May this book contribute to freedom of mind, freedom of speech, gender equality, human rights, cosmopolitan tolerance, environmental progress, scientific progress, medical and healthcare advances, and the rise of the individual's control of their health and body.

We dedicate this new standard reference textbook on artificial intelligence in medicine to all of you who deserve a better healthcare.

Foreword to Artificial Intelligence in Medicine

As the practice of medicine has evolved, so has the torrent of data and our inability, as clinicians, to get our arms around it as we care for patients. There is an extraordinary rescue path in sight – based on the use of artificial intelligence (AI) – that will likely be the most significant transformation for healthcare in generations. Indeed, this has the potential to be the Gutenberg moment for medicine.

While AI has been around for decades, it is only in recent years that deep learning algorithms have paved the way for interpreting medical images. Retrospective studies of large datasets of almost every type of medical image have now shown that machines can be trained to provide rapid and accurate “readings” that are often comparable to that of trained expert clinicians. There are some issues with these comparisons, however, since they have initially performed in silico rather than the real world of medical care. And instead of studying clinicians and AI technologies working in synergy, they typically pit algorithms versus physicians. Nevertheless, this is the first and early phase of substantial progress towards a revolution. Where we will lean on machines for help.

The first order for how AI can be applied in medicine is following the Hippocratic principle of first doing no harm by enhancing patient safety and decreasing medical errors. There are at least five million of these each year in the USA. Given the lack of time to assess patients, their data, their scans, and their slides, it will be a boost to get preliminary readouts from appropriately trained algorithmic interpretation. We are already seeing radiology and ophthalmology deep learning algorithms gaining approval by regulatory agencies for such use cases as brain, chest, and abdominal CT scans, mammograms, chest X-rays, and optical coherence tomograms for retinopathy. Eventually no discipline of medicine will be spared from the influence of AI.

For that to happen, better quality appraisal and substantiation will be needed for the medical community to buy into the change. That takes the assessment of these tools through classical and novel clinical trials, which have been scant to date. Until now, the most randomized trials have been performed by gastroenterologists for endoscopy, particularly real-time machine vision during colonoscopy for detection of polyps. We are fortunate that a recent global effort to provide rigorous standards for AI medical research is budding – the CONSORT-AI and SPIRIT-AI guidelines for trials and those forthcoming STARD-AI and QUADAS-AI for AI’s current mainstay of application in

diagnostics, pathology and imaging – these provide the template for researchers and peer-review journals going forward. The better the supporting evidence, the faster appropriate AI tools in medicine will be integrated into routine clinical practice.

There's the pressing order to alleviate burnout. That was already a global crisis in healthcare resource before the SARS-CoV-2 (COVID-19) pandemic set it. Not only are medical errors potentiated by burnout, but the mental health of clinicians is imperiled, as we have seen with unprecedented levels of clinical depression and suicides. A principal explanation for burnout is the inability to provide care for patients, overwhelmed with keyboard and screen data functions, with limited time to deal with complicated issues. This, too, can be addressed by AI. Using natural language processing and synthetic notes from patient–doctor conversations during a clinic visit are so encouraging that we could be seeing the first phase of keyboard liberation in the next few years.

What is desperately needed is the “gift of time.” The time for the human–human connection between patients and their clinician. This relationship has suffered greatly over recent decades, and we will have the opportunity to get it back, make it stronger than ever. The patient–doctor relationship is the essence of medicine. It is about trust, presence, empathy, and communication, that when you're sick, your doctor has your back. This will never be replaced by AI. It's what I labeled “Deep Medicine” and what should be considered the overarching goal of AI in the years ahead.

That gift of time can be realized not just through interpreting images and keyboard liberation, and synthesizing all of a patient's data from multiple sources, but also by giving patients more autonomy. That is what is starting now, the use of deep learning algorithms to provide screening diagnoses for common medical problems like skin rashes, urinary tract infections, ear infections in children, and even the diagnosis of heart arrhythmias via a smartwatch. That's democratizing medicine. No doubt this trend of promoting some autonomy for patients will further give clinicians time to concentrate on the most complex and serious matters. For all important diagnoses, and before treatment is implemented, the “human-in-the-loop” will be necessary for oversight, never allowing the AI to be the sole autonomous factor. All software is subject to malfunctions and adversarial attacks, which we must be mindful can occur in medicine.

How can all the vast information for AI in medicine be culled together in one resource? I would not have thought it was possible, but Niklas Lidströmer and Hutan Ashrafian have proved me wrong. They have brought together over 300 expert authors and 130 chapters to comprehensively cover the field, with an eminently logical framework of three parts as outlined in their preface. They deserve tremendous credit for this herculean undertaking, as do all of the authors for contributing to this endeavor. While some might question the value of such a textbook in the digital era with such dynamic changes, a book that I have relied upon to learn the nuances of AI, *Deep Learning*, by Ian Goodfellow, Yoshua Bengio, and colleagues, is an exemplar in this field that has been invaluable. I am confident that *Artificial Intelligence in Medicine* will follow suit for all of us in the medical community, as we all must aspire to learn about AI, to understand its nuances, strengths, and limitations.

Hopefully, AI will soon become an essential part of the medical school curriculum and this book will be a core reference.

I am honored to write this foreword and hope this extraordinary resource will help you as we go fast forward with integrating AI tools in our practice and enabling the real care of patients, as Francis Peabody wrote in 1927 in JAMA, “The secret of the care of the patient is in caring for the patient.” Almost 100 years later, a suitable use of AI in clinical practice may allow healthcare to ascend to a higher level of quality and value for patients.

Quotation

The saddest aspect of life right now is that science gathers knowledge faster than society gathers wisdom.

Professor **Isaac Asimov** (Айзек Азимов), 1920–1992

Preface

This is in all essence a book on the future of medicine. Artificial intelligence in medicine (AIM) is without doubt the hottest and most intriguing branch of medicine at the moment. It dwells into all areas and aspects of medicine. Creating human hubris and hypes, and provoking raging debates, fears, and intense hopes, it stretches the limits of medical science and researchers' minds, and raises questions of equality, humanism, emotional intelligence, and our very existence.

Without the ardor of dedicated experts, AIM is a vast territory, hard to vanquish. AIM will bestow medicine with unrivaled new tools, and it is the authors' cordial intention to deliver a broad systematic review of its entire history, scientific foundations, present advances, trends, possibilities, and future challenges.

Hitherto medical education has been lacking a profound and unabridged textbook overview for educational purposes. In the last few years, publications have been exponentially increasing within AIM. Soon, it will be very hard, if doable whatsoever, to compile a comprehensive overview within this field in medicine.

This book offers a wide and profound overview of all the latest advancements within the field of artificial intelligence in medicine. The book both explains the basic concepts of AI, proceeds to the applications of AIM, and then analyzes all of the commonest medical specialties and their AIM advancements systematically.

Although AIM will change medicine radically, the amount of AI taught in medical schooling is astonishingly limited. This book aims to bridge the gaps in profound understanding of AI in medicine for medical students, specialist doctors, and other researchers, whose areas will be hugely affected by AI in the very near future.

This AIM textbook brings the reader into the world of applied AI, from the mathematical foundations through the world of algorithms and computer programs to the ultimate benefits for patients and clinicians. It will be shown how AIM learned a lot from general AI for imaging, such as super-resolution, image reconstruction, image matching, inpainting, age estimation, generative adversarial network (GAN) image generation, and other areas.

Equipped with this book, the reader will no longer look at AI in medicine as a phenomenon happening inside an obscure black box – AI in medicine will be unboxed and opened for the imaginations, dissections, and alterations by students, clinicians, researchers, and other interested academics.

The book contains 130 chapters, as of its first edition, and is divided into three parts: the first is on AI in general; the second is on AI in medicine, covering the lessons for all doctors and the common trunk of AI applicable to all walks of medicine; and the third systematically goes through all medical specialties with as much width and depth as possible.

The first part contains 3 chapters (1–3), the second part contains 27 chapters (4–30), and the third part contains 100 chapters (31–130). These chapter numbers are referred to in this preface.

As we write this preface, we realize that our textbook has become the largest, most updated, unabridged, and comprehensive reference textbook on artificial intelligence in medicine, in the whole scientific world. To reach this altitude has been the outspoken ambitions of our publisher Springer Nature and of ourselves – to give this new and exponentially growing scientific community, for AI in all of healthcare, a standard reference cornerstone work.

The first part of this book contains general aspects of artificial intelligence, that is, the basic concepts primed for clinicians (► [Chap. 1](#)) for further understanding of this book. The pensum herein will likely be everyday ingredients in the self-evident curriculum of future medical students. Besides this chapter, we also present a chapter on what AI can learn from medicine (► [Chap. 2](#)). We also present the mathematical foundations of AI in medicine (► [Chap. 3](#)).

In the second part, we continue into the common trunk of AI in medicine, but still hold onto general aspects, that is, the ideas, concepts, problems, and branches that all medical specialties have in common. At first, we present again a basic concepts chapter (► [Chap. 4](#)), followed by an introductory chapter containing “lessons for all doctors” (► [Chap. 5](#)), and an analysis spread over several chapters on the importance of AI in medicine in general (► [Chap. 6](#)) and why it is so important right now, why it will transform the future healthcare.

Part two further contains chapters that drill into medical science through different angles, which are all common to all specialties, such as medical decision making (► [Chap. 11](#)), medical diagnostics (► [Chap. 12](#)), medical education (► [Chap. 22](#)), medical informatics (► [Chap. 16](#)), medical innovation (► [Chap. 7](#)), security associated to this technology (► [Chap. 20](#)) and AI in medical history (► [Chap. 13](#)), ethical challenges (► [Chap. 9](#)), and philosophical aspects (► [Chap. 26](#)).

In this part, we also present chapters on social, legal, and regulatory aspects (► [Chap. 8](#)), patient safety (► [Chap. 14](#)), contestability (► [Chap. 15](#)), and the patient’s perspective (► [Chap. 24](#)), all dedicated in-depth chapters. Since, of course, data is the gold mine of all AI, the electronic health records (EHRs) (► [Chap. 18](#)) are hence one of the focal points of interest here. A chapter is dedicated to educate on the unsupervised mining of large datasets (► [Chap. 21](#)).

To this common part, we also present chapters on AI in medicine from several other general perspectives, such as personalized medicine and precision medicine (► [Chap. 19](#)), with preserved privacy (► [Chap. 10](#)), and how AI will improve evidence-based medicine (EBM) (► [Chap. 17](#)), and AI in medicine and the evolutionary theory (► [Chap. 23](#)).

The global efforts to provide rigorous standards for AI medical research guidelines are demonstrated in a chapter (► [Chap. 23](#)).

We begin wrapping up the second part of this textbook with a chapter on AIM and meta learning and the concept of “learn to learn” (► [Chap. 29](#)), that is, how AI in healthcare can be taught not only to perform narrow tasks but to also do several tasks, and how it can be used for advanced medical learning, without having to build the model from scratch every time.

The final chapter of the second part is a forward-looking, futuristic chapter on quantum computing in the future of healthcare (► [Chap. 30](#)).

In the third part of the textbook, by far the largest one, we dive down from the high altitudes of medical AI into all medical specialties. These are grouped in the same way as they are normally related to each other clinically, practically, and rationally. Some fields have seen vast advances, others have just begun to scent the first nuances of AI.

The large Mahler-like symphony (like the *Symphony of a Thousand*, his 8th symphony) of the textbook’s third part begins with an advanced introduction, the overture, to the medical specialties and the broadly painted emergence of deep medicine (► [Chap. 31](#)). This first chapter of the third part is followed by chapters on a comprehensive and unabridged range of all medical specialties, systematically arranged.

Some fields have seen massive progress in AI, for example, medical imaging (Chaps. ► [32](#)–► [39](#)), all aspects of radiology (Chaps. ► [32](#)–► [36](#)), dermatological (► [Chap. 39](#)) and ophthalmological (Chaps. ► [110](#) and ► [111](#)) photos, and surgical pathology (► [Chap. 37](#)). Hence, we have drilled into these areas with chapters applying a whole array of angles.

Medical imaging is hence richly represented with a row of chapters ranging from an exposé of explainable methods (► [Chap. 35](#)) in medical imaging and diagnostics, musculoskeletal radiology (► [Chap. 34](#)), and interventional radiology (► [Chap. 32](#)) to the new AI-driven field of transdermal optical imaging (► [Chap. 82](#)); a chapter dedicated to an in-depth analysis of automated deep learning for medical imaging (► [Chap. 33](#)); and specialized chapters such as diagnostic radiology in Covid-19 (► [Chap. 36](#)), acute stroke (► [Chap. 109](#)), and many more.

Dermatology (► [Chap. 39](#)) has extensive representation in the book, and also pathology (Chaps. ► [37](#) and ► [38](#)), both represented directly and indirectly by several chapters. In some areas it has been motivated to dedicate a certain field to an independent chapter, for example, the main chapter on surgical pathology (► [Chap. 37](#)), followed by kidney pathology (► [Chap. 38](#)).

Nephrology (Chaps. ► [40](#) and ► [41](#)) is dealt with in several chapters, such as in the pathology chapter (► [Chap. 38](#)), but also in chapters specializing in hemodialysis (► [Chap. 40](#)), and prediction of kidney function and acute kidney injuries (► [Chap. 41](#)).

The impact of AI in healthcare on world economy is massive, and it will grow immeasurably in the coming decade. Several chapters delve into this from various perspectives and explain the impact on health economics, public health (► [Chap. 42](#)), and business models of healthcare (► [Chap. 43](#)).

This unabridged textbook encompasses both clinical and preclinical medicine. To the latter we can mention molecular biology (► [Chap. 76](#)), stem cell

research and regenerative medicine (► Chap. 79), genomics (► Chap. 77), transplantation biology (► Chap. 79), genomic applications (► Chap. 78), blood transcriptomics (► Chap. 80), and clinical biochemistry (► Chap. 57).

This book has largely been produced under the heavy pressure of the Covid-19 pandemic. This has had several profound impacts. What would have earlier resulted in a vast number of live meetings, and a large carbon dioxide imprint due to flights, has now only resulted in one trip for one of the editors, tour and retour Copenhagen–London, and for this flight it has been CO₂ compensated. It has also impacted gravely on the social lives of all authors, their families, and societies. In many cases, it has also had an effect on the authors' physical health or the health of their families. That this major reference book has been published without any delays is a major and united accomplishment by all contributors.

Several chapters deal with pandemics, and do directly mention and elaborate on Covid-19 from various different angles. This pandemic has been mentioned in the chapters on infectious medicine (► Chap. 95), epidemiology (► Chap. 96), infectious biology (► Chap. 98), radiological (► Chap. 36) and biochemical diagnostics (► Chap. 57), the dynamics of infections (► Chap. 99), immunology (► Chap. 101), and in the various pharmacological chapters as well. There are also chapters for other major infectious diseases, such as malaria (► Chap. 97).

Moreover, this book has good gender balance among its authors, who come from all over the world, and all continents are represented. It is literally the whole world's united and benevolent efforts that are gathered in this great volume. We have a chapter dedicated to gender aspects in AIM in general (► Chap. 28), and also on gender aspects in reproductive health (► Chap. 73).

Since this is a modern textbook, praising a sound gender balance and striving for representation from all continents of the planet, a special chapter deals with AI and its importance for healthcare in Africa (► Chap. 44), and we have also taken environmental factors into consideration, and have dedicated a chapter to AIM and its role in climate change and city pollution (► Chap. 45).

Another insight in this modern approach to a standard reference work is the fact that AI in healthcare is not necessarily developed at only traditional university institutions but at innovative frontline start-ups (► Chap. 7) and also in the hacker cultures – hence in the chapter on AIM and hackathon events (► Chap. 25), this phenomenon is further elaborated.

In the third part of the book, all the chapters have been systematically grouped subjectwise, with subjects related to each other ordered adjacently, for example, the immune system: clinical immunology (► Chap. 101), immunoinformatics (► Chap. 100), immunizations (► Chap. 100), and allergies (► Chap. 102) in one group. This group is followed by the field of hematology (► Chap. 103), which also contains specialized chapters on, for example, anemia (► Chap. 104).

Operating specialties, that is, surgery (► Chap. 61), orthopedics (► Chap. 63), and endoscopy procedures (Chaps. ► 66–69) spanning over several chapters, medical (► Chap. 59) and surgical robotics (► Chap. 60), ear-nose-throat (ENT) medicine (► Chap. 70), maxillofacial surgery (► Chap. 64), and dentistry (► Chap. 65) are placed together. Urology

(► Chap. 62) is also placed in this part, and gynecology and obstetrics (► Chap. 71) are placed close to medical disorders in pregnancy (► Chap. 72) and birth control. These are followed by pediatrics (► Chap. 74) and neonatology (► Chap. 75).

There are two robotics chapters: one introductory (► Chap. 59) and one deeper (► Chap. 60). Likewise, the endoscopy chapters encompass various types, from gastroscopy, with a special chapter on Barrett's esophagus (► Chap. 68), to colorectal polyps in colonoscopy (► Chap. 69), and a chapter on gastroenterology (► Chap. 66), followed by the main chapter on endoscopies (► Chap. 67).

Cancer-related subjects: oncology (► Chap. 90), radiotherapy (► Chap. 91) and cancer care (► Chap. 91), breast cancer (► Chap. 92), brain tumors (► Chap. 123), and cervical cancer (► Chap. 94) have been grouped together and placed in proximity to diagnostic chapters, such as breast thermography (► Chap. 93) and mammography (► Chap. 92).

The book contains a series of pharmaceutical chapters, encompassing subjects ranging from pharmacovigilance (► Chap. 46), 3D modeling, and drug discovery (► Chap. 48) to areas such as clinical trials (► Chap. 47).

The cardiovascular (► Chap. 58), cerebrovascular, and stroke medicine (► Chap. 124) chapters are completed with diagnostic chapters such as the one on acute stroke (► Chap. 109).

Neurology with neurosurgery (► Chap. 119) is also accompanied by chapters on neurodegenerative disorders, Parkinson and Alzheimer (► Chap. 120), amyotrophic lateral sclerosis (ALS) (► Chap. 121), and diagnostic specialties such as clinical neurophysiology and electroencephalography (EEG) (► Chap. 125), and chapters focusing on other neurological conditions such as Ménière's disease (► Chap. 122).

New and future specialties are richly represented with chapters on telemedicine (► Chap. 87), health blogs (► Chap. 81), mHealth, smartphones and apps (► Chap. 88), nanomedicine (► Chap. 84), electronic noses for medical diagnostics (► Chap. 86), wearable and implantable computing (► Chap. 85), longevity medicine (► Chap. 83), and the new advances of clinical biochemistry (► Chap. 57).

The ambition to be unabridged has also led to the inclusion of a chapter on alternative medicine (► Chap. 89).

The psychiatry section contains chapters specializing on eating disorders (► Chap. 118), autism spectrum disorders (► Chap. 113), anxiety and depression (► Chap. 112), schizophrenia (► Chap. 114), post-traumatic stress disorder (PTSD) (► Chap. 117), alcohol and drug dependence (► Chap. 116), but also several therapeutic approaches, such as cognitive behavioral therapy (CBT) (► Chap. 115).

A long range of chapters have emergency medicine as a common denominator, not only the already mentioned stroke and cardiovascular chapters, but also chapters dealing with anesthesiology (► Chap. 105), critical care (► Chap. 106), cardiac arrest (► Chap. 107), and clinical toxicology (► Chap. 108).

The endocrinology (► [Chap. 49](#)) chapter is followed by a chapter dedicated to diabetes (► [Chap. 51](#)) and another focusing on hypertension management (► [Chap. 50](#)).

In ophthalmology (► [Chap. 110](#)), large progress has already been made, and the book contains an extensive chapter in this field and also a second chapter on eye diseases in general practice (► [Chap. 111](#)).

The book's largest chapter is on physiotherapy (► [Chap. 128](#)), and it is also supported by neighboring chapters on rehabilitation medicine (► [Chap. 129](#)) and sports medicine (► [Chap. 130](#)).

The advances in AIM have also boosted the rise of a completely new forensic medicine (Chaps. ► [126](#) and ► [127](#)).

Primary care (► [Chap. 52](#)) is a highly interesting field within AIM, since a long range of specialist competences will be made more accessible here. Both the patients and their primary care doctors and nurses will be given AI-powered tools within a long range of medical specialties. A special chapter on nursing practice, primed for education of nurses (► [Chap. 53](#)), has been included. Patients who see their GPs for, for example, skin conditions will be able to benefit from AI advances in dermatology (► [Chap. 39](#)) much more rapidly. The same goes for many endemic conditions, for example, joint pain, rheumatological disorders (► [Chap. 55](#)), osteoporosis (► [Chap. 56](#)) and respiratory disorders (► [Chap. 54](#)), and many more. The radiological competences will reach out to the primary care setting.

As this book is printed, the preparations for the second edition have already started, and we are looking forward to presenting chapters on subjects such as elderly care and gerontology, sleep medicine, epilepsy, and palliative care and a chapter on the prediction of future pandemics. The pharmaceutical section will be expanded with several chapters, and a new section will engulf several aspects of health economics. Almost 40 newly written chapters are in pipeline.

But now, we proudly present to you the first edition of the world's largest and most updated reference work – we wish to accomplish the urgent need of a *standard* reference textbook – on artificial intelligence in medicine.

We hope this book will show how artificial intelligence in medicine, or *deep medicine* as our foreword writer *Professor Eric Topol* coined it, will boost the awesome power of AI and make medicine better, for all the humans involved. As he writes in the foreword – this is medicine's “Gutenberg moment.”

With this book, as an instrument of knowledge of artificial intelligence in medicine, we endeavor that it can be dually used as a source to crystallize the future, and for a refined tangibility of the present. With this in mind, through our human consciousness and artificially intelligent technologies, we hope to minimize the scourge of pathology to humanity and drive health and well-being across the globe.

In Memoriam

Our colleague, lecturer, and chapter author **Dr. Danny D Meetoo** joined this reference textbook with academic ardor and vivid enthusiasm. Danny contributed the chapter on AIM and nursing practice, which was created with impressive speed. This chapter was created in joy, together with his wife.

The chapter was delivered in the evening of Saturday, March 6, and a little more than a week later, we received the unbearably sad news that Danny had suddenly and unexpectedly died on Tuesday, March 9.

From 1996, Dr. Danny D Meetoo was a lecturer in the School of Nursing and Midwifery at Salford University. His main specialism was diabetes, with a PhD thesis on the study of diabetes non-compliance and self-care activities. He was prolifically published with articles on diabetes, nanotechnology, and artificial intelligence, and continued to support his former students all over the world, in their research.

At the time of his death, he was proposing a book of his own on the application of AI in nursing. He had started the preliminary work but decided to wait until having moved to a new house before progressing further – he was due to move on March 19.

Dr. Danny D Meetoo was filled with wonder about many things, the beauty of his native island Mauritius, which he left at the age of 17, the wonder of literature, the wonder of how infinite the mind could be for those who chose to open it. He regarded himself as a lifelong student, thereby fulfilling the promise he made to his parents when he left home 54 years ago.

