Among them, only two were original research manuscripts published in a peer-reviewed journal and inside of the Sports Medicine area [9, 10]. First, the University at Buffalo’s Orthopedics Department created an expert system to assist patients with self-diagnosis of knee problems and to thereby facilitate referral to the right orthopedic subspecialist with Bayesian versus Heuristic method for diagnostic decision support. However, neither approach truly outperformed the other, and accuracies were not statistically and significantly different [9]. Second, Deep Learning was used for detection of complete anterior cruciate ligament tear in patients among 18–40 years old and a high performance in detection of complete ACL tears with over 96% test set accuracy was found [10].

These findings show how much we still have to improve in this area of knowledge and this chapter is going to start this process by presenting advances, potential trends, and future challenges of AI in Sports Medicine.

Advances

One of the first manuscripts on AI in the Sports Medicine found in the scientific literature was on the controversies and effectiveness of a 12-lead electrocardiogram (ECG) to detect cardiac diagnoses such as hypertrophic cardiomyopathy in young athletes [11]. The authors reported that barriers would be overcome in the near future with the use of AI to assist the decision-making process. In about 5 years, an automated detection of heart defects in soccer and basketball athletes based on ECG and artificial neural network (ANN) produced acceptable results of up to 98%

accuracy, 98% sensitivity, and 99% specificity [12]. Beyond the Sports Medicine field, an analysis of more than 180 thousand people revealed that an AI-enabled ECG acquired during normal sinus rhythm permits, even using an inexpensive, noninvasive, widely available point-of-care test, the identification of individuals with a high likelihood of atrial fibrillation. This result could have important implications for atrial fibrillation screening and for the management of patients with unexplained stroke. The improvement of these AI algorithms will increasingly allow the application of mobile devices, wearables that are widely used in sports settings also for these and other purposes [13]. Therefore, the advances of AI applications in Sports Medicine related to the ECG can already be recognized in a short period of 7 years (from 2012 to 2019) [11, 13].

The speed of advances is largely due to digital transformation that is becoming increasingly common in modern life and sports medicine [14]. This digitization also allows the integration with other important professionals of physical fitness. For example, Fitness Coaches or Personal Trainers using their scientific knowledge and practical expertise add up to the AI [14]. This integrated system is able to do not only measured parameters but also provide advice for progress or preventive measurements and help to create individualized training plans, by taking into account daily changes in performance [14, 15]. Furthermore, an integrated framework of load monitoring by a combination of smartphone, wearables, and point-of-care testing provides feedback that allows individual responsive adjustments to activities of daily living of athletes aiming to enhance performance and/or reduce the risk for overuse, injury, and/or illness [16] (Fig. 1).

Potential Trends

In the near future, the assessment of injury risk will be in real time to assist in decision making regarding the formation of the match and consequently the use of substitutes [17]. The integration of data collection with tracking systems including real-time microsensor inputs using AI algorithms

Fig. 1 AI in Sports Medicine advances

will be likely a key factor in soccer [17], but still needing improvement in data veracity [18]. Additionally, examining technological evolutions expected until 2038, the possibilities can result in something very close to the ideal for the Sports Medicine approaches. Let's look at this futuristic timeline proposed in "Countdown to the Singularity" [19]:

- 2030 ⇔ "AI passes the Turing test, meaning it can match (and exceed) human intelligence in every area."
- 2038 ⇔ "Everyday life is now unrecognizable – incredibly good and hyper virtual reality and AI augment all parts of the world and every aspect of daily human life."

Another potential trend in this field is the humanizing AI. According to Irani [20], even with a huge advance in data processing and computing via AI, it would not easily compare with the true potential of human intelligence. Creativity is one of the greatest AI challenges facing the human mind. Because creativity always comes as a surprise to us, if it was not surprising, we would not need it. Machines are not capable of creativity. Human minds can generate counterfactuals, imaginative flights, and dreams. Using AI surprises are welcome in some fields as art and music; however, surprises in medical diagnosis or treatment are unwelcome [20]. Nonetheless, the point of greatest concern is yet another [20], if AI is going to make clinicians better at caring for

humans, the data sets being used must be representative of society and not biased by sex, race, ethnicity, socioeconomic status, age, ability, and geography [21]. This need for representation is not only a data science issue, but also a moral one. In the absence of equal representation, society has already seen inequitable criminal justice sentencing, unfair hiring practices, and loan-risk determination, to name a few injustices [22]. We will talk more about this in the next topic.