Our thoughts go to his wife and life friend Mrs. Gill Meetoo and the family. Even though words cannot express the shock and sadness, we would like to add this dedication, to the memory of **Dr. Danny D Meetoo**, who has bestowed us with his academic legacy, wisdom, and kindness.

His thoughts, work, and legacy can be reflected with these words by Socrates:

Wisdom begins in wonder

Διά τὸ θαυμάζειν ἡ σοφία

Plato, *Theaetetus*, 155c-d

About the Editors

Dr. Niklas Lidströmer – Karolinska Institute, MD, MSc, specialist physician, postgraduate researcher in AI in medicine, senior advisor in AI and medical investments, former AI entrepreneur and founder of an AI powered medical platform, former head of Medical AI at a variety of med-tech companies, and also previous co-leader of a handful of successful medical startups.

His experience also encompasses widespread global clinical work spanning 20 years within numerous regions across eight countries. After graduating with a master's thesis on global medicine in 2000, he began practicing as a medical doctor in 2002, followed by internship, specialized residencies, and clinical work all over the world, including 1 year circumnavigating as a maritime doctor.

His international work experience, fluency in nearly ten languages, practical familiarization with AI in the medical and pharmaceutical industries, and clinical specialist competence in general medicine have produced a passion for translational and educational aspects of artificial intelligence in medicine.

Dr. Niklas Lidströmer is eager to bestow upon the world this pivotal reference work – the new standard reference, for artificial intelligence in medicine, which has now become the largest and most comprehensive in the scientific community.

Hutan Ashrafiyan, MBBS, MRCS, PhD, MBA, is a clinician-scientist and active surgeon translating novel technologies and therapeutics in healthcare and policy. He has led R&D as chief scientific adviser at the Institute of Global Health Innovation at Imperial College London and as chief medical officer at a FTSE 100 multinational, and is currently chief scientific officer at the global biotech and venture firm Flagship Pioneering in Preemptive Medicine and Health Security and his own start-ups. He has over 20 years of translational clinical, computational physiology, digital and AI trial, and product development experience, including novel COVID vaccines and national tracing apps. He leads the STARD-AI and QUADAS-AI global guideline initiatives for AI diagnostic accuracy. As honorary lecturer at Imperial College London, he runs the collaboration with Imperial College London, NHS Hospitals, and Google on an AI algorithm for breast screening and also with NICE on health technological assessment classifications for AI. He was awarded the Royal College of Surgeons Arris and Gale Lectureship and the Hunterian Prize. He has authored more than 450 publications (including Lancet, Nature, NEJM) and 10 personally authored books ranging from medicine to philosophy and ancient history, also having discovered an ancient lion species and deciphering hidden realities in Renaissance art including those of Leonardo da Vinci. He has several eponymous medical signs named after him and described his own procedure – the Ashrafiyan Thoracotomy. His philosophical work in artificial general intelligence, human rights, and solving the simulation argument is taught at law schools, and he is regularly featured in historical and scientific documentaries. He has co-edited the major reference book *Artificial Intelligence in Medicine* by Springer Nature.

Abstract

With the urgent need for automatized algorithm applications to an ever-increasing amount of data and a further decrease of the chances of human errors on crucial tasks, artificial intelligence algorithms were introduced.

An expansive demand of AI applications in varying fields led to the development of specifically designed ad hoc algorithms with the role of better estimating (by learning) solutions to the problems.

The boost of AI in healthcare right now is a consequence of two things – the availability of big data and better processors, able to train and execute algorithmic tasks, i.e., implementations of these algorithms with neural networks.

It will soon be vital for medical students to grasp the principles of AI. The purpose of this major reference textbook on AI in medicine, of which this chapter is the base level introduction, is to become the greatest standard reference work. No area of medicine, preclinical or clinical, will escape the profound effects of AI: the whole healthcare domain will be reshaped thoroughly.

Keywords

Artificial Intelligence · Medicine · Basic Concepts · Introduction · Classification · Healthcare · Machine Learning · Deep Learning · Neural Networks · Programming

Introduction

Let's look at the AI landscape. Today we dwell on the plains of AI. It will heavily influence medicine, yet relatively few healthcare professionals still have a good understanding of the concept to come. Therefore, this chapter contains the scientific fundamental principles of AI – primed for clinicians. This serves as the path leading up to the basecamp location, where the evolution of deep medicine is elaborated. Hereafter, the path leads up to the mountainous high-level plateau of section III and its

presentation of AIM for the many medical specialties. These are the purposes of these first upward-sloping components of this book, which contents should be natural parts of the understanding of AIM by medical students and healthcare professionals of the future, in general.

After these general words on AI, a brief history of AI is presented, and an explanation to why it has become so famous right now. Then we must define exactly what AI is, its different stages, what language is best fitted for AIM, and how to properly communicate with programming experts. This part also contains a short intro to machine learning, with some medical demos. It will help to better grasp the contents of this large book, and understand the limitations of machines, and why machine learning is a necessity for the upcoming revolution of deep learning – a cornerstone in deep medicine. Other concepts in this first pedagogic book part are deep neural networks, natural language processing, and the practical implementation of the latter into medicine and in particular into AIM.

AI, Machine Learning, and Deep Learning per Definition

What exactly is AI? How was it defined when it first emerged as a term in 1956? According to John McCarty it is the *science and engineering of making intelligent machines*.

Hence, it is the theory and development of computer systems able to perform tasks normally requiring human intelligence, such as visual perception, speech recognition, decision making, and translation between languages.

AI is a technique of getting machines to work, act, or behave like humans. Recently we have started to realize this – robots and, in general, measurements-processing machines are used in many fields, such as healthcare, marketing, robotics, stock markets, business analytics, transportation, surveillance, etc.

Machine Learning (ML) is a subset of AI techniques and refers to a computer program that can *learn* how to produce behavior not explicitly programmed by the program's author.

This behavior is learned based on the data given, by minimizing the error between the current action and the ideal one, and a feedback mechanism (the famous “error backpropagation”) that uses it to lead the machine to self-recognize, and internally improve its performances.

Deep Learning (DL) is a subset of machine learning, which uses multilayer neural networks to solve complex problems. They exploit the processing of contextual data. Deep learning techniques are, therefore, more suitable for learning unstructured data.

A Brief History of AI

The history of AI is very old – it goes far back to antiquity and Greek mythology. Talos was a giant animated bronze warrior, programmed to guard the island of Crete, created by Hephaestus, to throw rocks at nearing enemy ships. But there are several myths about mechanical men and automata throughout human history. These were generally well thought of [1].

Modern medicine is intrinsically connected to advanced mathematical analysis, now requiring computers with fast processors. This has led to new diagnostics, pharmacovigilance, therapies, robot-assisted interventions, epidemiological data mining, and synthesis of evidence-based medicine and decision support.

Also, mathematics in medicine has a long history. Leiden professor of medicine *Archibald Pitcairne* (1652–1713) developed a theory of *iatro-mathematics* (medicine and mathematics) and can be regarded as the father of mathematical medicine [2]. During his career he stood under documented influence by mathematicians such as David Gregory (1659–1708) and Isaac Newton (1642–1727), whose *Philosophiae Naturalis Principia Mathematica*, heavily influenced the formation of a *Newtonian medicine*, and the formalized concept of iatro-mathematics, with lectures in Leiden during the early 1690s [3].

In 1920, *The Lancet* published an article of the topic of iatro-mathematics [4], where it was noted that the “rapprochement of medicine and mathematics is incomplete.” However, it was concluded

that the two sciences would “eventually become a firm alliance.”

In 1950, *Alan Turing* published a landmark paper, in which he speculates about the possibility of creating machines that think. He created a test known as the Turing test, aimed at determining whether a computer can think like a human being. He concluded that *thinking* is hard to define. *If a machine can carry out a conversation, which is indistinguishable from a conversation with a human being, then it would be reasonable to say the machine is thinking.* The machine would pass the Turing test. No machine until this day has achieved this result. The Turing test stands out as the first contribution to the philosophy of artificial intelligence.

Followed by this contribution came the era of “game AI” during the 1950s. In 1951 with the usage of the Ferranti Mark 1 machine, at the University of Manchester, the computer scientist Christopher Strachey wrote a checkers program, and Dietrich Prinz wrote one for chess at around the same time.

These were the first attempts to let computers play games such as chess, and compete with humans.

This was followed by probably the most important year in AI history. In 1956, the concept of AI was coined for the first time at the Dartmouth Conference by Professor John McCarthy. In 1959 the first AI laboratory was established, marking the next coming period as the AI research era. The lab is called MIT, and is still in operation and famous.

In 1960 the first AI robot was implemented into the GM assembly line, and the first chatbot ELIZA was invented. This is the great grandmother of Siri and Alexa. Soon hereafter came the very well-known IBM Deep Blue, which in 1997 beat the world champion Garry Kasparov in a game of chess. This is regarded as maybe one of the first great accomplishments of AI.

In 2005 at the DARPA Grand Challenge, the racing team of Stanford University participated with Stanley, an autonomous car, which won the race.

In 2011 IBM’s answering system Watson defeated two of the greatest Jeopardy! Champions Brad Rutter and Ken Jennings.

AI started as a hypothetical situation, evolved and is now the most important technology in today's world. AI has presented an exponential growth of its potential. Wherever we look around us AI deep learning or machine learning power many things.

Today AI dominates Knowledge Base, Expert Systems, Deep Learning, Computer Vision and Image Processing, Machine Learning and Natural Language Processing, etc.

Rising Demand for AI

A common query is how AI could have existed for over half a century and suddenly now appears as a “sudden” hype and attracting all attention? The main reasons for the present demand for AI are:

- *First of all*, we have more computational power now to train deep learning models, and one of the most important contributions to these technology improvements are graphic processors units(GPUs) for massively parallel processing at low cost. The improved computational power makes it possible to broadly and globally implement AI.
- *Secondly*, the enormous amount of data presently at hand. The data generated is at an immeasurable pace. The sources are vast networks of social media, IoT devices, mail, conversations, photos, medical imaging, and numerous other places. Hence, there is a demand for a method or solution to process this overload of data, in order to give us insight from it and let businesses grow as a result. This process is AI in essence. AI is trained on large datasets, big data, to help us make smart decisions, to classify objects in images, etc. These processes enable us to act more efficiently.
- Next up, we have far better algorithms. These are much more effective and based on the concept of neural networks, i.e., the deep learning architecture. All this enables quicker and more accurate computations.
- And last, but not least, governments, venture capitalists, tech giants, and start-ups are now all focused on AI and pour in investments. For instance, companies in the FAANG group (Facebook, Apple, Amazon, Netflix, Google),

Microsoft, and most car manufacturers, and a long list of major tech companies, are deeply investing in AI. The consensus among all mentioned instances is that AI is the way of the future.

For more details on the importance of the AI in medicine, please see the chapter “On the Importance of AIM,” by Dr Katarina Gospic et al.

AI Applications

Now that the definition is set, let us briefly mention a few significant applications, to highlight the importance of AI. The most famous is likely Google’s predictive search engine. It is in global use; whenever a person starts to type, Google makes immediate suggestions the user could use. This is AI in action literally. The predictability is based on collected data from individuals, browser usage, location, personal info, age, gender, and many more. Behind this guessing, there are many layers of natural language processing, deep learning, and machine learning.

Another striking application is in the financial field – J.P. Morgan uses the Chase’s Contract Intelligence Platform (COiN), which uses AI, machine learning and image recognition software to analyze legal documents. In this way the company avoided manually reviewing ca. 12,000 documents, which took more than 36,000 h. But when this monotonous task was replaced by the AI machine it took a few hours.

Since this book is focused on AI in medicine, let us mention some applications for healthcare. For instance, the Watson computer from IBM. Watson uses natural language processing, evidence-based learning capacities, and hypothesis generation, which has contributed to clinical decision support systems and contributed to AI in healthcare, and is today in use in an increasing number of medical specialties [5]. Medical doctors can pose questions to Watson, entering clinical facts such as symptoms, medications, and heredity, and Watson can then mine the patient data, examine available data, form a hypothesis, and finally provide a list of individualized confidence-scored suggestions [6].

Watson’s data sources encompass research articles, clinical studies, treatment guidelines, and electronic health record information [5]. In should

though be noted that not been directly involved into the medical diagnosing, it has only assisted with treatment alternatives for already readily diagnosed patients [7].

During the last 10 years Watson has partnered with a long range of organizations, companies, and universities, e.g., Columbia University, University of Maryland [8], Memorial Sloan-Kettering Cancer Center [9], MD Anderson Cancer Center, Manipal Hospital, Cleveland Clinic, and Case Western Reserve University [10].

The FAANG group and other large corporations have started AI initiatives within health; Facebook (*Preventative Health*, 2019–), Microsoft (*Health Vault*, 2011–2019, *Apple* (Health, 2014), *Amazon* (Amazon Care, 2018–), Google (*Google Health* 2006–2012, and with *DeepMind* 2018–) [11].

For instance, *DeepMind Health* collaborates with Moorfields Eye Hospital and are developing AI applications for healthcare, especially eye scanning [12], and with University College London Hospital aiming to develop an algorithm to differentiate between healthy and cancerous tissues in the head and neck region [13].

In global large networks, such as Facebook, AI is used in, e.g., face verification, both as password and auto-tagging of friends, and to personalize advertising systems using neural networks, machine learning, and deep learning concepts. Many people are not aware of how much AI they use on a daily basis in their lives – all social media platforms, e.g., Facebook, Instagram, Twitter, LinkedIn, heavily rely on AI. Through the 2016 US elections, political ads using social media are called to the spotlight. Specifically, the controversy of targeting users to obtain their personal information and determining what advertisement would persuade those electors.

Twitter uses AI to identify hate speech and terroristic language in tweets. In this way they detected ca. 300,000 terror-linked accounts. These nonhuman AI machines found 95% [14].

Also, virtual assistants such as Alexa and Siri have entered the market, and quite recently also Google Duplex, which responds to calls, can book appointments and with a human touch, making it sound realistic.

Some other examples of AI are Tesla's and many other car manufacturers' experiments with self-

driving cars and even taxis without a driver, based on a range of AI implementations. Also, Netflix uses AI and pattern recognition to make personal film recommendations. Gmail uses a similar principle to automatically sort incoming letters in mailboxes, spam filtering, etc. The latter uses buzzwords that are common in spam, e.g., full refund, lottery, etc., and then directs them to the spam compartment.

AI Staging

There are three main stages of AI

- **Narrow AI**, also known as weak AI. This can only be applied to specific tasks. Most applications today belong to this group, e.g., Alexa – although sophisticated, all functions are within a narrowly defined function range. Other examples are self-driving cars, chess computers, AlphaGo.
- **General AI**, or strong AI. We have not reached this stage. Strong AI refers to machines being able to possess the ability to perform any intellectual task that a human can. Machines now have strong processing powers, but hitherto no sign of reasoning capacity; hence we're stuck in the weak AI stage. Not even AlphaGo Zero, which learned without human intervention, could be defined as strong AI.
- **Super AI**, refers to a stage when computers would surpass human capacities. This stage encompassed big data statistics, symbolic mathematics, number of faces, generative adversarial networks (GANs).

AI Programming Languages

There are several languages used in AI applications, and one of the most popular and well-known is Python, partly because of its simple and functional syntaxes, and also for the great number of libraries designed for Python (to implement Machine Learning algorithms in a straightforward manner), such as Keras and Tensorflow.

The Python advantages are related to its simplicity and their maintainability as well as the possibility to connect and integrate with files written in other programming languages. Problems of memory usage and not having multithreading are substantial Python disadvantages [15].

Python was created in 1989 by *Guido Rossum*, and is an interpreted, object-oriented high-level programming language with dynamic semantics. Hence, it is a high-level language (no concerns with low-level details, e.g., memory allocation), which is free and open-source. Python is portable, i.e., it is supported by many platforms, e.g., Linux, iOS Mac, Windows PC, FreeBSD, Solaris, OS/2, Amiga, AS/400, BeOS, OS/390, PlayStation, Windows CE, etc.

Python supports various programming paradigms, i.e., both object-oriented, and procedure-oriented programming, and is extensible, i.e., it can invoke C and C++ libraries, and can integrate with a multitude of other languages, such as Java and .NET products. Python is the most rapid gainer in AI, with a huge momentum. Its use is ubiquitous to create AI algorithms, machine learning, IoT projects, etc. With Python, the developer doesn't need to code very much, because there are ready-made packages, with algorithms. For instance, *PiBrain* (for Machine Learning), *NumPy* (scientific computing, Pandas, etc.) can be implemented, and a vast range of libraries.

Apart from Python, another popular programming language used mainly for statistical tasks is called R. This language well-performs in analysis and manipulation of incoming data for statistical purposes. R is well known for its publication-quality plots and its compatibility with other programming languages. However, R is less suitable for handling big data analysis tasks for its consuming memory characteristic compared to Python and its speed in other programming languages.

R is almost as easy as Python to learn. Both languages are very similar to English in syntax and construction, hence they belong to the easiest to master. They both have an enormous number of libraries to provide all thinkable predefined algorithms, statistical models, data scientific inputs, AI, machine learning with algorithms, NLP, etc.

Moreover, Java is also used in AI, especially for artificial neural networks and genetic programming. Here Java has its benefits with, e.g., simple packaging and debugging, user interaction, and functionality for mega-project scalability and graphics. The latter is one of the outstanding assets of Java with its standard interface and graphics' toolkit – the graphical presentation is,

of course, a vital part of AI, and which will be seen in AIM, especially when applications are directed toward patients and students. Java provides better managing tools of garbage and provides multi-threading, differently from Python.

Another alternative language is *Lisp*, less known, but the most ancient and perhaps best-adapted language for AI development. Lisp goes all back to the origins of AI, and was introduced by John McCarty in the late 1950s, and can process symbolic information, can prototype, create dynamic objects, automatic garbbing, and is deemed easy by developers. Though, nearly all of its excellent features have migrated into many other languages. It is the Sanskrit, Swahili, or Latin of AI languages. The latter are more effective, have better packaging, etc.

SWI Prolog is a language, which is relevant in AIM, since it is often used in knowledge base and expert systems – it has features such as pattern matching, freebase data structuring, and automatic backtracking. This gives a strong and flexible framework for programming, which makes it frequently used in AIM.

Other languages worth mentioning are *C++*, *SaaS*, *JavaScript*, *MATLAB*, and *Julia*. All of these can be used for AI.

Machine Learning

Machine Learning (ML) is one of the most important instruments in AI. It is a way of feeding data into a machine, so it can make its own decisions. The need for ML is as old as the technical revolution, which has generated immeasurable loads of data. In research we generate over 2.5 quintillion bytes of data per day. In 2020 an estimated 1.7 MB of data was created every second for every person on earth. With this vast amount, models can be created to study and analyze complex data, insights and more precise results can hence be delivered. In the last 2 years alone, the astonishing 90% of all the world's data has been created. At the end of 2020, 44 zettabytes (10^{21}) made up the entire digital universe. 2.5 quintillion (10^{18}) bytes are created by humanity every day. It is estimated 463 exabytes (10^{18}) of data will be generated every day by

humans in 2025 [16]. The rememberable fact is also that we have decided to store this forever, costing us substantial energy.

In a worst-case scenario, computer technology could use as much as 51% of global electricity in 2030. This will happen if not enough improvement in electricity efficiency of wireless access networks and fixed access networks/data centers is possible. However, until 2030, globally generated renewable electricity is likely to exceed the electricity demand of all networks and data centers. Nevertheless, a recent investigation suggests, for the worst-case scenario, that electricity for computer technology usage could contribute up to 23% of the globally released greenhouse gas emissions in 2030 [17].

With machine learning in the finance sector, a wide range of profitable opportunities and avoidable risks can be identified. An understatement is of course that the equivalence will enter the medical and healthcare domains. The simple foundation of all machine learning, and of AI, is *data* per se. Data is the solution, we just need to know how to handle it, and ways to do this are ML, deep learning, and AI.

In medicine the needs for machine learning are associated with

- Increased *data generation* from electronic health records (EHRs), digitalization
- Improvements in *decision making*, risk prediction
- Uncovering of *patterns* and trends in data, finding hidden patterns, key data extraction
- Building statistical models, time saving
- Solving of complex problems for humans

An illustration of *Machine Learning* (ML) [18]

When *Arthur Samuel* coined Machine Learning in 1959, the definition was “*a computer program is said to learn from experience E with respect to some class of tasks T and performance measure P if its tasks in T, as measured by P, improves with experience E.*”

In other words:

Data > Training the Machine
 > Building a Model > Predicting Outcome

Machine learning (ML) in all essence, is a subset of AI, which provides machines the ability to learn automatically and improve from data pattern analysis. The ML has been programmed in a way that it can adjust its parameters. Some more definitions of terms used in this textbook are the following:

Algorithms – Set of rules and statistical techniques to learn patterns in data, mapping all decisions that a model can take.

Model – A mathematical equation, i.e., a computation or a formula, which is the result of an algorithm that takes some values as input and produces some values as output.

Predictor feature – Variable of the data that helps predict the output, e.g., a physical factor in patients, where a gene, height, lab value, vital sign, or weight can predict a symptom or diagnosis.

Response Variable – The feature, output variable, or target variable that will be predicted.

Training data – The data, which is used to train the ML model.

Testing data – Unseen data used to test the ML model after the training procedure.

The *machine learning process* involves the construction of a Predictive Model, which is then used to identify a solution to a Problem Statement. Hence the process of ML involves several steps:

Definition of the objective > Data gathering
 > Data preparation > Data exploration
 > Model construction built on training
 > Model testing > Predictions

AIM ML case example:

- **Definition of Objective**

Formulation of the problem idea: e.g., to predict if an infected patient will recover, yes or no.

Q: What target feature: e.g., temperature, blood pressure, or other specific symptoms

Q: What input data: medical records, vital signs history, lab results, etc.

Q: What kind of problem: Binary classification? Clustering? Regression problem?

Hence, at step 1 we define how we will solve the problem, what kind of data we need, and what we are trying to predict, what information is needed to predict.

- **Data Gathering**

Data such as temperature curves, lab values, vital signs, physical examinations, massive loads of previous comparable patients EHRs etc., and where can we get this data – gathered manually or scrapping from the web, from EHRs, from other sources? This is the most time-consuming element of the ML process. We create the dataset.

For ML exercises there are a lot of training datasets online, e.g., Kaggle (<https://www.kaggle.com/>) and Grand Challenge (<https://grand-challenge.org/challenges/>), where a whole range of sets can be downloaded, having numerous different themes; weather forecasts, economic forecasts, etc. Hence, developers can skip the time-consuming data gathering step, and just download the dataset.

- **Curating**

Data preparation, or cleaning, involves erasing inconsistencies, e.g., missing factors or redundant information, erasing unnecessary data, format correction, and getting the data ready for analysis. Step 3 is likely the hardest step to perform. It is easy to bias the dataset if, e.g., one factor's values are missing more frequently. Any mistake will affect the result.

- **Exploratory Data Analysis**

This is the ML brainstorming step, which involves the understanding of patterns and trends in the data. Insights are concluded, such as correlations between variables. For instance, low blood pressure and alternating fever or other pre-septic signs are factors that

the output result will depend on. Exactly how, we have to find out in the patterns of the vast material, i.e., the correlations of such variables.

- **Building a Machine Learning Model**

A predictive model is created with ML algorithms, e.g., Linear Regression, Decision Trees, etc. This stage always starts with data splicing, into training data and testing data. The former is always used to build the model. Training data is usually 80% of the total.

In this AIM example, we are predicting the outcome of classification variables, also known as *categorical variables*, i.e., recovered patient yes or no. Two alternatives. In this case we can use linear regression, support vector machines, K nearest neighbor, or Naïve Bayes, etc. Which algorithmic model can be used depends on the problem statement, i.e., it depends on the task to solve. The methods suggested to better approach a specific type of task are the results of a continuous process of trial and error.

- **Model Evaluation and Optimization**

This step evaluates and tests the model, so it can be improved, parameters tuned, etc. A part of the testing dataset is used as a validation dataset. The accuracy and errors as a form of ML performance metrics are calculated.

- **Predictions**

The final outcome is used to make predictions about the given medical condition, and in this case the outcome will be a categorical one. First you get a probability, and based on a preset range, the clinician can decide whether the answer is yes or no.

Types of Machine Learning

There are basically three types of ML – supervised, unsupervised, and reinforcement learning.

In *supervised* learning, we train the machine with labeled data. In other words, the labels act like guides. In AIM, we may feed the machine with expert interpretations of, e.g., X-ray images, such as fracture or no fracture of a specific bone. We explicitly train the machine with these labels. This type is suitable for regression and

classification problems. The approach involves mapping labeled input to known output. Applicable algorithms include linear regression, logistic regression, Support Vector Machines, KNN, etc.

In *unsupervised* learning the machine trains with unlabeled data, which lets the machine work on unguided information. No labels are fed into the procedure. Here the machine classifies by itself; it will identify dissimilarities between an X-ray with a fracture and one without, by noticing another pixel pattern, other shadows, fracture lines, and other classifying features. It clusters into two groups in this example. This type is suitable for association and clustering problems. The approach is to understand patterns and discover output. Applicable unsupervised algorithms include Clustering using hierarchical clustering algorithms, k-means, and mixture models. Furthermore, Anomaly Detection algorithms such as k-nearest neighbor in medical image analysis are widely used algorithms together with Deep Neural Networks approaches such as Deep Belief Nets, autoencoders, and Self-Organizing Map (SOM).

In *reinforcement* learning, the agent is placed in an environment and learns how to behave inside these surroundings by performing certain actions and noting what kind of rewards are received for these. An example is how Robinson Crusoe started to adapt to the desolate island. He explored the environment and identified possible rewards and dangers. This type of learning is suitable for reward-based problem solutions. The approach is a trial and error method. Applicable algorithms include Q-learning, SARSA, etc.

Machine Learning Problem Solutions

ML problems can be classified into three types – regression, classification, and clustering problems.

Regression problems – Solved with supervised learning. The output will always be a continuous quantity, i.e., a variable with an infinite range of values, for instance, medical lab results. The body temperature can be 36.8, 36.9, 35.9, etc. The data is variable. The aim is to forecast or predict. It is solved with algorithms like linear regression. Regression is fitting a curve through data.

Classification problems – Solved with supervised learning. The output is always a categorical quantity. The main goal is to calculate the data category, for instance, classification into skeletal injury or undamaged structure. Or gender, two categorical outcomes. On ImageNet there are even 1000 classes. Solved with algorithms such as logistic regression, support vector machines, K nearest neighbor, etc.

Clustering problems – Solved with unsupervised learning. Assigns data points into clusters. The principal aim is to group similar entities into >2 clusters, based on feature similarity, for instance, to find hidden signs of severe disease. Hence, when the data is insufficient, and we don't know the output of, e.g., two categories, then we form clusters. Solved, e.g., by the algorithm of K-means.

Supervised Learning Algorithms

Below seven useful algorithms to a class of supervised learning are presented.

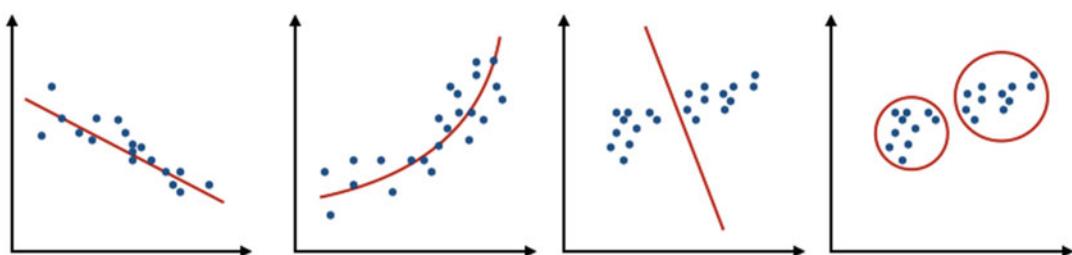

Fig. 1 Illustration of three machine learning problems; left to right: linear and nonlinear regression, classification, and clustering [19]

- *Linear Regression* – A method to predict the dependent variable that belongs to the y-axis, based on the values of independent variables along to the x-axis. The variables are continuous or discrete. Used for predictions of a continuous quantity. Hence the curve fitting the data is linear. The equation is:

$$Y = \beta_0 + \beta_1 X + e$$

Y Dependent variable

β_0 Y-intercept

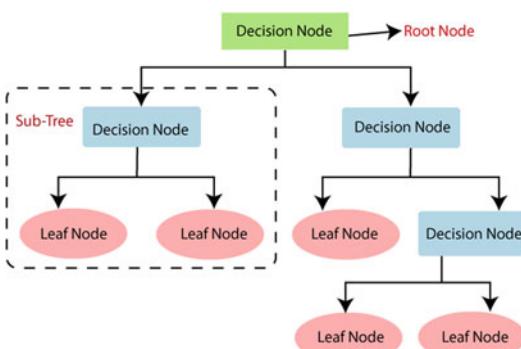

β_1 Slope

X Independent variable

e Error

For instance, variables with lab results can be imported in a CSV format into Python and then prepared, analyzed, and adequate algorithms applied.

- *Logistic Regression* – A method used to predict a dependent variable, from a dataset, when the dependent variable is categorical, and the outcome is 1 or 0, e.g., in orthopedic medical imaging, this would correspond to the presence of a bone fracture or no fracture. The function is sigmoid with values that go from 0 to 1. Afterward classification algorithms can be applied. See: https://en.wikipedia.org/wiki/Logistic_regression.
- *Decision Tree* – This is another classification algorithm, and looks like an inverted tree. It is a ML algorithm where each node signifies a *predictor variable* (aka feature), and the links between the nodes are decisions and at each branch there is a leaf, which stands for an outcome, or *response variable*.

An image showing an example of a decision tree [20]

Let us assume we have a large data set of ICU patients, and we would like to predict whether an infected patient faces the risk of a serious complication, e.g., sepsis, or not. Every step in the inverted tree represents a categorical classification step, i.e., a choice between two values in a binary tree. For instance, we use these short queries – “feverish or not,” then “normal blood pressure or not,” “normal pulse or not,” “shills or not,” “affected general condition or not,” etc. Each node that represents observations is directed through the branches, purely conjunctions of features, to the leaves also known as targets/labels. A common approach in triage or telephone consultation, where the nonmedical operator tries to decide whether a patient should seek the emergency room, see his/her GP the day or just wait.

The most significant clinical factor should be the initial root node, followed by internal nodes and then the terminal nodes or leaves lead to a suggested outcome. Branches are the answers, yes or no, 1 or 0, etc.

ID3 algorithm, *Iterative Dichotomizer 3* algorithm, is one of the most effective ways of building the tree within healthcare:

- Step 1: Selection of the best attribute (A) – e.g., affected general condition?
- Step 2: Assign A a decision variable for the root node – affected or unaffected patient?
- Step 3: For every value A can take, create a node descendant – if yes, if no, etc.
- Step 4: Add classification labels to the lead node
- Step 5: If the date results in correct classification, then stop.
- Step 6: If not, then iterate.

What best separates the data in a clinical decision tree is of course the most important factor first, and which classifies the patient group the best. During the construction, it is common to repeatedly try with different variables and analyze which is the most suitable. The two most important factors to consider here are *information gain* and *entropy*. The variable that best separates the data into the desired output classes is the variable with the highest information gain.

The entropy is a measure of *uncertainty* or impurity, which the data contains. The information gain (IG) signals how much *information* a specific variable or feature brings us, in regard to the final outcome, which can be concluded with this logic:

E.g., has the patient had a fever?

$p(\text{yes}) = \text{No. of yes outcomes in the parent node} / \text{total number of outcomes}$

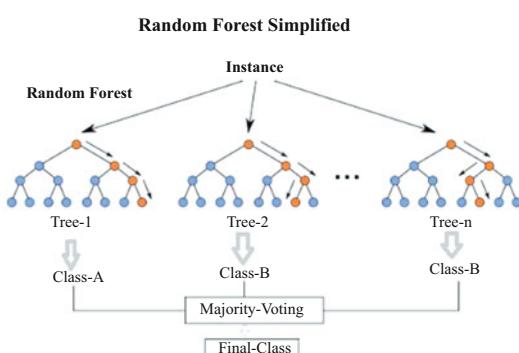

The entropy can be calculated in a similar manner:

$$\begin{aligned}\text{Entropy}_{\text{parent}} &= -p_{\text{yes}} \log_2(p_{\text{yes}}) \\ &\quad + p_{\text{no}} \log_2(p_{\text{no}})\end{aligned}$$

In this way, the variables' data splitting capacities are calculated to deem their suitability in a given place of the decision tree:

$$\begin{aligned}\text{Information Gain} &= \text{Entropy}_{\text{parent}} \\ &\quad - [\text{weighted average}] \\ &\quad * \text{Entropy}_{\text{children}}\end{aligned}$$

- *Random Forest* – Builds multiple decision trees (a forest) and fuses them and achieves a more precise and stable prediction. The forest gives more accuracy, avoids overfitting (when the models learn also the noise or disturbance and takes this into the model, which negatively affects the models' ability to predict from new data), and provides bagging, which means multiple trees test the data. This is suitable for more complex medical situations, e.g., a patient with multiple symptoms. From huge data sets of medical records, then bootstrapping can be executed in a row of circuits to make predictions.

An illustration of a *Random Forest* [21]

With the bootstrapped dataset we build a decision tree, starting at the root node, for which the best attribute is used to split the dataset. For each of the upcoming branch nodes, the process is repeated. For each step, the best attributes are chosen. The iteration is operated hundreds of times, and hence a forest of trees arises. The bootstrap dataset is used multiple times.

Finally, the prediction stage is reached. If we intend to predict a medical condition in a patient, we run the data through the forest of decision trees, and after all trees have been used it is presented which classification the majority of trees have voted for.

The model can be evaluated with a part of the dataset, which was not bootstrapped, in the so-called out-of-bag dataset.

- *Naïve Bayes Classifier* – A supervised classification algorithm, which is based on Bayes' Theorem, which solves classification problems with a probabilistic approach. The main idea is that the predictor variables in an ML model are intrinsically considered independent of each other. The concept is called naïve, since it does not consider any correlations between the variables. In medical real-world problems, there are often exactly such correlations anyway, but those are disregarded in this model.

The mathematics building up this model calculates the probability for an event to occur based on events in the past:

$P(A|B)$ – the conditional probability of the event A happening, given event B

$P(A)$ – the likelihood of event A happening

$P(B)$ – and of event B happening

$P(B|A)$ – the conditional probability of the event B happening, given event A

which gives

$$P(A|B) = \frac{p(B|A)p(A)}{p(B)}$$

In a medical example this model could be used to classify, e.g., the likely infectious agent, based

on its diagnostic features – lab tests, microscopy, X-ray, quick tests, clinical signs, etc.

Infectious agent	One lab test	Microscopy	Quick test	Clinical signs
Infection type 1	4500/5000	0	0	5000/ 5000
Infection type 2	500/5000	5000/5000	4000/ 5000	0
Infection type 3	5000/5000	0	1000/ 5000	500/ 5000

Above, we have 15,000 patients, which can be divided into three groups of 5000 with one specific infection per group. Let's say we are given the following observation then:

	One lab test	Microscopy	Quick test	Clinical signs
Observation	Yes	No	Yes	No

To predict whether the infection is of a certain type, Naïve Bayes can be used. P is the probability. H is the hypothesis. C is a specific class. C1, class 1, etc.

$$P(H|\text{Multiple Evidences}) = P(C1) | H) * P(C2|H) \dots \\ * p(Cn|H) * p(H)/P(\text{Multiple Evidences})$$

All of the above alternatives are calculated, by inserting them separately, hence we receive the probability of which one is the likely infection in the observation. The conditional probability is delivered. There is a plethora of educational and clinically relevant examples online [22].

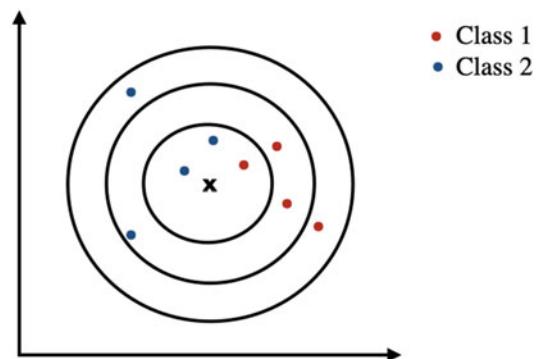

- *K-Nearest Neighbor* – KNN is a supervised learning algorithm, also used in unsupervised learning problems, which classifies a new data point into a target class, led by its distance to its closest neighbor points. For instance, this model is used to present medical images to the model, which classifies it into, e.g., if a skin mole is a melanoma, or a benign nevus.

KNN is a simple and easily applied ML algorithm of both classification (mainly) and regression type. It is nonparametric, i.e., it has no assumption, which is the case with Naïve Bayes, which assumes there are no relations between the variables. It is also a *lazy algorithm*, meaning it

remembers the training set, instead of learning a discriminative function. The most important feature is that it is based on feature similarity with neighboring data points.

The K value stands for the number of nearest neighbors, within a radius defined by, e.g., Euclidean or Manhattan distances – there are many possible distance metrics. When determining the nature of a novel data point, the number of members of preexisting class categories as neighbors are crucial. If a new data point would have one data point within its radius, which is of type A and two out of B, then it would be assigned the type B, if K were set to 3 (to include the three closest neighbors). If more neighbors are enclosed, then the type may change. The adequate K value can be calculated with, e.g., the elbow method, see below.

The data points (y, x) in a diagram are separated with a length, which is calculated with the Euclidean distance. Its simple equation is used by KNN to check the closeness of a new data point from its closest neighbors.

Example of K-Nearest Neighbors (KNN). Calculating the Euclidean distance of each point to the unclassified gray point and defining the K number of neighbor points to consider, the classification occurs. For instance, if K = 3, then x will belong to class 2. The x is in the center of the circles, which indicate the distance to a point (the cross). [19]

- *Support Vector Machine* – This is a classification and regression algorithm, which separates data, with the use of *hyperplanes*. SVM studies labeled training data. Support Vector Regressors are useful in regression problems; otherwise SVMs are mainly used in classification problems. Nonlinear data can be classified by

SVM with the use of kernel tricks. Nonlinear means the data cannot be separated with a sole linear line, elaborated below.

SVM works by drawing a boundary, a hyperplane, between different classes, and hence separating them in the best way. Support vectors are the data points closest to the hyperplane. The boundary will be drawn based on info on the support vectors. The optimal hyperplane has a maximal distance, i.e., margin, to the support vectors. It is easy as long as the hyperplane separation is linear. If this is not the case nonlinear SVM is used. Here the Kernel trick transforms the data into another dimension, e.g., separating them on the z-axis instead, if a 2D-approach didn't allow separation with a straight line. In the 3D-space a clear hyperplane might then be visualized, if the data allow.

Python can easily demonstrate and run all of the mentioned algorithms mentioned in this introductory part of the book.

Unsupervised Learning Algorithms

The main aim of the unsupervised learning algorithm *K-means clustering* is to group similar data points into a cluster. The process classifies objects into a predefined number of groups, so they are as dissimilar as possible between the groups, and as similar as possible within the group.

Every cluster has a *centroid*, from which distances to the objects are calculated. Grouping is then based on minimum distance. When faced with new medical population material, we need to first guess how many clusters there may be, and then provide a centroid for all these. The algorithm then calculates the Euclidean distance of the points from each centroid and assigns the point to the most proximate cluster. Over and over the clusters can be recalculated and new points added, and these steps are repeated until the centroids become the average of the cluster, i.e., iteration until the centroid value doesn't change.

With the *elbow method* the most optimal K value for a given problem is calculated. First the *sum of squared errors* (SSE) is computed for some values of K. The definition of SSE is defined

as the sum of the squared distance between each data point, or member, of the cluster and its centroid. The method can be plotted as graph of the WCSS(x) value (within-cluster sums of squares), using this formula:

$$\text{WCSS}(k) = \sum_{j=1}^k \sum_{x_i \in \text{cluster } j} \|x_i - \bar{x}_j\|^2$$

Where \bar{x}_j is the sample mean in cluster j

Elbow method equation [23].

The *distortion* will decrease with increased number of clusters, i.e., with a higher K value. At one point the distortion tilts abruptly, like an elbow in the graph. In large AIM studies, it is critical to pick the best amount of clusters.

Reinforcement Learning

Reinforcement learning algorithms consist of two main components – agent and environment.

For instance, the RL agent learns from the environment by rewards or failures, like if exposed to a new computer game. The RL iterates the game until it masters it. Some main concepts:

Reward (R) – The instant return from the environment to feedback the last agent action

Policy (π) – The approach the agent uses to decide the next action

Value (V) – The expected long-term award with *discount*, in opposition to short-term reward

Action-value (Q) – Like Value, but includes an extra parameter, the *current action (A)*

The Reward Maximization Theory states that an RL agent must be trained in such a manner that it takes the best action, so that the reward is maximized.

Discount means escaping negative events. Discounting is measured with a *gamma* value between 0 and 1, with larger discount the smaller gamma value.

Two other very important terms are *exploration* and *exploitation trade-off*. The former is about exploring the environment, the latter about exploiting the environment.

Another concept is the *Markov's Decision Process*, which is the mathematical approach for mapping a solution in reinforcement learning, and includes the following parameters:

Set of actions, A
 Set of states, S
 Reward, R
 Policy, π
 Value, V

For example, this can be shown in the shortest path problem, i.e., to calculate the shortest path between two nodes, with the minimum possible cost.

Q-Learning algorithms are among the most important examples of reinforced learning, which can be used to reinforce, e.g., the pathways taken by an agent, which is taught to get out of a labyrinth with several rooms, if this is the set goal.

The memory learnt by the agent with experience is represented as a *Q matrix*, where the rows represent the current agent state and the columns the possible actions leading to the next state, which results in the final formula:

$$\begin{aligned} Q(\text{state}, \text{action}) &= R(\text{state}, \text{action}) \\ &+ \text{Gamma} * \text{Max}[Q(\text{next state}, \text{all actions})] \end{aligned}$$

The γ (gamma) parameter ranges as said 0 to 1, and if γ is closer to 0, the agent will consider immediate rewards, and if closer to 1, the agent will weigh future rewards greater.

Hence, γ closer to 0 leads to exploitation, while γ closer to 1 leads to exploration.

With these words I round off this simple mathematical review, and tilt our focus to other general considerations on AI, ML and DL, e.g., the definitions and their limitations, which come next.

Limitations of Machine Learning

ML is first of all not capable of handling high-dimensional data, where the input and output is very large, since this complex data consumes resources, and causes curse of dimensionality, as several new dimensions are added. Just going

from 1D, 2D, and to 3D demands quite new requirements. And in a real-life situation such as in AIM there can be thousands of dimensions.

One of the big challenges with traditional ML models is a process named feature recognition, involved in object recognition, handwriting recognitions, and natural language processing, which consume a lot of resources. In these types of tasks, the dataset size has a big impact on machine learning performances. It is necessary to have a larger dataset for learning such variety and complex data. Therefore, the usage of deep learning approaches, such as CNN with hundreds of millions of trainable weights, is required.

Introduction of Deep Learning

Deep learning (DL) models are capable of focusing by themselves on feature extraction with very little guidance from the programmer, and can solve especially the dimensionality problem – to avoid the curse of dimensionality [24]. The main idea is to imitate the structure of the brain. DLs learn by themselves automatically, and they can quickly identify the decisive factors.

For instance, DL can be used for facial recognition. If ML is used, all specific elements of a face must be separately defined; but with the neural networks of DL, they will automatically detect the key features of each individual.

Deep learning is a form of ML, which uses a computing model, hugely inspired by the cerebral structure, where dendrites receive signals to the neuron from other neurons, the neuronal cell bodies summarize all the inputs and the axons transmit these to other cells, by firing off at a certain threshold, etc.

In DL the dendrites are represented by artificial neurons, also called perceptrons. They hence receive input of data from multiple sources, and deliver an output. The input and output are exactly like predictor variables. Data fed to a perceptron will undergo different functions and transformations, and then give an output. The perceptrons are connected into an artificial neural network. DL is a collection of statistical ML techniques, which

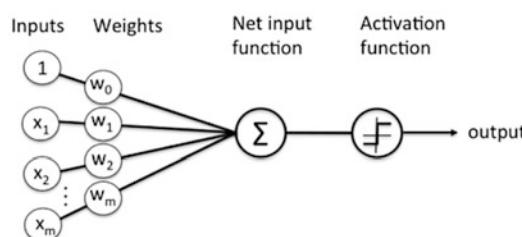

learn feature hierarchical structures, based on the concept of artificial neural networks.

In this neural network structure, there are different types of layers – the input layer receiving all the inputs, and the delivering output layer. Between these layers are numerous amounts of hidden layers. The number of perceptrons in each layer and the number of layers depend on the problem in question.

For image recognition in radiology, at first the high dimensional data is presented to the input layer, which in this case due to the massive load will contain multiple sublayers of artificial input neurons to digest the entire input. The output received from the first input layer contains extractable patterns, identifying the edges of the images, based on contrast levels. This data will be relayed to the first hidden layer, which will be able to identify certain clinically relevant features (or in facial recognitions, facial features), further transfer to the second hidden layer will be able to create a fuller picture (or the entire face). If the deeper recognition's entirety is sufficient (and no more layers needed), then the data is transferred to the output layer to deliver the classification.

Single-Layer Perceptrons

An Artificial Neural Network (ANN) with a single layer used for binary classification tasks is a linear model. The ANN, like the neuron, has a set of inputs, and each of these is dedicated to a certain weight, and it computes some specific functions on these weighted deliverances and produces an output. It separates the data into two separate classes (low or high).