AI also represents a great potential for healthcare applications in areas such as imaging and diagnoses, risk analysis, lifestyle management and monitoring, and health information management [23, 24]. This trend will allow a holistic approach applied 24 h per day, 7 days per week [16]. Thus 24/7 approach is expected to be facilitated by the availability of smart spaces (i.e., smart homes, smart cities), including training complex – facilities, athlete's home, type of transport, and/or the hotel, where mobile, wearable devices, and the internet of things will capture practically everything what athlete does inside and off the field. Such smart spaces may include, for instance, the possibility for monitoring quantity and quality of food and sleep, psychological, physical, physiological, medical and social demands of training/competition, energy expenditure, changes in body mass, hydration, and recovery levels outcomes. In addition, an integrated analysis including all these outcomes will be possible thanks to the advances in cloud computing, internet, big data, and specially AI that in

Fig. 2 24/7 approach: a potential trend

near future it will be expected to be at full levels of efficiency (Fig. 2).

Future Challenges

AI-related ethics is one of the greatest challenges for the future. Racine et al. [24] highlighted three potentially problematic aspects of AI use in healthcare and it certainly included the sports medicine area: (i) dynamic information and consent, (ii) transparency and ownership, and (iii) privacy and discrimination. The authors propose that AI-related ethical challenges may represent an opportunity for growth in organizations. The ethical data monetization is already today simultaneously an opportunity and a concern. The world is preparing to deal with this scenario via some regulations; the General Data Protection Regulations (GDPR) is a set of compliance

requirements applied in Europe and the Health Insurance Portability and Accountability Act (HIPAA) sets the standard for sensitive patient data protection in the United States. Some questions still need to be answered [24]:

- Does consent to evolving knowledge about treatment or prognosis, or to potential consequences formatters such as life insurance, need to be revisited? (Dynamic information and consent)
- Another important question concerns the ownership of the data upon which algorithms are developed. If the data come from an individual patient/athlete or an identifiable pool of individuals/athletes, will the intelligence developed be solely owned by the person (e.g., the club, the clinician, or the device company) stewarding its development? (Transparency and ownership)

- How much health information should patients/athletes be encouraged to share and how informed can they ever be regarding its future uses, possibilities for which seem to be growing every day? (Privacy and discrimination)

Furthermore, media enthusiasm for AI may pressure professionals and institutions involved to explore AI-based technology and adopt AI-informed practices prematurely without proper ethical guidance or empirical evidence of the validity/reliability of this technology [24, 25].

Finally, based on the open science approach, the dataset sharing should be performed aiming at area evolution both in academia and industry [26–28]. This culture of data sharing has already been strongly recommended in several areas [26, 27] including healthcare [28]. The authors reported that open science approaches should be adopted by AI Research and Development Departments in the healthcare domain, because, the use of “black-box” systems or the introduction of systems that have not demonstrated clinical effectiveness may not be acceptable approaches for the safety-critical healthcare context [28].

Before finalizing, we would like to do a brief statement that it is important to keep in mind that currently AI has the potential to classify, cluster, associate, visualize, and even select attributes (important variables). On the other hand, we cannot expect AI, for example, with Machine Learning techniques to be able to make extremely accurate predictions of such a complex phenomenon as a sport injury. Just remember that weather forecasts rely on extremely powerful computers and yet there are many errors. We must gather much more information to break the limit that AI currently presents. Larger datasets will give better results, but not close to the 99% that everyone wants. Initiatives such as that of the University of Waikato (New Zealand) as WEKA (Waikato Environment for Knowledge Analysis; an open source machine learning software in JAVA) [29] as well as that of the OpenAI (an AI research and deployment company with the mission to ensure that artificial general intelligence benefits all of humanity) [30] are so important for the future because these initiatives popularize AI and allow

progress in the search for real prevention, which would be to prevent the events before its occurrence. Therefore, so far what we have are classifications, prognostic, and prediction, but still searching for the significant capacity to really prevent a sport injury or other applications in sports medicine.

In conclusion, AI already presented deep advances in the field (e.g., ECG applications). The potential trends are related to allow real-time decision making in sports medicine, humanizing AI and a holistic approach applied 24/7. AI-related ethics is one of the greatest challenges for the future, thus actions and plans are warranted to solve it from now.