Schematic of Rosenblatt's perceptron.

Principle of single-layer perceptron [25]

The perceptron above receives different inputs X_1, X_2, \dots, X_n , etc., and biases, and those are weighted accordingly to $W_1, W_2, \dots, W_{n1}, Y_2, \dots, Y_n$.

The word activation function alludes to its equivalent in the human cerebral cellular function with the action potential, where the neurons are activated at a certain threshold. It is mirrored here mathematically, when the function becomes saturated above a given threshold.

There are several types of activation functions, e.g., signum, sigmoid, tan, hedge, etc. All functions match the input to the respective output. The bias can shift the activation function in order to get an exact output.

As a medical perception analogy – should a person at the ER be sent to the ICU or not? There are three cardinal symptoms, X_{1-3} , and those have an importance or weight of W_{1-3} . If the symptom is present X attains the value of 1 and if not 0. W_1 is set to 6, W_2 to 2, and W_3 to 2. Then the firing threshold is considered. If the threshold is 5, it means the patient will be admitted if symptom 1 is present, even if the two others are not. If the threshold is 3, then either symptom 1 or the two other symptoms together will be sufficient for patient transfer.

X_1 – symptom 1 with W_1 of 6

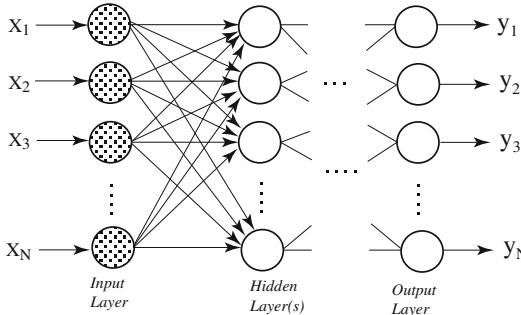

X_2 – symptom 2 with W_2 of 2

X_3 – symptom 3 with W_3 of 2

The limitations of perceptrons are associated with the absence of hidden layers, with the consequence it can only be applied to linear problems. When dealing with a nonlinearly separable data a single-layer approach is not feasible. A multilayer perceptron with back-propagation can though be used to solve non-linear problems.

Multilayer Perceptron – Artificial Neural Network

A multilayer perceptron has the same structure as a single layer perceptron, but with one or several hidden layers, and hence is considered a deep neural network.

A multilayer Artificial Neural Network (ANN) [26]

The weights between the layers of the deep network are the principal way in which long-term info is stored in artificial neural networks. The ANN learns new info by altering the weights or keeping them up to date. A set of new inputs passes through the first hidden layer, and then to the next as shown in the figure. Initially in an ANN the weights are assigned as random. With backpropagation, which is the quintessence of supervised neural network training, the weights of a neural network are fine-tuned. The tuning is based on the error rate obtained in the previous epoch (or iteration). Done properly this reduces the error rates and makes the model reliable by increasing its generalization. In order to have a correct output and a reduced error rate, the weightage needs to be adequate. The back-propagation is a way to train the perceptron by updating the weights.

The most common DL algorithm for supervised training of a multilayer perceptron is back-propagation. After the forward pass through the whole network, it is propagated backward, the

results updated with new weightage to minimize the error (compared to the wanted output). The procedure is iterated using gradient descent to do it faster and the errors/losses are reduced and the output optimized.

The limitation of a feed forward network can be exemplified with, e.g., image recognition. The network is exposed to a set of images, where the first photo presented will not really change the way it classifies the next photo. So the output at the time T is independent of the output at time T-1. This concept cannot be a logic approach if the T-1 information is necessary to understand the next information coming at T. Here we need a concept, which is the same as you apply, when you read this book – you need to understand parts I–III before you proceed to the systematic review in part IV. In an ANN the info at T + 1 has nothing to do with the info at T or T-1. Hence, an ANN cannot be used in situations where the output is based on previous outputs, e.g., for predictions of words in a sentence.

The solution to this problem is a *Recurrent Neural Network* (RNN), which is a type of ANN designed to recognize patterns in series of data, e.g., genomes, text, speech, handwriting, or numerical times series from medical sensors, or from stock markets, government agencies, etc. The applications are vast for RNNs. The prediction is based on past output.

Another concept is the *Convolutional Neural Network* (CNN), which is useful for image processing. A computer sees an image by breaking it down to three color channels, red-green-blue

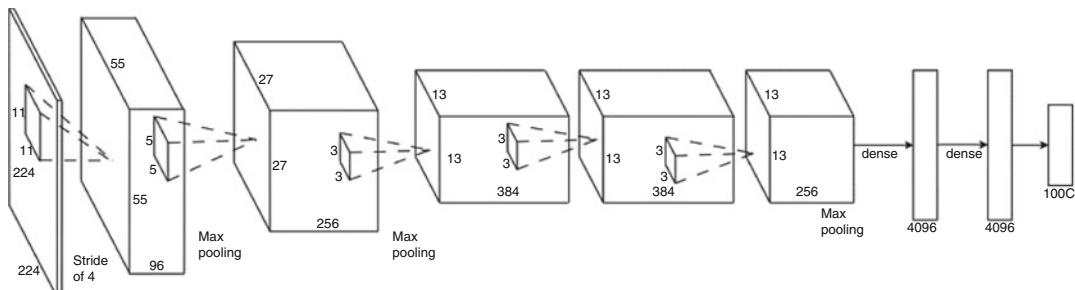

Fig. 2 A Convolutional Neural Network (CNN) architecture, with (fully connected) dense layer of 4096 units, derived from the last max-pool layer to the right (dimensionality change) [27]

(RGB), and reads the image with RGB values. Each of the channels is mapped with the pixels of the image. (The computer calculates the value of each pixel, and delivers the image size). In a CNN, a neuron will only be connected to a small portion of the previous layer. The CNNs are not fully connected.

Natural Language Processing

The main reason for the need of text mining and Natural Language Processing (NLP) is the stratospheric amount of data generated *every day*, and it is expected to grow. For instance:

Instagram	8.95 million photos posted/day
Twitter	500 million tweets/day
Facebook	3.2 billion likes and 350 million photos/day
Mail	300 billion emails sent/day

The vast majority of all data is completely unstructured. With the mining, structuring, and analyzing the data, huge scientific and economic values can be harvested. This is the essence of text mining – the process of deriving meaningful data out of natural language. NLP is a method used in text mining, and is the part of computer science and AI, which deals with human languages, and helps computers read human texts. A few applications of NLP and text mining are: auto-correction, auto-completion in searches, spam email detection, predictive typing, spell-checkers, and email classification. Sentimental analysis provides insights into the public or customer opinions in certain topics or products. Social media platforms use this analysis continuously. Chatbots are widely used in, e.g., customer services. Speech recognition in use by Siri, Cortana, and Alexa are all NLP applications. Machine translation is also an example of NLP, for instance, in use by Google Translate. Other NLP applications include information extraction, keyword search, and advertisement matching.

The *Generative Pre-trained Transformer* (GPT-3) is an autoregressive language model, which uses deep learning to produce human-like text. In the GPT series, it is the third-generation language prediction model, and was created by OpenAI in San Francisco [28]. The capacity of

GPT-3 is 175 billion machine learning parameters, and is the currently largest example of natural language procession (NLP) model [29].

A major concept in NLP is *tokenization*, which is the splitting process of the whole data (corpus) into smaller items (chunks). First it breaks a complex sentence into words, then analyses each single word's importance in the sentence and then translates. *Stemming* is the procedure of normalizing the word into its root or base or nominative state. The stemming algorithm provides this, with limitations though. In order to improve the accuracy *lemmatization* uses a large dictionary to group different inflected forms of a word, i.e., *lemma*.

Similar to stemming it labels a group of words into a common bundle. The output is then a usable proper word. Stemming may lead to an indiscriminate cutting of the word, so that the grammar or the understanding is lost, hence the introduction of lemmatization, which always delivers a word found in a dictionary. Lemmatization occurs after the morphological analysis.

Stop words are critical to applications – they can be removed with no loss of meaning, in order to focus on the *keywords*. The stop words will only decrease search accuracy.

Another concept, useful in natural language processing (NLP) is the *document-term matrix*, which is a mathematical matrix, which describes the frequency of terms occurring in a set of documents. Columns correspond to terms and rows to documents. Features can also be used besides terms [30].

Natural language processing has enormous potential for text mining of electronic health records and other medical applications, as will be elaborated in many other chapters of this reference textbook.

Conclusions

In conclusion, machine learning and deep learning algorithms have been widely implemented in various sectors with noticeable exponential application demand.

There will be no single area in preclinical medicine or clinical specialty, which will not be

profoundly affected by applications of artificial intelligence in medicine. AI will execute a thorough recast of all fields of healthcare.

The era of *mathematical medicine*, which can be said to have started with Archibald Pitcairne already in the seventeenth century [2], now with the emerging AI in medicine era, comes into full fruition.

This book encompasses the future potential of medicine and the benefits that can be unleashed when AI platforms can unlock the strengths of Big Data for Healthcare.

Abstract

As artificial intelligence (AI) advances emerge, they are often incorporated into the field of medicine. However, the reverse of this process is an important one also—many of the breakthroughs in the field of AI are due to knowledge and inspiration *from* biology, psychology, and encompassing medical sciences. The artificial neuron, one of the first achievements in AI, is discussed. Knowledge about the visual cortex

inspiring the creation of the neocognitron leading to the convolutional neural network, leading to the deep learning revolution in AI, is discussed. Cognitive architectures, which intentionally incorporate knowledge from the medical sciences, including biology and psychology, into a form that can add to the field of AI, are reviewed. While deep learning models can recognize patterns and play games at a human-like level, they are poor at causal understanding and solutions, especially if there are limited numbers of training examples. The causal cognitive architecture is reviewed. This architecture stores information in the form of navigation maps, which it can update and link/retrieve to/from other navigation maps, and produces precausal behavior. If intermediate maps from its navigation center are fed back, stored, and operated on again, then full causal

behavior can emerge. The architecture provides hypotheses and predictions about the emergence of schizophrenia in humans. The ability to navigate a world of concepts, explainability, and analogies also emerge from this architecture. Inspiration from the medical sciences can continue to provide AI with future breakthroughs.

Introduction

As advances in artificial intelligence have developed over the last half century, they have been applied to the field of medicine with the hopes of automating many processes in medicine, resulting in better research towards an understanding of diseases and their treatments and a lower cost, higher quality health care service to patients. Consider, for example, the development of expert systems and deep learning and their application to medicine.

An expert system obtains knowledge, essentially if-then rules, from a human expert about some field and contains an inference engine that logically uses the if-then rules to answer questions or solve problems posed to it. Buchanan and colleague's DENDRAL expert system, which helped to identify an unknown organic chemical, was created in the late 1960s [1]. By the early 1970s, a medical application of an expert system, MYCIN, had been developed [2]. In response to answers to questions it asked, MYCIN could identify bacteria causing severe infections and recommend specific antibiotic treatments [3]. MYCIN had several hundred rules, used a straightforward inference engine, and produced reasonable responses for its very narrow range of expertise. However, it never was used in a practical clinical sense. Expert systems such as MYCIN raised hopes for the practical use of artificial intelligence in all aspects of science, technology, and

commerce. By the 1980s, expert systems had become a major focus of the field of artificial intelligence, and international commerce and competition in the field had started. However, by the early 1990s, it had become apparent that while it was possible to build interesting demonstration applications with expert systems, they largely failed to produce useful results for the complex tasks they had been promised for, medical applications included. The early 1990s period is often called the "AI winter," with analogy to the term "nuclear winter," in which the expert system companies failed, and institutional research funding was cut back in the field [4].

Deep learning generally refers to machine learning using many layers of artificial neural networks (ANNs); i.e., there are middle layer(s) of artificial neural networks between the input and output layers. The theory and technology behind various machine learning approaches, including ANNs with multiple hidden middle layers, had started to greatly improve in the mid-2000s. In 2012, work by Krizhevsky, Sutskever, and Hinton using deep learning won a computer vision competition by a large margin over older methods [5]. In the ImageNet contest, a computer-based system needed to classify as accurately as possible over a million different images into some thousand different classes. Hinton and colleagues used a deep convolutional neural network. In such a neural network, there are multiple layers of artificial neurons connected with layers where the artificial neurons act as convolutional layers where such layers extract features from the previous layers, preserving the spatial relationships but essentially mapping into a small-size receptive field and extracting features as such. This achievement of Hinton and colleagues is regarded as an approximate start of what is called the "deep learning revolution" and propelled the utilization of deep learning into many domains, including, of course, just about every branch of medicine. For example, consider the field of schizophrenia research and patient care. A review by Veronese and colleagues in 2013 gives an overview of machine learning approaches in schizophrenia but describes little of deep learning [6]. However, within a few years, deep learning was being widely used in the field. In 2016, Kim and

colleagues noted that deep neural networks (DNNs) with multiple hidden layers were performing much better in classification tasks compared to support vector machines (SVMs) and earlier AI models. Kim and colleagues used a DNN classifier of resting-state functional magnetic resonance imaging to diagnose schizophrenia patients from healthy controls and showed better results than the same analysis performed with an SVM classifier [7].

As artificial intelligence enhancements and technologies emerged, they eventually became incorporated into the field of medicine, reaching the point where there is now a scientific discipline of “artificial intelligence in medicine.” The journal *Artificial Intelligence in Medicine* defines the field as “the scientific discipline pertaining to research studies, projects and applications that aim at supporting decision-based medical tasks through knowledge-and/or data-intensive computer-based solutions that ultimately support and improve the performance of a human care provider” [8]. However, in this chapter, the reverse idea is considered. Rather than advances in the field of artificial intelligence being applied to medicine, there is examination here of the principles and advances in the medical sciences, including biology and psychology, being applied *back* to the field of artificial intelligence.

In this chapter, some examples of concepts from the medical sciences being applied *back* to the field of artificial intelligence are reviewed (Video 1):

- (i) Neural networks
- (ii) Cognitive architectures
- (iii) Causal cognitive architectures

Concepts from the Medical Sciences Being Applied Back to the Field of Artificial Intelligence: Neural Networks

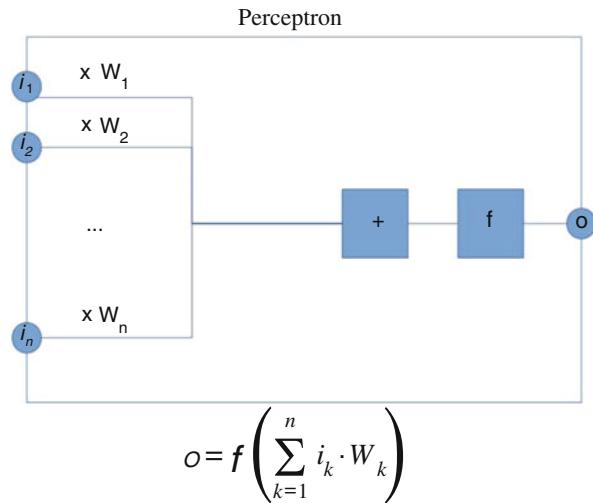

The basis of the “deep learning revolution” described above is the artificial neural network. As is obviously implied by the name, neural networks were inspired by biological neurons.

Neural networks were one of the earliest contributions to the field of AI. In 1943, Warren McCulloch and Walter Pitts took the basics of biological neuronal functioning and applied this knowledge to artificial neurons, which could be on or off and could activate other neurons [9]. They described a “logical calculus” for neural networks of their artificial neurons. A few years later, Donald Hebb described a method on how neurons could make connections with each other, i.e., “neurons that fire together wire together” [10], and an early learning mechanism arose that could be used with artificial neurons.

The artificial neuron, of course, does not simulate even a fraction of the complexity of an actual real neuron, but what it does do was sufficient for the emergence of neural networks. Rosenblatt’s “perceptrons” continued the use of these simplified neurons as functional elements of networks that could learn to classify inputs as belonging to a particular class [11]. Figure 1 shows a functional schematic of a perceptron. Inputs i_1 to i_n are multiplied by weights w , which are summed, and then passed through a function producing output o . Unfortunately, due to limitations in the way the perceptron networks were constructed (e.g., single-layer perceptron machine), it was shown that these simple neural networks could not function well enough to solve interesting problems [12]. Years later, more powerful and functional multilayer deep learning neural networks emerged, all with roots in the biological origins of the work of McCulloch and Pitts and which, as noted above, at the time of this writing are responsible for many of the modern applications of artificial intelligence, including applications in medicine.

Work by Hubel and Wiesel on the receptive fields of simple and complex cells in the visual cortex [13] inspired Fukushima’s neocognitron [14]. The neocognitron has simple (S) and complex (C) cells, with local features discerned by the simple cells and integrated into higher layers, and as such detects patterns. The neocognitron in turn inspired the convolutional neural network, which, as noted above, was used by Krizhevsky, Sutskever, and Hinton in their deep learning neural networks [5], which is often taken as the start of what is called the “deep learning revolution”

Fig. 1 Functional diagram of a perceptron, i – input, w – weight, f – function, o – output. (Creative Commons License BY-SA. Credit to Mat W.)

and resulted in the use of deep learning in many domains, including medicine.

Concepts from the Medical Sciences Being Applied Back to the Field of Artificial Intelligence: Cognitive Architectures

A cognitive architecture attempts to formally put a myriad of results from the medical sciences, including biology and psychology, into a model that gives a structure and functioning of the mind. As a result of the formal nature of the model, it can be implemented as a computer program, i.e., a computer program that exhibits varying degrees of intelligence. Concepts from the medical sciences, including biology and psychology, thus end up being applied back to the field of artificial intelligence.

ACT-R is a long-standing popular cognitive architecture [15]. ACT-R models the human mind as declarative knowledge (“chunks” which represent properties and are held in buffers) and procedural knowledge (“productions” which represent procedures to do various operations). There are two main types of long-term memory modules—declarative memory (i.e., facts, e.g., the pencil is brown) and procedural memory (i.e., productions, e.g., how to sharpen a pencil). Unlike typical databases in

computer science at the time which stored mainly facts, note that ACT-R’s memory is or can be substantially comprised of productions, i.e., procedures, as well. Just as humans have a short-term working memory, ACT-R also has a working memory. Depending on the internal state of ACT-R, which depends on the values in its various modules, including modules that interface with the real world, a best production will be selected and executed, and this in turn will change the internal state of the ACT-R, and then another production will be selected and executed, and so on. A cognitive architecture such as ACT-R is not just a collection of concepts but exists as a computer program, which can be run as well as modified. ACT-R has evolved over the years from 1973 to 2019 incorporating additional, modified, or newer theories of cognition, and also, its software implementation has changed [16].

The operation of a cognitive architecture such as ACT-R is inspired by the medical sciences. For example, in a recent ACT-R model, in its production system, the matching of productions is inspired by the striatum, the selection of a production is inspired by the pallidum, and the execution of a production is inspired by the thalamus [16]. In turn, the ACT-R contributes to the field of artificial intelligence, in which there are many diverse applications, e.g., human-robot interactions [17] or flying an airplane [18].

A variety of cognitive architectures exist. Samsonovich in 2010 and Kotseruba and colleagues in 2016 reviewed many of these different architectures [19, 20]. Ritter and colleagues organized cognitive architectures into five main groups [16]:

1. Cognitive architectures using advanced knowledge structures such as plans, with an emphasis on performance, e.g., JACK multiagent systems [21].
2. Symbolic architectures with emphasis on modeling human cognition, e.g., Soar cognitive architecture [22] (although some versions of Soar also have subsymbolic operations and would be thus classified in the hybrid group below)
3. Subsymbolic/connectionist architectures with information distributed across multiple nodes, e.g., Leabra cognitive architecture [23].
4. Hybrid architectures with both symbolic and subsymbolic components, with emphasis on modeling human cognition, e.g., ACT-R, since it has symbolic production and declarative memory components, but it also has subsymbolic operations in the operation of the architecture
5. Nongenerative architectures that do not produce behavior but are largely used as design tools to predict time and other requirements to accomplish some set of procedures.

Although O'Reilly and colleagues' work describes in particular the Leabra architecture, their work applies more broadly to the design of other cognitive architectures [23]. They note that cognitive architectures represent a complex way to do computational modeling, but the reason they are used is that modeling human cognition does not seem possible with a simpler generalized algorithm. O'Reilly and colleagues give a list of principles that they used to develop the Leabra architecture and are broad enough to be used for other architectures. Some of these principles are:

1. Balance the tradeoffs associated with different approaches, often using a compromised approach that may integrate multiple solutions.

2. Biology is important. The human brain is the only working truly successful cognitive system, so there is merit in trying to understand its details.
3. Occam's razor—regardless of the complexity required, it is best to use the simplest model that is sufficient for the modeling required.
4. Again, there is a need to balance tradeoffs between biological constraints, cognitive constraints, and computational constraints, depending on the model desired.
5. Experience-driven learning mechanisms are essential.
6. Microstructural mechanisms will affect the macrostructural mechanisms.
7. Changes in neural firing, i.e., activation, can occur more quickly than changes in synapses.
8. Meaning, in a connectionist system, is due to the patterns across the entire system, not individual neural messages.

An interesting cognitive architecture is the very hybridized OpenCog, which has the goal of creating a human-equivalent artificial general intelligence (AGI) [24–26]. OpenCog uses a graphical database that links to a myriad of different cognitive processes, including forward and backward chaining of essentially production rules, Bayesian inference (i.e., update probabilities as more information becomes available), an economic attention allocation mechanism where there are numerous attention values attached to various pieces of information, probabilistic logic networks (allow reasoning with uncertain information in the real world), meta-optimizing semantic evolutionary and probabilistic evolutionary mechanisms (where “evolutionary” mechanisms are not actual biological genetics but refer to the field of genetic programming, i.e., of applying fitness selection to large numbers of, for example, random-like programs and selecting and evolving the more fit programs), a natural language input and output processing system, and the use of emotions. While at this time of writing OpenCog has obviously not even come close to its goal of a human equivalent AGI, and while OpenCog contains a potpourri of cognitive concepts, many of these do stem originally from animal and human

minds and show the potential of applying principles from the medical sciences *back* to the field of artificial intelligence.

Concepts from the Medical Sciences Being Applied *Back* to the Field of Artificial Intelligence: The Causal Cognitive Architecture

As noted above, a cognitive architecture incorporates results from the medical sciences, including biology and psychology, into a system that models a mind, whether natural or artificial. This model is formal enough that it can be implemented as a computer program. Like other cognitive architectures, what is termed the “causal cognitive architecture” arises from observations in the medical sciences [27–32]. A simplified block diagram of an implementation of a causal cognitive architecture, the Causal Cognitive Architecture 1 (CCA1), is shown in Fig. 2 [32]. Some of the many observations and concepts from the medical sciences, including biology and psychology, that the causal cognitive architecture incorporates will be discussed first. Then its basic properties as well as its emergent properties will be considered.

In most of the animal world, in both invertebrates and vertebrates, there is the ability to move and the ability to navigate. In mammals, Hafting and colleagues [33] showed neural maps of the spatial environment in the dorsocaudal medial entorhinal cortex, with location activation of “grid cells” in these maps. Schafer and Schiller note that it is possible that these maps intended originally for navigation in the physical world can be used to navigate concepts [34]. Evolutionary precursors to the mammalian cortex go back to the earliest vertebrates [35]. Thus, in the design of the causal cognitive architecture, it was decided that information would be stored as navigation maps. Operations on these maps could be effected in a “navigation module” where maps would be modified, updated, stored adjacently, retrieved, linked to other maps, and so on. Except for some typical neural network-like hierarchical processing of input signals and output signals, all information would be stored and manipulated in map-like data

structures, and much of the higher processed information would pass through the navigation module [32].

The mammalian cortex appears to be made up of large numbers of repeating cortical minicolumns [36]. Also, there is a generative aspect in how the mind processes information. As a result, a basic pattern recognizing circuit, a Hopfield-like network (HLN), was chosen for many of the causal cognitive architecture’s circuits. HLNs can be dynamically reconfigured with other HLNs to extract what is described in the architecture as maximal “meaningfulness” from input vectors, where meaningfulness is the reciprocal of the Shannon entropy, favoring activation of the maximal number of HLNs further downstream [27, 31, 32].

Just as a child is not a tabula rasa, neither is the causal cognitive architecture. The instinctive primitives module shown in the architecture in Fig. 2 contains procedural vectors, which can be triggered by processed sensory inputs, by the navigation module, or by other modules of the architecture. If triggered, an instinctive primitive will be applied to the navigation map currently in the navigation module and can, for example, move along the map to trigger another instinctive or learned primitive or change the map or cause another linked map to be retrieved and so on. The instinctive primitives include physics primitives, mathematical primitives, psychology primitives, and planning primitives. Also, there are learned primitives that as the name implies are learned from experience. There is a letter “D” in many of the boxes in the architecture in Fig. 2. “D” stands for the internal developmental timer; i.e., as the CCA1 shown in Fig. 2 gains more experience, different levels of instinctual primitives or operations in these modules will be executed.

Examining Fig. 2, note that the sensory inputs are processed by hierarchies of input sensory vector association modules and then a binding module. Inputs are then sent to the navigation module. (They also go to the learned and instinctive primitives where they can trigger primitives to be executed, to the sequential/error correcting module which is useful for sequential data, to the autonomic modules, and to other modules.)

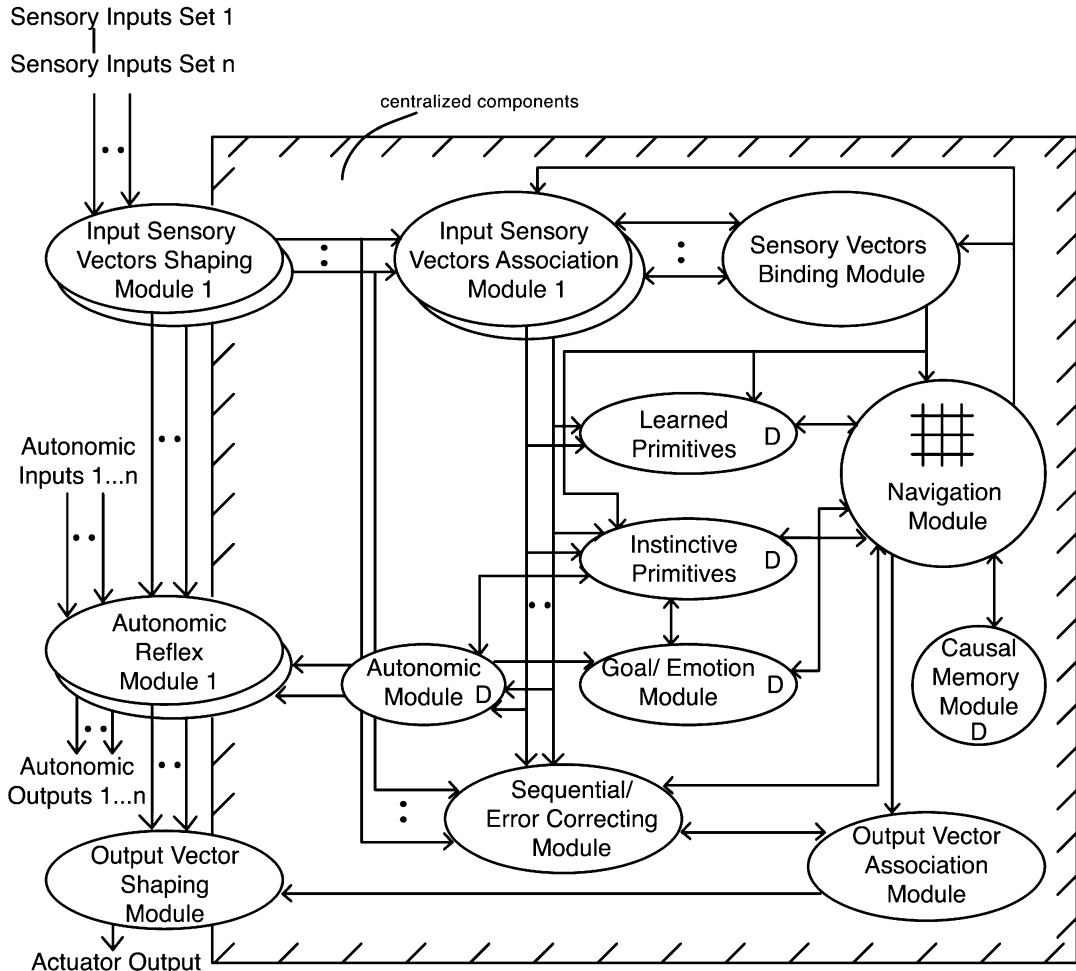

Fig. 2 Causal Cognitive Architecture 1 (CCA1) Not all connections are shown. D – internal developmental timer. (License – Original work for this publication)

Applying primitives, i.e., vectors that cause a modification of the current map in the navigation module, allows the input signal to be modified in a precausal fashion. The map already has some causality built into it; i.e., this goes to that, which goes to that and so on. The output of the navigation module is processed, in its most basic form, via the output vector association and shaping modules, into a movement of an actuator. As such, precausal behavior emerges from the Causal Cognitive Architecture 1 shown in Fig. 2 [32].

Deep learning can recognize patterns and use reinforcement learning to operate at human-like levels for certain skills such playing games [37, 38]. However, if deep learning needs to

causally make sense of a problem, especially if there are not large numbers of training examples, its performance is poor compared to a four-year-old child [39, 40]. In the causal cognitive architecture, instinctive and learned primitives applied against map-like memories or input signals represented in map-like structures will produce outputs that the maps lead to, which as noted above results in a precausal complex associative behavior. Many birds as well as mammals can exhibit precausal behavior, i.e., not a full understanding of cause and effect but a complex association of causes with outcomes that is more than just a simple reflex or association. However, it is unclear whether *any* nonhumans can effectively

understand cause and effect and can truly use full causality in making decisions.

Asian elephants have brains much larger than humans, but in experiments by Nissan [41] behavior was due to associative learning rather than causal learning or behavior. New Caledonia crows are frequently claimed to show causal behavior in solving physical problems. However, in research by Neilands and colleagues where the crows must drop a weighted object down a tube, the crows did not understand causally the idea of force, and there was little causal understanding overall [42]. Tayler and colleagues examined crows solving string pulling problems and came to the conclusion that there was little causal understanding but that the problems were solved instead by a perceptual-motor feedback loop [43]. If the behavior of primates, obviously closer in origin to humans, is considered, there still is not a clear indication that robust causal behavior occurs. For example, Visalberghi and Limongelli showed that while capuchin monkeys were able to use a stick to push a reward out of tube, if a hole and a trap are added to the tube, the monkeys showed poor understanding of cause-and-effect relations in not pushing the food into the trap [44]. This tube with a trap and food-reward-type problem is also difficult for chimpanzees. However, work by Seed [45] and colleagues showed that if the tube problem is simplified a bit, there appears to be some understanding by the chimpanzees about the functional properties of the problem. However, while the chimpanzees were able to solve this simplified problem, it still required dozens of trials [45].

While there remains controversy concerning the extent of causal behavior possible in non-humans, note that chimpanzees are the closest extant relatives to humans and yet are not capable of a robust understanding of cause and effect or causal behavior. Thus, a design requirement of the causal cognitive architecture was that there should be a simple mechanism to explain how the architecture can transition from the precausal behavior described above to a fully causal behavior [32].

Almost all the circuits of the causal cognitive architecture have feedback pathways. Feedback from downstream hierarchical levels as well as

lateral levels send back signals which will allow the CCA1 to better anticipate what the next input sensory vector should be and thus better recognize such input signals. In Fig. 2 showing the Causal Cognitive Architecture 1, if the feedback pathways from the navigation module to the input sensory various modules are enhanced, then full intermediate navigation maps from the navigation module can be stored temporarily in the input sensory modules. In the next input cycle, rather than considering actual sensory input signals, the intermediate results can be fed back to the navigation module and operated on again by the instinctive and learned primitives [32].

The ability of the causal cognitive architecture to temporarily store intermediate values of the navigation module and then process these map-like structures and values again, and again as many times as necessary, results in the ability of the causal cognitive architecture to have robust causal behavior [31, 32]. Note that the transition from precausal to full causal ability merely requires enhanced feedback pathways and a slight change in how input signals are processed, in keeping with the requirement above that the architecture be able to provide a mechanism for a simple transition from precausal to causal abilities.

In a simulation of the Causal Cognitive Architecture 1 (CCA1) controlling a search and rescue robot in a rain forest searching for a lost hiker [32], in precausal mode, if the robot comes to a fast-moving, noisy river, it will cross the river since it is able to cross rivers. As sensory inputs are processed in the navigation module, intuitive and learned primitives are activated and will not prevent the robot from entering the river. However, in this rain forest, the fast-moving, noisy river is the start of a waterfall, and unfortunately the robot is swept over the edge of the waterfall and is damaged. If the robot is repaired and goes out into the rain forest and senses another fast-moving, noisy river, then by associative mechanisms, i.e., via the learned primitives (as well as the goal/emotion module), it will avoid the river.

In the same situation in full causal mode [32], “fast moving” + “water” will cause an intuitive physics primitive to cause the navigation module

to produce the navigation map “push” + “water” (where there are not actually discrete symbols but instead a map of the robot moving in water). The intermediate navigation map “push” + “water” is fed back to the sensory circuits, and in the next cycle processing input signals, the “push” + “water” navigation map loads back in the navigation module and is operated on by the intuitive and learned primitives. The result is pulling up or creating a new map with the robot underneath water. This intermediate result is fed back and then used as the input signal in the next cycle. An intuitive primitive is triggered by this map of the robot underneath the water, with an output from the navigation center to not go in this direction. As a result, in full causal mode, the search and rescue robot does not enter this fast-moving, noisy river and become damaged, even though it has never seen a waterfall or a noisy fast-moving river before or trained on such examples.

An emergent property of the causal cognitive architecture is the ability to not only handle navigation in the physical world but also use the map-like data structures in the navigation center to hold and link to more abstract concepts and to navigate this world of concepts. Causal operations can be performed on these concepts as they are modified and stored and cause retrieval of other concepts [32].

The navigation module shown in Fig. 2 stores the many navigation maps it constructs in the causal memory module. When a similar situation occurs again in the future, then similar navigation maps are triggered in the causal memory module and fed into the navigation module, thus providing a learned representation of which actions occurred in the past and which can be used for the new situation, with modifications as needed. An emergent property of this is explainability—the sequence of navigation maps used in an action or decision gives a very reasonable explanation of why a particular answer was given for a particular problem. (Note that the subsymbolic aspects of the causal cognitive architecture, such as the initial steps in processing an input signal through a hierarchy of Hopfield-like networks or equivalent, are not fully captured by the navigation maps.) Gilpin and colleagues [46] describe the property

of explainability as a model being able to give the reasons for its behavior. The lack of explainability in conventional deep learning models is an important concern when using such models for critical applications, including those of AI in medicine.

Another emergent property of this architecture is the ability to generate and handle analogies [32]. For example, consider asking the almost philosophical question to the search and rescue robot in the example above after returning from its rescue mission of whether it wants to spend time with either person A or person B, who are both similar but person B is more smiley and more outgoing, i.e., very noisy. Person A and person B would be put onto a temporary map in the CCA1’s navigation module (Fig. 2). The Causal Cognitive Architecture 1 has to essentially decide whether to navigate to person A or person B. Its instinctive primitives, which include psychology primitives, favor smiling people. However, person B is also noisy, and this results in the navigation center pulling up a previous navigation map—the river was noisy, and thus the link on the map with person B now ends up pointing to a dangerous situation. Intermediate results would be fed back to the sensory input stages and processed again, temporary maps would be switched back again, and the noisy person B is now associated with possible danger. Thus, there is a navigation output to navigate to person A. Note that without any elaborate, specialized algorithms and without any special central controlling stored program, other than the inherent and relatively simple operational cycles of the architecture, the CCA1 has made what would seem like a cognitively advanced decision. Analogies readily emerge from the causal cognitive architecture.

The causal cognitive architecture was not intended to model disease, and indeed no pathological predispositions were intentionally designed into its architecture. However, an interesting emergent property of the architecture is that when the mode switches from precausal to fully causal (i.e., send back intermediate results from the navigation module to the sensory stages so they can be operated on again in the next sensory input cycle), psychotic behavior may emerge.

Any number of varied imperfections or combinations of them can result in psychotic behavior (but in precausal mode usually would not have had catastrophic effects as such) [29, 31, 32]. The intermediate navigation maps that the navigation module stores temporarily in the input sensory vector circuits, under a faulty operation, can be interpreted as a real input sensory signal, i.e., effectively hallucination-like and then delusional-like responses when instinctive and learned primitives are applied to it in subsequent operations, and then cognitive dysfunction of the system. Hallucinations, delusions, and cognitive dysfunction are typical of psychosis. Note that it is not just one defect that can cause this, but many different defects in various circuits.

Since the causal cognitive architecture is inspired by biology (although *not* pathology), then if it predicts that psychosis easily emerges, why is it that only approximately 1% of the human population has schizophrenia and not a larger percentage of the population? Actually, as van Os and colleagues show in their research [47], more than 10% of the population (a large figure from a population point of view) will experience some sort of psychotic-like symptoms—there are many causes why humans may experience psychotic-like symptoms, as the causal cognitive architecture predicts. Work by Anttila and colleagues [48] looking at the genomes of 265,218 psychiatry patients and 784,643 controls found considerable genetic overlap between what should be very different formal psychiatric disorders, including schizophrenia, again in keeping with the causal cognitive architecture predicting that psychosis does not emerge from a single or small group of genes.

In the causal cognitive architecture, in the non-causal mode, i.e., in the precausal mode, the psychotic-like behavior does not happen as easily. Note that humans readily develop psychosis (i.e., the 10% figure above) but humans do have robust causal abilities. While there is still controversy concerning the extent of causal behavior possible in nonhumans, from all the evidence available, as discussed above, nonhumans do not have robust causal behavior. Should psychosis readily arise in nonhumans? The causal cognitive

architecture would predict no. In fact, in just about all other mammals, psychosis is rare, and in psychopharmacological research settings, large efforts are needed to induce at best unreliable models of schizophrenia in research animals [49].

Causal aspects of the causal cognitive architecture are inspired by the abilities of human working memory. The causal cognitive architecture would predict that in asymptomatic relatives of patients with psychosis, there are also defects in the causal process and the working memory, even though perhaps in that person the cumulative effects of the defects do not result in psychosis. In fact, decreased working memory abilities are found not only in patients with schizophrenia but also in unaffected relatives [50].

It is interesting to look at the transition from nonhumans, where the closest extant relatives of humans, chimpanzees, do not have full causal abilities nor readily develop psychosis, and it would be assumed that the last common ancestors of both modern humans and chimpanzees did not either. The “schizophrenia paradox” is that schizophrenia reduces an individual’s ability to reproduce and should be naturally eliminated from the population yet continues to be found throughout the world at a relatively high prevalence approaching 1%. There are all sorts of rationalizations for this [51–54]. However, the causal cognitive architecture rejects the schizophrenia paradox and these explanations. Instead, it predicts that the transition to a brain architecture that allows causality is also vulnerable to many different defects allowing psychosis to emerge. Thus, there should be many different genetic alleles that prior to the transition to full causality were not harmful, that now would allow psychosis to emerge more easily, and that removing a myriad of different genetic characteristics from a population will not occur as easily as removing a single faulty allele [29, 31, 32].

Work by Liu and colleagues [55] published in 2019 compared single nucleotide polymorphisms (SNPs) associated with schizophrenia in modern humans with those present in the recovered genomes of extinct archaic Denisovan and Neanderthal humans (thought to have split from the modern human ancestors approximately 440,000

to 270,000 years ago [56]). Liu and colleagues showed that the risk alleles for schizophrenia appear to have been gradually removed from the modern human genome due to the negative selection pressure, as the causal cognitive architecture predicted.

Discussion

As artificial intelligence advancements and technologies emerge, they are often incorporated into the field of medicine. However, it is noted that the reverse of this process is an important one also. Many of the large improvements and breakthroughs in the field of artificial intelligence are in fact due to knowledge and inspiration *from* the medical sciences, including biology and psychology. A number of examples were discussed above.

The basis of neural networks, the artificial neuron, was one of the first achievements in the field of artificial intelligence. It was derived from knowledge in the biological and medical fields. Similarly, scientific knowledge about the visual cortex inspired the creation of the neocognitron. In turn, the neocognitron led to the convolutional neural network, which in turn led the start of what is sometimes called the deep learning revolution. Deep learning neural networks have at this time been applied to almost every field of academia, industry, and, of course, medicine.

Cognitive architectures intentionally attempt to take knowledge from the medical sciences, including biology and psychology, and incorporate this knowledge into a formal structure, which then can be implemented as a computer program. A variety of cognitive architectures were discussed above. While many cognitive architectures make only small contributions to the field of AI but may be more useful to provide insight into the operation of the human mind, some are intended as bona fide contributions to artificial intelligence. The OpenCog cognitive architecture, for example, has the goal of becoming a human equivalent artificial general intelligence, although admittedly at the time of writing, it is far from this achievement.

As was noted above, deep learning can recognize patterns and use reinforcement learning to play games at a human-like level [37, 38]. However, if a deep-learning-based system needs causal understanding to solve a problem, especially if there are not large numbers of training examples, its performance is poor compared to a 4-year-old child [39, 40]. For many situations, it simply is not possible or practical to have extensive training on every type of example that could arise. This certainly happens in the medical applications of AI as well as in almost all other fields as well. Work by Amodei and Hernandez [57] note that the famous Moore's law has a 2-year doubling period (i.e., the number of transistors on integrated circuits fabricated by manufacturers doubles approximately every 2 years), which means from 2012 to 2018 there should have been an approximately eight-fold improvement in the power of computer hardware. A 800% increase is, of course, significant and impressive. However, what really happened in the training of deep learning networks from 2012 to 2018 was that a 300,000-fold increase (i.e., a 30 million % increase) in hardware computational power was used to train deep learning networks. This number has only increased in the years since 2018. These exponential increases in computing power are not sustainable, nor is the ever-increasing need for more training examples. The resources and costs simply become prohibitive, despite the improvements by hardware manufacturers and despite the improvements in deep learning training algorithms. Thus, deep learning neural networks may start approaching pragmatic limits in their ability to do more complex tasks at a human level, certainly those requiring causal decisions and limited training examples.

Others in the field of AI have started to recognize the problems that current implementations of deep learning face and the need to consider alternative approaches. Discussed above, for example, was the interesting cognitive architecture OpenCog, which has the goal of creating a human-equivalent artificial general intelligence [24–26]. Graves and colleagues [58] discuss using a neural network that can read and write to an external memory, i.e., a hybrid system. Huyck [59] describes work on a neuromorphic-like

cognitive architecture with a fast implicit subconscious system and a slow explicit conscious system. Epstein [60] discusses cognitive modeling of spatial navigation. Lake and colleagues [61] discuss building causal models of the world and discuss intuitive physics and psychology present in infants. Hawkins and colleagues [62] and others, such as Schafer and Schiller [34], discuss how abstract concepts can be represented in a spatial framework. Laird and Mohan [63] discuss using architectures that contain more innate learning mechanisms. Taatgen [64] discusses using multiple levels of abstraction for learning. In a recent paper discussing deep learning for higher-level cognition [65], Goyal and Bengio write: “Have the main principles required for deep learning to achieve human-level performance been discovered, with the main remaining obstacle being to scale up? We argue that having larger and more diverse datasets is important but insufficient without good architectural inductive biases.”

While the causal cognitive architecture discussed above is largely at an experimental level, it is a technology that is essentially derived from the medical sciences, including biology and psychology [32]. As noted above, the causal cognitive architecture creates navigation maps from input sensory vectors and produces a navigation output, i.e., related to movement. A precausal behavior can result from this architecture. There is no understanding of cause and effect, but the maps navigate from problem to solution that may seem to be related to this or that cause. However, intermediate solutions to a problem, i.e., the maps created in the navigation module, can be fed back along existing but enlarged feedback pathways and stored as an input sensory value, and in the next input cycle processed again, and repeatedly so as needed. Maps of intermediate parts of the problem solution can be created and stored, new maps made, previous maps retrieved, and so on. In this fashion, true causal behavior can result with an understanding of cause and effect.

The causal cognitive architecture, inspired and derived by the medical sciences, including biology and psychology, offers features, albeit in toy

models tested to date [27–32], useful for the field of AI. It allows problems to be mapped and processed causally. It stores the intermediate maps it creates in solving a problem or performing a behavior—retrieving and replaying the maps allow explainability about a decision the architecture made. While solving physical navigation problems is obvious, the causal cognitive architecture can similarly navigate a world of concepts. Another emergent property of the architecture is the ability to handle analogies automatically.

As shown above, many of the large improvements and breakthroughs in the field of artificial intelligence are in fact due to knowledge and inspiration *from* the medical sciences. An appreciation for the origin of the technologies in AI can help with their application in general as well as to the medical fields.

Abstract

With the tremendous success of deep learning in recent years, the field of medical imaging has undergone unprecedented changes. Despite the great success of deep learning in medical imaging, these recent developments are largely empirical. Our goal in this chapter is to provide an overview of some of the key mathematical foundations of deep learning to the medical imaging community. In particular, we will consider ties with traditional machine learning methods, unrolling techniques which connect deep learning to iterative algorithms, and

Introduction

Since groundbreaking performance improvements were first demonstrated by AlexNet [1] at the ImageNet challenge, deep learning has provided significant gains over classical approaches in various fields of artificial intelligence and data science. Availability of large-scale training datasets and advances in neural network research such as development of effective network architectures and efficient training algorithms have resulted in unprecedented successes of deep learning in innumerable medical imaging applications such as disease diagnosis, image segmentation, and image reconstruction.

In contrast to classical shallow machine learning approaches, which require “feature engineering” to extract features to feed into simple classifiers for diagnosis and recovery, one of the most important advantages of deep learning is that deep neural networks automatically discover the features and design appropriate classifiers and recovery methods in a data-driven way. This greatly simplifies the workflow of machine learning algorithm development and deployment. More importantly, the features are optimized toward specific tasks, which generally offer enhanced representation of the underlying data. In particular, for classification tasks the learned features can be much more discriminative than handcrafted features, whereas for reconstruction problems the learned features may better preserve the details and enable a more faithful reconstruction. As data representation plays a critical role, better features typically lead to superior performance in practice. Therefore, deep learning has become an increasingly important and versatile tool for medical imaging.

Nonetheless, the success of deep learning largely remains a mystery. From an architecture

perspective, deep neural networks are typically composed of a series of convolution, pooling, and nonlinearity layers, which from a mathematical point of view are regarded as primitive tools. Interestingly, with abundant training samples available, the cascaded connection of these primitive tools results in superior performance over traditional approaches which are carefully designed and tailored toward specific applications.

A popular explanation for the success of deep neural networks is that neural networks are developed by mimicking the human brain. One of the most famous numerical experiments is the emergence of hierarchical features from a deep neural network when it is trained to classify human faces [2]. This phenomenon is similarly observed in human brains, where hierarchical features of the objects emerge during visual information processing. However, when asked why, it is surprising to find out that neuroscientists usually rely on numerical simulations with artificial neural networks to explain how hierarchical properties arise in the brain [3].

To understand this fundamental question, one can go back to classical approaches to understand the similarities and differences from modern deep neural network methods. Recent studies have shown that there is a close relationship between deep learning approaches and sparse representations [4–8]. Specifically, neural networks have been interpreted as unrolled versions of sparse recovery, where each unfolded block is learned from the training data [4, 9–11]. The authors in [5, 6] showed that a deep neural network can be interpreted as a piecewise linear representation, whose data-driven basis is learned from training data and automatically adapted to various input signals [12]. In this chapter, we will consider these and other mathematical underpinnings of deep networks in order to offer insights into their unprecedented performance.

We begin in section “[Classical Machine Learning and Its Limitations](#)” by reviewing typical machine learning models and explain their limitations in representation power which motivate the development of modern deep learning techniques. We then review standard modern deep neural networks and illustrate conceptually how they have successfully achieved superior representation power compared to classical approaches in section “[Modern Deep Learning Revolution](#).[“Modern Deep Learning Revolution.”](#)

We next

review algorithm unrolling in section “[Algorithm Unrolling: From Iterative Algorithms to Deep Networks](#)” which connects traditional iterative algorithms with modern deep neural networks. To gain further insights into deep learning, we discuss how it can be interpreted, both from a biological and a geometric perspective in section “[Interpretations of Deep Learning](#). ” Finally, we summarize this chapter in section “[Summary and Outlook](#). ”

Classical Machine Learning and Its Limitations

In this section, we provide historical context on how deep learning evolved into its current form. We review two relevant classical machine learning models, the perceptron and support vector machine, and illustrate the limitations of these “shallow” models.

The Perceptron Model

One of the earliest machine learning models is the single layer perceptron [13]. As illustrated in Fig. 1, it is built by fully connected neurons at a single hidden layer, where each neuron is formed by an affine transformation of the input vector followed by a nonlinear mapping. Formally speaking, let $\varphi : \mathbb{R} \mapsto \mathbb{R}$ be a nonlinear activation function, and let $\chi \subset \mathbb{R}^n$ denote the input space. Then, a single layer perceptron $f_\Theta : \chi \mapsto \mathbb{R}$ is represented by

$$f_\Theta(x) = \sum_{i=1}^d v_i \varphi(w_i^\top x + b_i), \quad x \in \chi \quad (1)$$

where $w_i \in \mathbb{R}^n$ is a weight vector, $v_i, b_i \in \mathbb{R}$ are real constants, and $\Theta = \{(w_i, v_i, b_i)\}_{i=1}^d$ collectively represents the model parameters. To estimate the unknown parameters, a collection of training data $\{(x_i, y_i)\}_{i=1}^N$. The model parameters are then estimated by solving the following error criterion:

$$\min_{\Theta} \sum_{i=1}^N \ell(y_i, f_\Theta(x_i)) + \lambda R(\Theta) \quad (2)$$

where $\ell(.,.)$ is a desired loss function, λ is a regularization parameter, and $R(\Theta)$ is a regularization function with respect to the parameter set Θ .

When the single layer perceptron was first introduced, it was not clear how to simultaneously optimize the weights $\{w_i\}_{i=1}^d$ for all neurons. Instead, a heuristic algorithm called *the perceptron algorithm* was used to estimate the neuron weights. When the training data set is linearly separable, the perceptron algorithm is guaranteed to find an exact separation in a finite number of steps. Later on, the back-propagation algorithm was introduced [14], which applies gradient-based learning to learn all neuron weights simultaneously.

One of the classical results regarding the representation power of a single layer perceptron is the universal approximation theorem [15], which states that a feed-forward network with a single hidden layer containing a finite number of neurons can approximate continuous functions on compact subsets under mild assumptions on the activation function. The universal approximation theorem promoted research into neural networks as a powerful functional approximation; however, it turned out to be a limitation in the development of machine learning by circumventing construction of deeper neural networks. Although the theorem conceptually justifies that a shallow network with sufficiently many neurons can be a universal approximator, the proof of the theorem does not offer even a loose upper bound on how many neurons are required. Therefore, it is entirely possible that the networks which act as universal approximators are too large to be practical. However, at the time, deeper neural networks were difficult to train. Therefore, the prevalent approach was to increase the width of the network, namely the number of nodes, rather than the depth. Only recently has it been realized that depth matters, i.e., there exists a function that a deep neural network can approximate but a shallow neural network with the same number of parameters cannot [16–19].

Support Vector Machine

Another typical example of a “wide” model is Support Vector Machine (SVM). Similar to the neuron model, it classifies the data samples by learning an optimal separating hyperplane. However, in order to ensure that all data samples are far apart from the hyperplane, it employs a maximal

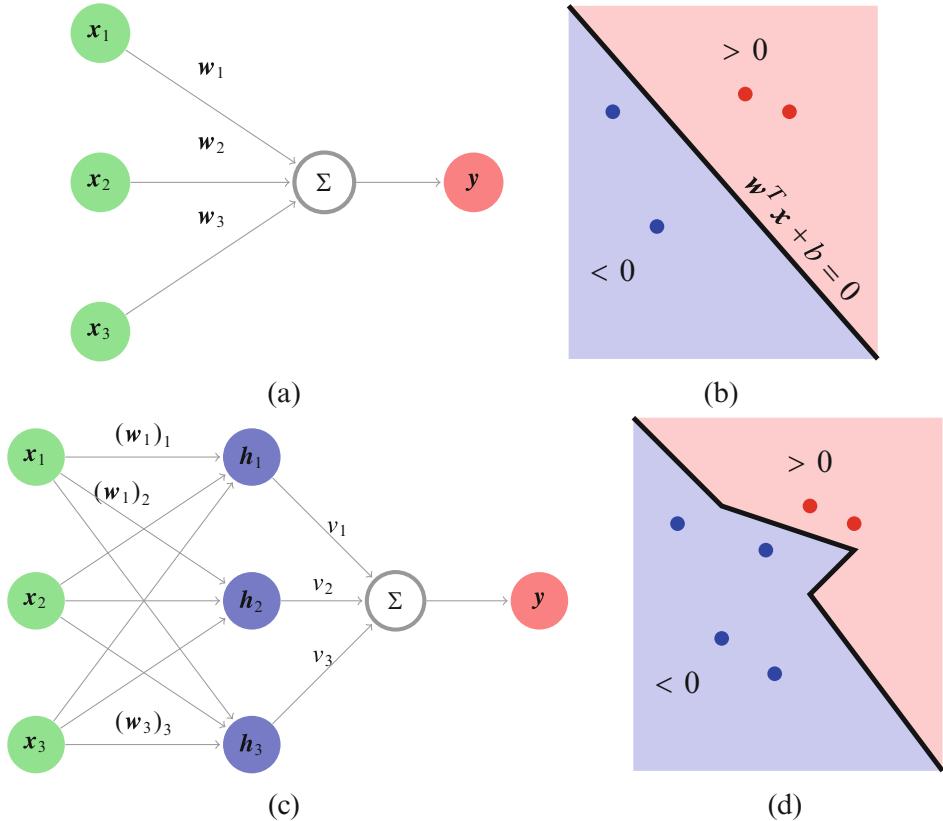

Fig. 1 Geometric interpretation of the perceptron model. (a) Architecture of the perceptron model for a three dimensional input. A neuron first applies an affine mapping of the input x and then performs thresholding to determine the predicted class y ; (b) geometrically, a neuron divides the

input space into two decision regions through a separating hyperplane; (c) the perceptron model is formed through a combination of multiple neurons; and hence (d) its decision boundary corresponds to a piecewise linear surface

margin loss function for training the weights of the separating hyperplane. Specifically, given training samples $\{x_n, y_n\}_{n=1}^N$, it solves the following minimax problem [20]:

$$\max_{w, b} \left\{ \frac{1}{\|w\|} \min_n [y_n(w^T x_n + b)] \right\} \quad (3)$$

which can be interpreted as maximizing the distances (margin) from the closest data samples (support vectors) to the separating hyperplane. A visual illustration of this criterion is given in Fig. 2a.

In practice, it is possible that the data samples cannot be classified by a single separating

hyperplane, i.e., the data samples are not linearly separable. In this scenario, SVM employs a non-linear mapping ϕ which embeds the data manifold into a high-dimensional feature space [21], where the data samples are assumed linearly separable. In practice, instead of explicitly designing the embedding ϕ , one can seek a *kernel function*, which characterizes the inner product $\langle ., . \rangle$ in the underlying feature space:

$$k(x, x') = \langle \phi(x), \phi(x') \rangle. \quad (4)$$

The aforementioned SVM technique is then employed in the feature space. In this way, the explicit form of ϕ does not need to be specified and only the kernel function has to be designed.

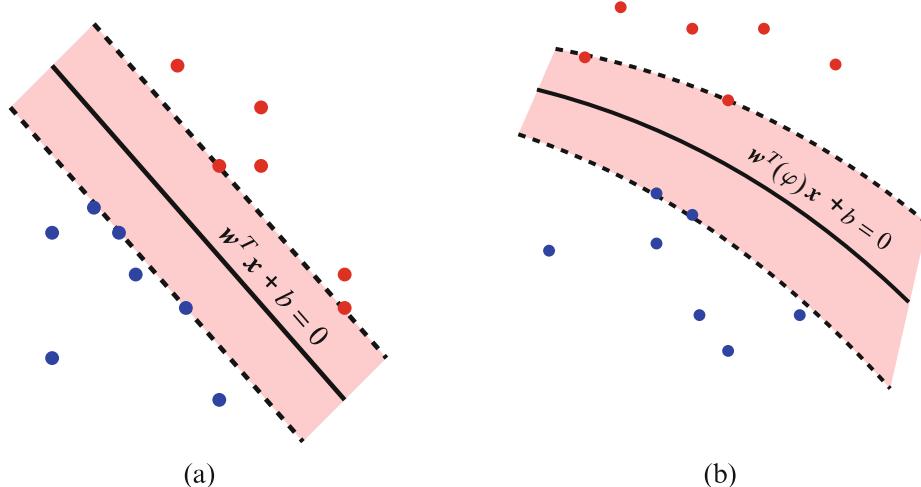

Fig. 2 The decision regions of SVM. (a) Linear SVM forms its separating hyperplane by maximizing the margins of data samples; (b) through the kernel trick, SVM is

This technique is commonly called the *kernel trick* [21]. In order for the kernel function to correspond to a valid inner product, Mercer’s theorem [22] requires φ that the kernel function is symmetric and positive definite. As depicted in Fig. 2b, the kernel trick enables SVM to form nonlinear decision boundaries. As the feature space is often of higher dimensionality compared to the ambient space, kernel SVM can be regarded as increasing the “width” of the classification model in order to enhance its capacity, instead of employing hierarchical architectures which follow the “depth” dimension.

In principle, any symmetric positive definite kernel function can be associated to an inner product. Therefore, the kernel generates a wide variation of functions within the feature space. Indeed, one of the main research thrusts in classical machine learning approaches is to find appropriate kernels that are suitable for specific applications. That said, kernel methods still have fundamental limitations. First, the kernel function is typically handcrafted instead of learned from data. Second, once the kernel machine is trained, the parameters are fixed, and it is not possible to adjust them at test phase. These drawbacks lead to fundamental limitations of expressivity of kernel-based learning models [21].

able to form nonlinear decision boundaries and classify samples that are not linearly separable

Modern Deep Learning Revolution

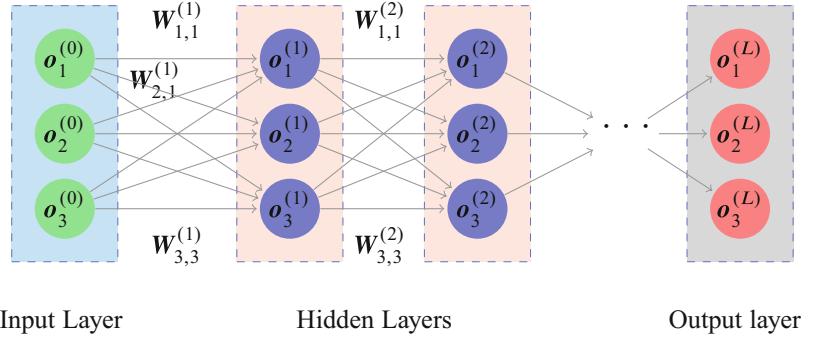

One of the main reasons for the success of deep learning is its significantly extended expressivity by learning hierarchical features through deep neural networks. Before we delve deep into this claim, we first provide a brief review of modern deep network architectures.

Architectures of Modern Deep Neural Networks

In early neural network research, the Multi-Layer Perceptrons (MLP) was a popular choice. A diagram illustration of this architecture is given in Fig. 3. As can be observed, this model can be regarded as the extension of a single layer perceptron shown in Fig. 1c, by introducing multiple hidden layers. This scheme can be viewed as adopting a hierarchical feature representation and increasing its “depth.”

Similar to perceptron, each neuron in MLP is fully connected to every neuron in the previous layer, except for the input layer. The layers are thus commonly called *fully connected* layers. Analytically, in the l -th layer, the

Fig. 3 Architecture of MLP. The input vector passes through a few hidden layers and reaches the output layer. Each layer comprises an affine transformation followed by a nonlinear activation function. We omit drawing the activation functions for brevity

relationship between the neurons $o_j^{(l)}$ and $o_i^{(l+1)}$ is expressed as

$$o_i^{(l+1)} = \sigma \left(\sum_j w_{ij}^{(l+1)} o_j^{(l)} + b_i^{(l+1)} \right) \quad (5)$$

where $W^{(l+1)}$ and $b^{(l+1)}$ are the *weights* and *biases*, respectively, and σ is a nonlinear *activation function*. Popular choices of activation functions include the logistic function and the hyperbolic tangent function. In recent years, they have been superseded by Rectified Linear Units (ReLU) [23] defined by

$$\text{ReLU}(x) = \max \{x, 0\}. \quad (6)$$

The W's and b's are generally trainable parameters that are learned from datasets, using back-propagation [24] for gradient computation.

Nowadays, MLPs are rarely seen in practical medical applications. The fully connected nature of MLPs contributes to a rapid increase in their parameters, making them difficult to train. To address this limitation, Fukushima et al. [25] designed a neural network by mimicking the visual nervous system [26]. The neuron connections are restricted to local neighbors only, and weights are shared across different spatial locations. The affine transformations then become convolutions (or correlations in a strict sense), and the resulting networks are commonly called Convolutional Neural Networks (CNN). A visual illustration of a CNN can be seen in Fig. 4. With significantly reduced parameter dimensionality, training deeper networks becomes much easier.

While CNNs were first applied to digit recognition, their translation invariance is a desirable

property for analyzing image features and are broadly applied in various medical problems, including medical image retrieval [27], segmentation [28], and reconstruction [4], to name a few. In reality, the architecture of CNN can be more sophisticated than illustrated in Fig. 4. There may be advanced types of convolutions, such as stridden convolutions which reduce spatial resolution [29], transposed convolutions which perform up-sampling [30], and more. There may also be other layers, such as pooling layers which perform spatial aggregation [29], batch normalization layers which stabilize training [31], and dropout layers which perform network assembling to reduce overfitting [32].

In some medical applications, the data may exhibit certain sequential forms. A concrete example is video processing, where video frames have temporal dependencies [33]. In such scenarios, Recurrent Neural Networks (RNN) [14] are a popular choice. RNNs explicitly model the sequential data dependence in different time steps in the sequence and scale well to sequences with varying lengths. A visual depiction of RNNs is provided in Fig. 5. Given the previous hidden state $s^{(l-1)}$ and input variable $x^{(l)}$, the next hidden state $s^{(l)}$ is computed as

$$s^{(l)} = \sigma_1 \left(W s^{(l-1)} + U x^{(l)} + b \right) \quad (7)$$

while the output variable $o^{(l)}$ is generated by

$$o^{(l)} = \sigma_2 \left(V s^{(l)} + b \right)$$

Here, U , V , W , and b are trainable network parameters and σ_1 and σ_2 are activation

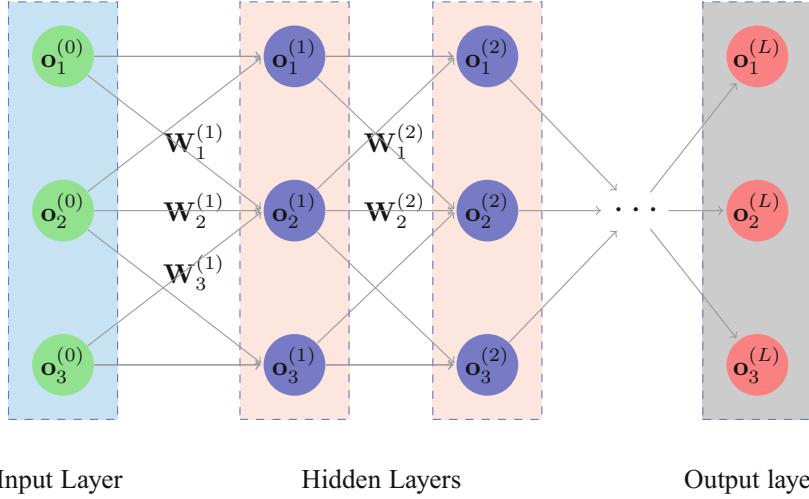

Fig. 4 Architecture of CNN. Instead of connecting all neurons in adjacent layers, CNN only connects each neuron to its spatial neighbors in the previous layer. Furthermore, the weights are shared across different spatial

locations. The output neurons in each layer can then be generated by convolving the input neurons with weights, followed by a nonlinear activation function. We omit drawing the activation functions for brevity

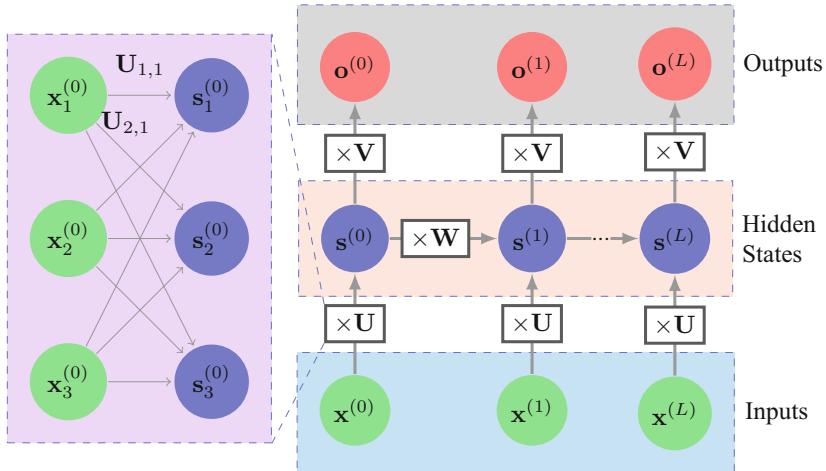

Fig. 5 Architecture of RNN. The inputs $\{x^{(t)}\}_1$ are fed into the network in a sequential order. The state variables $\{s^{(t)}\}_1$ evolve according to a linear transition model, thus capturing sequential dependencies. The outputs $\{o^{(t)}\}_1$ are

generated by combining the state variables and the inputs. Parameters U , V , and W are shared across different time steps

functions. We again omit the activation functions and biases in Fig. 5. In contrast to MLPs and CNNs where the layer operations are applied recursively in a hierarchical representation fashion, RNNs apply the recursive operations as the time step evolves. A distinctive property of RNNs is that the parameters U , V , and W are shared across all time steps, rather than varying from layer to layer. Training

RNNs can thus be difficult as the gradients of the parameters may either explode or vanish [34].

In practice, the state-space relation (7) suffers from a few limitations: It does not favor long-term dependencies which is crucial for modeling long sequences, and it brings about difficulties in training by introducing the gradient vanishing and exploding phenomena. To address these issues,

more advanced architectures have been suggested. Long-Short-Term-Memory [35] and Gated Recurrent Network [36] employ gating units and allow information to flow freely both in the forward pass and during back-propagation, which effectively mitigates the aforementioned limitations of vanilla RNN. Recently, self-attention mechanisms have become popular as an effective structure to reduce computational complexity and enable parallel computations, and better capture long-term dependencies [37]. However, the basic prototype remains the same: The input sequence is first encoded into state vectors, and then decoded into an output sequence. The decoder models the temporal dependencies between the current and previous timestamps, which can be regarded as an auto-regressive model.

Representation Power of Deep Neural Networks

In order to understand the superior representation power of modern deep neural networks over classical machine learning models, we will explore the decision regions of MLP by analyzing its per-layer mapping (5). Without loss of generality, we omit the bias term. For the nonlinear activation function σ , we adopt the ReLU function defined in (6), and let

$$o^{(l)} = \sigma(g^{(l)}) , \quad g^{(l)} := W^{(l)} o^{(l-1)}. \quad (8)$$

For an L -layer MLP, the neural network output for a given input x can be represented by

$$f_{\Theta}(x) := (\sigma \circ g^{(L)} \circ \sigma \circ g^{(L-1)} \dots \circ g^{(1)})(x) = B(x)^T x \quad (9)$$

where $0 = [W^{(1)} \dots W^{(L)}]$ and

$$B(x) = W^{(1)} \Lambda^{(1)}(x) W^{(2)} \Lambda^{(2)}(x) \dots \Lambda^{(L-1)}(x) W^{(L)} \quad (10)$$

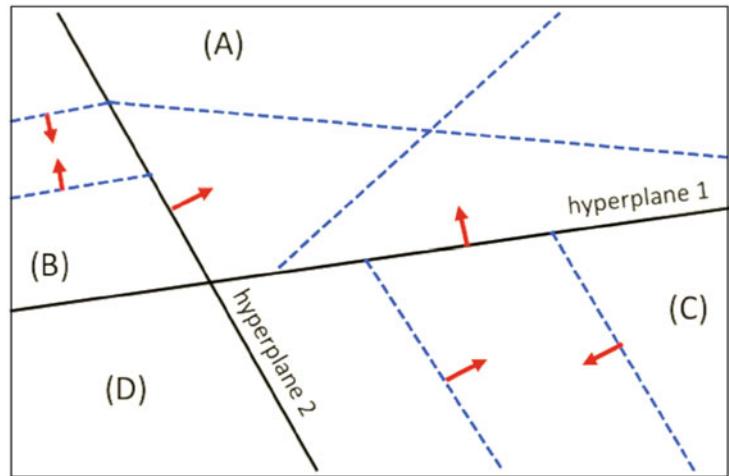

Here, $\Lambda^{(l)}(x)$ is a diagonal matrix with 0 and 1 elements indicating the ReLU activation patterns.

Note that the matrix $B(x)$ in (10) depends on the ReLU activation patterns $\Lambda^{(l)}, l = 1, \dots, L - 1$, which are determined by the input x . In fact, this ReLU activation-dependent diagonal matrix plays a key role in enabling inductive learning and emergence of hierarchical features. Specifically, the nonlinearity is applied after the linear operation, so the on-and-off activation pattern of each ReLU determines a binary partition of the feature space at each layer across the hyperplane that is determined by the weight matrix. Accordingly, in deep neural networks, the input space is partitioned into multiple nonoverlapping regions so that input images for each region share the same linear representation, but not across the partition. This implies that two different input images are automatically switched to two distinct linear representations that are different from each other depending on the partition as shown in Fig. 6 [38].

This leads to an important insight: Deep neural networks search for the distinct linear representation for each input. However, in contrast to classical optimization-based approaches, deep neural networks do not solve the optimization problem for a new input, rather they switch to different linear representations by changing the ReLU activation patterns. This is an important advance over the classical signal-processing approach.

To quantify the representation power of modern deep networks such as CNN, researchers are conducting rigorous theoretical analysis to extend the classical universal approximation theorem. Zhou et al. [39] prove that deep CNNs can approximate continuous functions supported on a compact space of any accuracy as long as its depth is sufficiently high. They also analyze the approximation property of deep CNNs over a family of functions in Sobolev space, which, loosely speaking, comprises smooth functions that are differentiable to a certain order. Similarly, Yarotsky et al. [19] analyze the approximation property of deep neural networks with ReLU activation functions on the Sobolev space. In addition, they provide upper and lower bounds of network complexity, i.e., the number of networks layers, weights, and neurons required to reach a given approximation error.

Fig. 6 Piecewise linear representation by a deep neural network

Other Properties of Deep Neural Networks

Splines, or piecewise polynomials, are another form of function approximators. It is therefore interesting to see how splines are connected to deep neural networks. Unser et al. [12] establish a conceptual connection between deep neural networks and piecewise linear functions, i.e., first-order uniform splines. Suppose we are given an MLP of the following form:

$$f\left(x; \left\{W^{(l)}, \sigma^{(l)}\right\}_l\right) := \left(\sigma^{(L)} \circ g^{(L)} \circ \sigma^{(L-1)} \circ g^{(L-1)} \dots \circ g^{(1)}\right)(x)$$

where $g^{(l)} := W^{(l)} o^{(l-1)}$ and $\sigma^{(l)}$'s are arbitrary nonlinear activation functions.

Given a collection of training samples $\{\mathbf{x}_m, \mathbf{y}_m\}_m$, we train the network f through the following optimization problem:

$$\begin{aligned} \min_{\{W^{(l)}, \sigma^{(l)}\}} & \sum_{m=1}^M \ell\left(y_m, f\left(x_m; \left\{W^{(l)}, \sigma^{(l)}\right\}_l\right)\right) \\ & + \lambda \mathcal{R}\left(\left\{W^{(l)}\right\}_l\right) + \mu \mathcal{T}\left(\left\{\sigma^{(l)}\right\}_l\right) s \mathcal{T} \end{aligned} \quad (11)$$

where ℓ is a general convex loss function, \mathcal{R} is some arbitrary convex regularization function over the network weights, \mathcal{T} is a regularization over $\sigma^{(l)}$'s which promotes sparsity of their derivatives, and λ and μ are positive regularization parameters. The authors prove that, in order for f to be an optimal solution to the problem (11), it

must be the case that $\sigma^{(l)}$'s are piecewise linear. In other words, the original infinite-dimensional optimization becomes finite-dimensional because $\sigma^{(l)}$ now adopts a parametric spline form.

Another intriguing property of deep neural networks is their amazing generalization capability, which seems mysterious from the perspective of classic machine learning. In particular, the number of trainable parameters in deep neural networks is often greater than the training data set, this situation being notorious for overfitting from the point of view of classical statistical learning theory. However, empirical results have shown that a deep neural network generalizes well in the testing phase, resulting in high performance for the unseen data.

This apparent contradiction has raised questions about the mathematical foundations of machine learning and their relevance to practitioners. Recently, the authors in [40, 41] have suggested how to reconcile classical understanding and modern practice in a unified framework. In classical machine learning theory, models with exceedingly high capacity are subject to overfitting and exhibit high test errors due to the fundamental bias-variance trade-off. However, the authors argue that, once the model capacity increases beyond a certain point called interpolation point, its performance starts improving in the test phase. Increasing the functional class capacity to the overparameterized area thus improves the generalization performance of the resulting

classifiers. The authors further justify their claim empirically through experiments.

Algorithm Unrolling: From Iterative Algorithms to Deep Networks

Parallel to the revolution of machine learning models, another thread of research constructs deep networks from iterative algorithms by mapping each iteration to a network layer. This line of research centers around an important technique called *algorithm unrolling*, which originated from Gregor et al.'s seminal technique on learnable sparse coding, called Learned Iterative Shrinkage and Thresholding Algorithm (LISTA) [7]. We first review this method and related theoretical findings. We then discuss general formulations of algorithm unrolling and provide practical examples.

Learned Iterative Shrinkage and Thresholding Algorithm

LISTA aims to approximately solve the *sparse coding* problem at a higher efficiency than iterative methods, by learning an unknown dictionary from real data. Specifically, given an observation vector $y \in \mathbb{R}^m$, we seek a vector $x \in \mathbb{R}^n$ such that $y \approx Wx$ and encourage as many coefficients in x to be zero (or small in magnitude) as possible [42]. A typical approach to achieve this is by solving an unconstrained convex minimization problem:

$$\min_{x \in \mathbb{R}^m} \frac{1}{2} \|y - Wx\|_2^2 + \lambda \|x\|_1, \quad (12)$$

where $\lambda > 0$ is a regularization parameter that controls the sparsity of the solution. A well-known class of methods for solving (12) are proximal methods such as Iterative Shrinkage and Thresholding Algorithm (ISTA) [43], which perform the following iterations:

$$x^{l=1=s_\lambda} \left\{ \left(I - \frac{1}{\mu} W^T W \right) x^1 + \frac{1}{\mu} W^T y \right\}, l = 0, 1, \dots \quad (13)$$

Here, $I \in \mathbb{R}^{n \times n}$ is the identity matrix, μ is a positive parameter that controls the iteration step size, $S\lambda(\cdot)$ is the soft-thresholding operator defined as for a scalar x , and $S\lambda(-)$ operates element-wise on vectors and matrices.

$$S\lambda(x) = \text{sign}(x) \max \{|x| - \lambda, 0\}, \quad (14)$$

The slow convergence rate of ISTA can be problematic in real-time applications. Furthermore, the matrix W may not be known exactly. In their seminal work, Gregor and Lecun [7] propose a highly efficient learning-based method that computes good approximations of optimal sparse codes in a fixed amount of time, with the help of W learned optimally from real data [7]. Specifically, iteration (13) can be recast into a single network layer as depicted in Fig. 7. This layer comprises a series of analytical operations (matrix-vector multiplication, summation, and soft-thresholding), which is of the same nature as a neural network. A diagram representation of one iteration step reveals its resemblance to a single network layer. Executing ISTA L times can be interpreted as cascading L such layers, which essentially forms an L -layer deep network. Note that, in the unrolled network, an implicit substitution of parameters has been made: $W_t = I - \frac{1}{\mu} W^T W$ and $W_e = \frac{1}{\mu} W^T$.

After unrolling ISTA into a network, named Learned ISTA (LISTA), the network is trained through back-propagation using real datasets to optimize the parameters W_b , W_e , and λ . Training is performed in a supervised manner, meaning that for every input vector $y^t \in \mathbb{R}$, $t = 1, \dots, T$, its corresponding sparse output $x^{*t} \in \mathbb{R}^n$, $t = 1, \dots, T$ is known. The sparse codes x^{*t} can be determined, for example, by executing ISTA when W is known. Feeding vector y^t into the network results in a predicted output $\tilde{x}^t(y^t; W_t, W_e, \lambda)$. The network-training loss function is formed by comparing the prediction with the known sparse output x^{*t} :

$$\ell(W_t, W_e, \lambda) = \frac{1}{T} \sum_{t=1}^T \| \tilde{x}^t(y^t; W_t, W_e, \lambda) - x^{*t} \|_2^2 \quad (15)$$

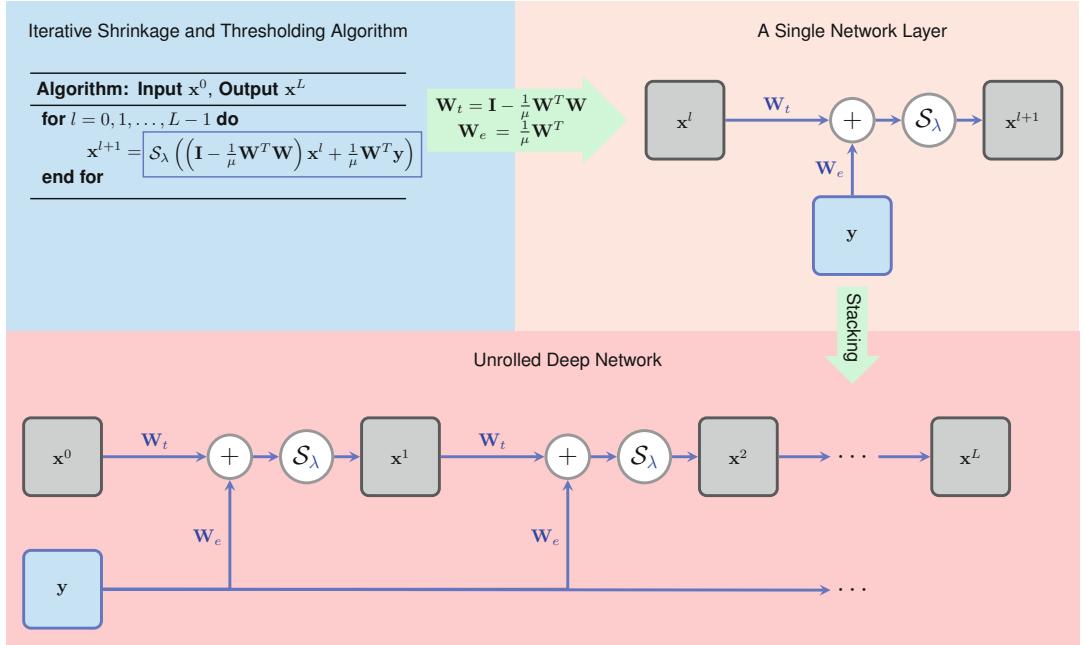

Fig. 7 Illustration of LISTA: One iteration of ISTA executes a linear and then a nonlinear operation and thus can be recast into a network layer; by stacking the layers, a deep network is subsequently

The network is trained through loss minimization, using popular gradient-based learning techniques such as stochastic gradient descent, to learn the unknown parameters W_b , W_e , and λ [24]. With optimized parameters, LISTA may achieve higher efficiency compared to ISTA. Indeed, it has been shown empirically that the number of layers L in (trained) LISTA can be an order of magnitude smaller than the number of iterations required for ISTA to achieve convergence corresponding to a new observed input, thus dramatically boosting the sparse coding efficiency [7]. Furthermore, when the dictionary W_t and W_e are unknown or hard to determine analytically, they can be learned from real datasets. In practice, W_t , W_e , and λ can be untied and vary in each layer.

In addition to empirically observed superior efficiency, researchers have recently confirmed the faster convergence speed of LISTA over ISTA by conducting rigorous theoretical analysis. In particular, recent studies reveal the convergence rate of LISTA, and relevant techniques,

trained using paired inputs and outputs by back-propagation to optimize the parameters W_e , W_t , and λ . The trainable parameters in the network are colored in blue

and characterize the optimality conditions. For instance, Xin et al. [44] study the unrolled Iterative Hard Thresholding (IHT) algorithm, which has been widely applied in various sparsity-constrained estimation problems. IHT largely resembles ISTA except that an ℓ^0 norm is employed instead of the ℓ^1 norm. The authors prove that, in order for the unrolled IHT network to recover a maximally sparse solution (i.e., a vector with minimal ℓ^0 norm), a weight coupling scheme must be satisfied; furthermore, under the weight-coupling constraint and certain additional Restricted Isometry Property (RIP) conditions [11], a linear convergence rate can be deduced. Compared to classical IHT, the learned version poses a much milder requirement on the RIP condition, meaning that the unrolled network is capable of recovering sparse signals from a much broader family of dictionaries.

Chen et al. [45] observe similar behaviors of the LISTA network with layer-specific parameters. They prove that, in order for LISTA to

recover the underlying sparse solutions, a similar weight-coupling constraint must be satisfied asymptotically. They further introduce a so-called support-selection scheme, which, together with weight coupling and a few other mild conditions, ensures linear convergence rate of the unrolled network. As a follow-up, Liu et al. [46] introduce certain mutual coherence conditions and analytically characterize optimal network parameters based on those conditions. Similar to the networks with trained weights, networks adopting analytic weights converge at a linear rate, which implies that analytic weights can be as efficient as learned weights. In addition, analytic weights are of much lower dimensionality compared to trained weights. However, determining the analytic weights can be a nontrivial task as they are solutions to another dedicated optimization problem.

Unrolling Generic Iterative Algorithms

Although the initial focus of Gregor et al.'s work [7] was on sparse coding techniques, the underlying principles could be easily generalized. More specifically, provided with a certain iterative algorithm, we can unroll it into a corresponding deep network, following the procedures depicted in Fig. 8 [8]. The first step is to identify the analytic

operations per iteration, which we represent abstractly as an h function, and the associated parameters, which we denote collectively as θ^l . The next task is to generalize the functional form of h into a more generic version \hat{h} , and correspondingly expand the parameters θ^l into an enlarged version $\hat{\theta}^l$ if necessary. For instance, in LISTA, the parameter W is substituted with W_t and W_e through the formula $W_t = I - \frac{1}{\mu} W^T W$ and $W_e = \frac{1}{\mu} W^T$. After this procedure, each iteration can be recast into a network layer in the same spirit as LISTA. By stacking the mapped layers together, we obtain a deep network with undetermined parameters and then obtain optimal parameters through end-to-end training using real-world datasets.

The exact approach to generalize h and θ^l 's toward \hat{h} and $\hat{\theta}^l$'s is largely case specific. An extreme scenario is to strictly follow the original functional forms and parameters, i.e., to take $h = \hat{h}$ and $\theta^l = \hat{\theta}^l, \forall l$. In this way, the trained network corresponds exactly to the original algorithm with finite truncation and optimal parameters. In addition to efficiency enhancement thanks to training [7], the unrolled networks can aid with estimating structured parameters such as filters [47] or dictionaries [48] which are hard to design either analytically or by handcrafting. Alternatively, some operations may be replaced with a stand-

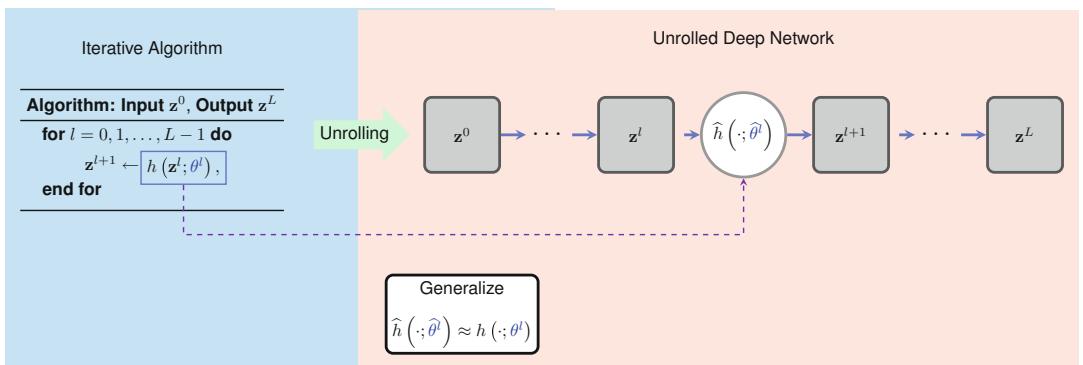

Fig. 8 Illustration of the general idea of algorithm unrolling: given an iterative algorithm, we map one iteration (described as the function h parametrized by $\theta^l, l = 0, \dots, L-1$) into a single network layer, and stack a finite number of layers to form a deep network. Feeding the data forward through an L -layer network is equivalent to

executing the iteration L times (finite truncation). The parameters $\theta^l, l = 0, \dots, L-1$ are learned from real datasets by training the network end-to-end to optimize the performance. They can either be shared across different layers or varying from layer to layer. The trainable parameters are colored in blue

alone deep neural network such as Convolutional Neural Network (CNN) or Recurrent Neural Network (RNN). For instance, in [49], the authors replace a proximal gradient update step with a CNN. In addition, the parameters can be layer specific instead of being shared across different layers. For instance, in [50], the authors plug in a CNN in each iteration step (layer) and allow the network parameters to differ. As it is, networks with shared parameters generally resemble RNN, while those with layer-specific parameters mimic CNN, especially when there are convolutional structures embedded in layer-wise operations. While custom modifications may potentially invalidate the convergence guarantees, they are practically beneficial and critical for performance improvement because the representation capacity of the network can be significantly extended.

In addition to performance and efficiency benefits, unrolled networks can potentially reduce the number of parameters and hence storage footprints. Conventional generic neural networks typically reuse essentially the same architectures across different domains and thus require a large amount of parameters to ensure their representation power. In contrast, unrolled networks generally carry significantly fewer parameters, as they implicitly transfer problem structures (domain knowledge) from iterative algorithms to unrolled networks, and their structures are more specifically tailored toward target applications. These benefits not only ensure higher efficiency, but also provide better generalizability especially under limited training schemes.

Unrolling techniques have been widely used in medical applications. An important imaging modality is ultrasound, which has the advantage of being a radiation-free approach. When used for blood flow depiction, one of the challenges is the fact that the tissue reflections tend to be much stronger than those of the blood, leading to strong clutter resulting from the tissue. Thus, an important task is to separate the tissue from the blood. Various filtering methods have been used in this context such as high-pass filtering, and filtering based on the singular value decomposition. Solomon et al. [51] suggest using a robust Principal Component Analysis (PCA) approach by

modeling the received ultrasound movie as a low-rank and sparse matrix where the tissue is low rank and the blood vessels are sparse. The robust PCA problem can be solved via a generalized version of ISTA, which is further unrolled into a deep network, called Convolutional rObust pRincipal cOmpoNent Analysis (CORONA). As the name suggests, they replace matrix multiplications with convolutional layers, effectively converting the network into a CNN-like architecture. Compared with state-of-the-art approaches, CORONA demonstrates vastly improved reconstruction quality and has much fewer parameters than the well-known ResNet [52].

In optical microscopy, a fundamental challenge is to enhance spatial resolution, which is limited by the physics of light. Solomon et al. [47] exploit the sparse nature of the fluorophores distribution and improve the spatial resolution via a sparsity-constrained estimation approach, called SPARSity based super-resolution COrrelation Microscopy (SPARCOM). Recently, Dardikman et al. [53] unroll SPARCOM into a deep network called Learned SPARCOM (LSPARCOM). The structure of the network resembles LISTA, except that they adopt a customized proximal operator. Experimental results show that LSPARCOM can obtain super-resolution images from a small number of high-emitter density frames without knowledge of the optical system, and has clear runtime advantages.

Interpretations of Deep Learning

We have so far covered the origin of deep learning and how it connects to classical machine learning models and traditional iterative algorithms. In this section, we investigate other ways to interpret deep neural networks, in addition to a methodological perspective. Specifically, we first take a biological perspective, where we illustrate how hierarchical features, an essential component of deep neural networks, are also commonly found in biological visual systems. We then switch to a geometric standpoint and contend that deep neural networks effectively capture the low-dimensional data manifolds.

Hierarchical Features in the Visual System

The visual system is a part of the central nervous system that enables organisms to detect and interpret information from visible light to create a representation of the environment. In pursuit of understanding the visual system, Hubel and Wiesel [54] found two classes of functional cells in the primary visual cortex: simple cells and complex cells. More specifically, simple cells at the primary visual cortex at the V1 L4 layer respond best to edge-like stimuli with a certain orientation, position, and phase within their relatively small receptive fields. They realized that such response of the simple cells could be obtained by pooling the activity of a small set of input cells with the same receptive field that is observed in Lateral Geniculate Nucleus (LGN) cells. This observation

has been extended to higher areas of the visual cortex to result in a class of object recognition models [3]. Specifically, there is a neuronal connection along this path, which forms a neuronal hierarchy such that neurons become sensitive to more complex inputs. An extreme form or surprising example of this information-processing hierarchy can be found in the discovery of the so-called “Jennifer Aniston Cell” [55], which identified a single neuron that is sensitive to a complex but specific concept or object.

A similar phenomenon can be observed in the convolution neural network, once it is properly trained. In particular, VGGNet [2] provides very intuitive information that is well correlated with the visual information processing in the brain. For example, Fig. 9 illustrates the input signal that maximizes the filter response at specific channels and layers of VGGNet [2]. Here, an input image

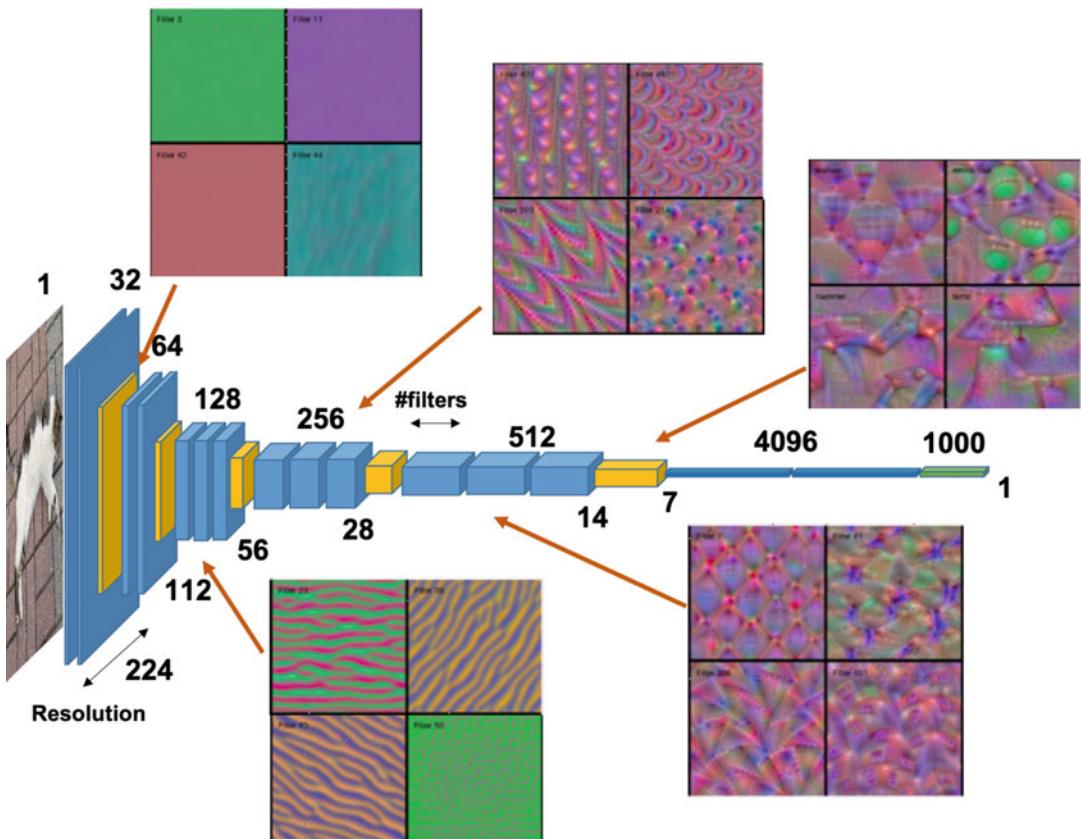

Fig. 9 Input images that maximize filter responses at specific channels and layers of VGGNet

that activates this filter most is displayed for specific channel and layer filters. This is similar to the Hubel and Wiesel experiments where they analyzed the input image that maximizes the neuronal activation. Specifically, at the earlier layers the input signal-maximizing filter response is composed of directional edges similar to the Hubel and Wiesel experiment. As we go deeper into the network, the filters build on each other and learn to code more complex patterns. Finally, in Fig. 9 the input images that maximize the response on the last softmax level in the specific classes correspond to the visualization of the input images that maximize the class categories. The emergence of the hierarchical feature from simple edges to the high-level concept is similar to visual information processing in the brain.

Geometric Understanding of Deep Neural Networks

The manifold structure of real-world data has been heavily exploited in classical machine learning techniques. Structured data are often assumed to lie on a manifold whose dimensionality is much lower than its ambient space. In particular, it has been long recognized that natural images lie on a low-dimensional manifold [34], and the key to

success in many machine learning tasks hinges on capturing the underlying manifold structure. As illustrated in Fig. 10, researchers have spent intensive efforts to model the bidirectional mapping between the data manifold and the underlying latent space. The forward mapping φ_α , commonly called the *encoder*, maps each data sample (such as an image) into a low-dimensional latent vector, while the inverse mapping $\varphi_{\alpha-1}$, commonly called *decoder*, generates a sample (such as an image) from a provided latent vector.

In classical machine learning, modeling the encoder and decoder has been a key topic in unsupervised learning. For instance, Principal Component Analysis (PCA), as a widely applied linear dimensionality reduction technique, estimates a linear encoder which projects the data onto a low-dimensional subspace, and a linear decoder which recovers the data approximately from this subspace. However, the subspace usually does not offer an accurate approximation when the data manifold is nonlinear. To improve the approximation accuracy, nonlinear dimensionality techniques have been developed by either modeling the topological relationship among inputs [56], or capturing their metric structure [57]. Nonetheless, these techniques lack a deep hierarchical decomposition of the mapping, φ_α , and hence do not faithfully model the data manifold.

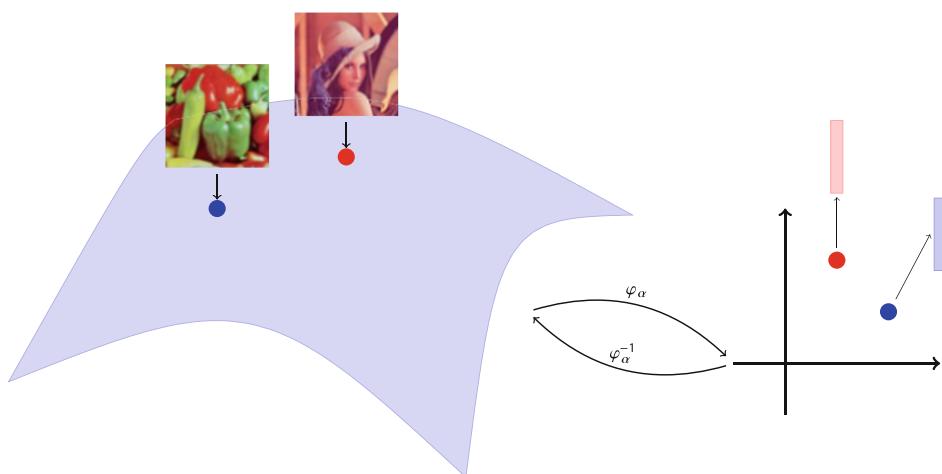

Fig. 10 Manifold structure of natural images. Many unsupervised learning techniques aim to discover the encoding mapping φ_α from the low-dimensional manifold

of natural images to its latent space. Generative models capture the inverse mapping, which generates natural image samples given the latent vectors

In recent years, deep unsupervised learning has achieved tremendous progress. The essence of many such techniques is how to learn the encoder/decoder using deep neural networks. Variational Auto Encoders (VAE) [58] jointly learns both the encoding mapping φ_α and the decoding mapping $\varphi_{\alpha-1}$ by integrating auto-encoder with variational Bayes. There are also generative models which effectively learn the mapping $\varphi_{\alpha-1}$ and generate high-quality data samples providing the latent vectors. Typical generative models include Generative Adversarial Networks (GAN) [59] and Normalizing Flows (NF) [60]. The deep hierarchical architecture ensures high capacity in modeling complicated functional mappings, which is the key to success for these approaches.

Summary and Outlook

In this chapter, we reviewed the historical developments of deep learning, following two main threads: the evolution from classical machine learning models to modern deep learning models, and the transition from traditional iterative algorithms to contemporary deep networks. We explained the limitations of traditional machine learning models and algorithms, in terms of expressivity, and discussed how deep learning successfully can overcome these limitations. We also reviewed recent theoretical breakthroughs which justify the superior representation power of deep networks and help in understanding their properties and behaviors.

Although there is already a rich body of research on the mathematical foundation of deep learning, we are still far from understanding the full mystery of deep learning. As it is, so far there is little knowledge on what weights are optimal in order for the networks to approximate a certain function. In addition, currently network training is largely empirical, and network performance largely relies on heuristics in training and hyperparameter tuning. In the context of medical imaging, developing more methods that are interpretable and robust is of key importance. With the many recent exciting advances and the many researchers entering this field, the next

decade will surely lead to further insights and methods in these directions.

Abstract

The urge of computerized, automatized medical decision making as well as having more efficient and organized health data records for financial and medical purposes have brought the necessity to introduce artificial intelligence algorithms to healthcare.

The first artificial intelligence applications in the medical field were to be seen in the introduction of Electronic Health Records followed by the development of Learning Health Systems and Clinical Decision Support systems.

Currently, the development and increment of artificial intelligence applications by larger and smaller entities from all over the world is in an ongoing process, following the market and its needs.

Introduction

Artificial intelligence in medicine (here abbreviated AIM) encompasses the use of complex algorithms and software to mimic or estimate the human cognition and analysis of complex medical and health-related data. The definition of AI in healthcare is fluidly changing with progress.

Before attempting to properly define AIM, it is noteworthy to remember the concept's "inborn autophagous definition problem." With this we refer to the fact that AIM users tend to forget the progress as they get used to them. For instance, the auto-interpretation of ECG, an early example of AIM, is often not referred to as AIM by many users. We humans very quickly adapt and take innovations for granted, hence as AIM advances, its end-users tend to think that it "can't be counted as AI," and start to expect something more advanced in the future.

It should be pointed out that, in this textbook on AIM, we refer to *narrow AI* (see definitions of AI in this section), i.e., very well-defined tasks, where AI can outperform humans, and not to *general AI*.

"**AI in medicine** refers to the use of **artificial intelligence** technology/automated processes in the diagnosis and treatment of patients who require care."

"**Artificial Intelligence in Medicine** mainly **uses** computer techniques to perform clinical diagnoses and suggest treatments. AI has the capability of detecting meaningful relationships

in a data set and has been widely **used** in many clinical situations to diagnose, treat, and predict the results."

Here are the early **examples of artificial intelligence in healthcare**.

- **Artificial Intelligence** assistance for general well-being purposes, such as fitness etc.
- **AI-assisted robotic surgery.**
- Clinical judgment or diagnosis.
- Precision medicine.
- Drug discovery (pharmacovigilance).
- Personalized healthcare.

At the core of these procedures is machine learning. Its algorithmic approach is designed to recognize behavioral patterns and from these produce deductive reasoning. Before algorithms can be used further, they must be tested and optimized, in their architectural design and hyperparameters, numerous times to diminish the error margins.

The algorithms in AI naturally differ in numerous ways from humans, but to just set out two main paradigms of major difference:

1. Algorithms read literally – they follow the goal set and obey explicitly according to algorithm layout.
2. Algorithms are scientifically black box objects (can only be viewed in terms of their inputs and outputs) – they can predict and generate data without having previous knowledge about causality and relationship between input and output data [1]. However, released in June 2020, an autoregressive deep learning model by OpenAI, called Generative Pre-trained Transformer 3 (GPT-3) has been created that is able to generate human-like text data by pre-analyses of huge amounts of input text data for their meaning and their relationship with other words [2].

The underlying algorithm in AIM must aim at the analysis of the logical connection between the seen clinical results in a patient and what treatment or prevention is deemed causative (Fig. 1). In other words, aiming at the relationship between

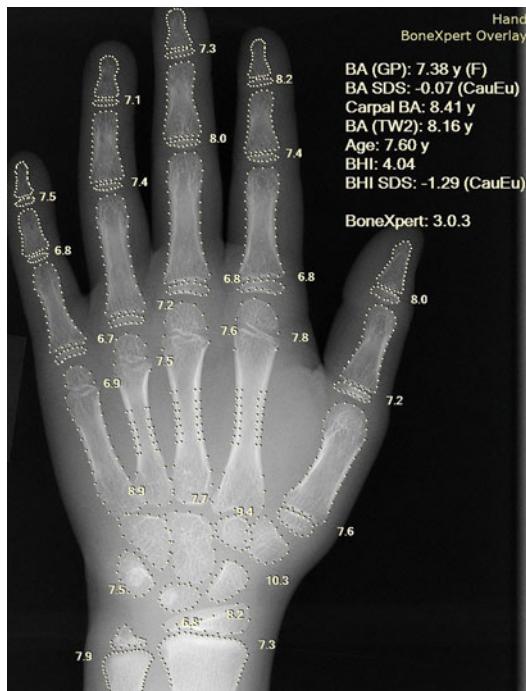

Fig. 1 A casual left-hand X-ray, with automated calculation of the relative bone age, using AIM powered software, BoneXpert. Taken on a Caucasian male 16.27 years old, with delayed puberty. The bone shows the age of 13.49 years by the Gruenlich and Pyle algorithm and 13.21 by the Tanner-Whitehouse algorithm. With these values a final adult height of $188.3+/-3.6$ cm can be approximated [3]

an input (treatment, prevention, procedure, diagnostics) and the output (the result in patient or diagnostic conclusion) [4].

With these above capabilities AI applications are used to ease, monitor, analyze, or respond to treatment regimens, personalized healthcare, diagnostic procedures and even the de novo development of pharmaceutical substances and chemical screening to find lead candidates. This former screening can be done much more efficiently than any chemist could obtain, and hence they could focus on more complex tasks, once released from mere routine work in labs.

Several of the world's leading clinics and healthcare systems such as Massachusetts General Hospital, the National Health Service in the UK, The Mayo Clinic, and the Memorial Sloan Kettering Cancer Centre have contributed to the

development of tools based on AI algorithms for their respective needs. In most cases the development has been possible through collaboration with large tech corporations, or with prominent newcomers such as the software companies Aysadi and Welltok [5].

With these AI-powered systems, hospitals can, apart from the obvious potential medical benefits to patients and their families, also economize with resources, improve the hospital working environment, and manage customer relations. It is necessary, in, e.g., a political context, to emphasize the monetary and purely operational benefits of AIM [6]. It is maybe a laconic conclusion that medical advantage per se will not be sufficient to convince hospital managements or politicians, but needless to say the use of predictive analysis in use by the latter, which optimize the resource usage and other factors [7].

The long-term AIM effects on the health industry, and outside of the medical realm, remain to this date held in obscurity. An in-depth investigatory survey was carried out among the economic faculty specialists, especially economists, with the query of if and how AI, in general, and robotics and machine learning applied into a broad multitude of civic fields, would affect long-term unemployment. The consensus turned out to be a considered net benefit – under the condition's productivity gains were (oddly or evenly) redistributed [8].

Short AIM History

It can be argued at what time period the historical exposé of AI per se should be commenced in a review, since the concept of AI is like a snake eating its own tail – as soon as something exists commonplace and is deemed too simplistic, it is continuously redefined as being outside of AI. A speedometer in a car is definitely far from it, lane keeping assistance used to be high tech, like also thermostats and other trivial items, today taken for granted.

The technique behind this early AI was based on 1960–1970s research, which also gave rise to the Dendral, then considered a problem solution software, i.e., a software designed to emulate the

decision of a human expert [9]. The fields in which this software operated was organic chemistry, leading up to the MYCIN system, which is often regarded a very important major step in the then nascent AIM applications [10, 11], and which evolved into more advanced systems in the 1980s, but the use was limited and never reached any breakthrough in clinical medicine. Maybe the explanation is one of the etiological components of the AI winter that followed [12].

During this following period up until the 1990s the microprocessor seriously emerged on the market, providing the hardware prerequisite for further AIM advancements. AIM must deal with the presence of imperfect input, given the nature of medical science in theory and the patient and doctor inputs, i.e., clinical case inputs, in practical medicine. To then build AIM on medical expertise, would rather lead to the emergence of medical diagnostic decision support systems [13].

To tackle the special criteria in healthcare, the AI programming grounds must be based on, e.g., artificial neural networks (e.g., in cardiology [14] or in oncology [15]), Bayesian networks [16], and the fuzzy set theory (in mathematics aka uncertain sets, of what are somewhat like sets, whose elements have merely degrees of unifying membership) [17]. It is archetypical that these advanced mathematics must be applied for the nature of healthcare AI, with its abundance of previous misinterprets, vaguely presented patient verbalization of symptoms and other patterns, which cannot be identified with AI lacking deeper components of machine learning.

Other vital components in the AIM evolution would hence include milestones, such as the computer hardware per se, augmenting the processor power, enabling rapid collections and handling [18]. The AIM evolution is parallel with the development of graphics processing units (GPUs), which have unlocked new possibilities in gaming, content creation, machine learning, and more. The GPU evolves as a massively parallel component to its close cousin, the central processing unit (CPU). The digitalization in itself of the health records, with widespread EHRs, lead to increased volumes to feed and test the AIM algorithms [19]. Simultaneously we saw the emergence of

robot-assisted surgery and its enhanced precision [20].

Furthermore, large genetic international projects, such as the HUGO project, with human genome mapping, have created an exponential growth of the genomic sequencing databases [21].

Likewise, the outburst of EHR usage worldwide has, as mentioned, led to an increase in the actual substrate to the AI algorithms, by providing big data for the algorithmic AIM foundation [22]. The growth of the EHR contents will likely not decrease with the introduction of computer vision [23] and natural language processing [24], both important AIM achievements, aiming at human perception mimicking.

In 2018 Google launched its DeepMind artificial intelligence system to work with recognition of eye diseases (Fig. 2). The DeepMind system made correct diagnoses 94.5% of the time in a trial with Moorfields Eye Hospital [25].

Examples of AI applications in Medicine that initially brought high benefits to the respective medical specialties are:

- *Preoperative imaging:* For instance, in orthopedic surgery to more exactly plan and evaluate the operative procedures, as well as in complex maxillofacial surgery of several categories, e.g., the probable aesthetic outcomes can be calculated with AIM [27].
- *Diagnostic imaging and radiology:* The most radical soon coming changes are probably to expect within this field [28]. Several radiological societies' [29] annual symposia regularly implement AIM imaging discussions and novel study presentations. In these discussions, the fears [30] and pros [31] of the game-changing AIM applications are ventilated with different weighting toward advantage or disadvantage to the specialty.

Likely all routine analysis of diagnostic imaging will be taken over by AIM. The radiologist will only focus on the complex cases, to check the outcomes, and discuss with colleagues and patients directly, the latter hitherto unusual. The AIM will likely aid in delivering, e.g., a more refined and detailed X-ray result – a human doctor

Fig. 2 Google DeepMind used in eye disease recognition [26]

does occasionally miss some minor X-rays details. For instance, a Stanford study programmed an AIM algorithm used in radiology, which could diagnose pneumonia in a given pulmonary site with a higher precision, i.e., higher mean F1 score (more accurate) than the human radiology specialists included in the study [32].

For several clinical safety reasons, the temporarily novel use of telemedicine with, e.g., mobile applications, and the steeply rising costs for society, tax payers, or insurances, have raised serious concerns among medical professionals and researchers alike – the diagnostic lack of precision via an app has been appalling and likewise the subsequent treatment, often without any decent follow-up. Several reviews in, e.g., the Scandinavian countries have raised serious concerns about the professionalism in using online applications to diagnose and treat patients in these manners, and moreover the spiral of costs have been beyond control at present (2018–2019). In theory the parallel rise of plausibly easing AIM online apps, or the powering of the mentioned doctor-online services with such AIM applications, could at least momentarily tilt this imbalance [33]. Such apps could facilitate patient monitoring at distance and improve the interface to boost the

intractability – a suggestible approach could be synchronized items of the internet of things, such as those wearable, inoperable, or in any other way with measurable assets. In any case, gadgets with continuous monitoring will surely be used by clinic or hospital bound healthcare, and could in real time update the EHRs with uninterrupted flow of data points. Such handling, especially combined with AIM, would notice even minute changes, maybe invisible to the human eye and habitude.

Electronic Health Records (EHRs) and AIM Interaction

EHRs were initially developed and implemented for billing purposes and workflow management; meanwhile few prototypes of EHRs were used for sharing information between physicians as well as between healthcare providers and organizations.

Due to poor design, user unfriendliness, combined with the presence of inefficient workflow ergonomics on healthcare structures, EHRs are deemed to cause burnout in healthcare professionals [34].

As a consequence of EHRs' mismanagement, many healthcare professionals are forced to spend

a large proportion of their working day instead as data input engineers.

However, they still represent the crucial step of digitalization of the healthcare industry and clinics, and their information spread. Some partial relief, or only input technique, could be the use of natural language processing (NLP) tools. Several other EHR automation projects are underway. The adequate integration of AIM into the EHRs will be a crucial step for diagnosis prediction, or mere decision support in the future (Fig. 3).

EHRs are treated in a full chapter in the second part of this book, and especially considering their central role in AIM, if synchronized wisely with clinical decision support systems (CDSSs), automated radiographic interpretations, and other relevant tools and applications.

Learning Health Systems

In deep connection with two of the most frequently used terms in this book, AIM and deep medicine, lie the vital concept of **Learning Health Systems** (LHS) [36].

Fig. 3 Electronic Health Record (EHR) [35]

All in all, the LHSs are EHRs where auto-educational and hence self-improving processes are fused with the medical record system [37] – i.e., on a daily working basis in a clinic the EHRs would become better the more you use them [38].

One early idealistic idea for LHSs was to let evidence-based medicine (EBM) become the scaffolding, or role model for under what conditions or rules the LHSs would be auto-learning [37].

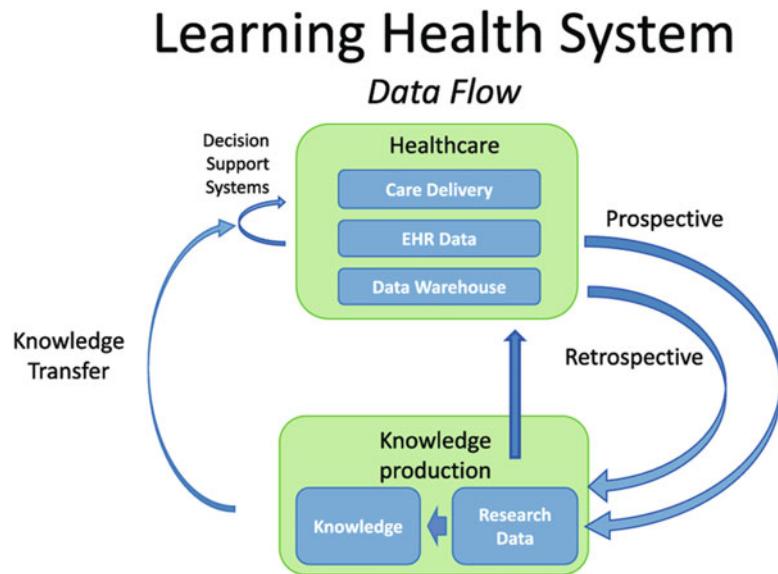

It is also worth noting that not all clinics, or very few, follow the sharpest EBM principles; rather their experience or clinical-practice-based evidence and the differences can be great [39].

The growing field of AI powered EHRs have led to the foundation of the medical journal *Learning Health Systems* from Wiley Publishers [38] (Fig. 4).

The LHS usage is based on the EHR and receives big data substrate from it [41].

The LHSs have, over the last few years, evolved into containing the following core components [42]:

Fig. 4 A model of Learning Health Systems [40]

1. The platform for possible research even at local clinic level
2. Personalized statistic modules for each individual patient
3. Synchronization of clinicians and researchers to handle the growing mass contents
4. Structured use of big data
5. Organization supporting subgroups and communities of patients or professionals
6. Intercommunication tools

The natural circuit of an LHS encompasses medical data collection from a large data set of patient cases, and a problem formulation derives [43]. This data compilation and its inputs is the fruit of work carried out by healthcare professionals. With correct use of computer programs this substrate can be analysed, the assembled science may affect future treatment practices, i.e. improved algorithms - and when the data quality per se is augmented, an auto-enhancing substrate cycle arise [45].

The following taxonomy can be used for LHS classification subtypes:

- (i) Assortment with cohort identification, that is, patients with similar patterns [46]

- (ii) Care optimization benchmarking – searching for better treatment options – with positive deviance [47]
- (iii) Suboptimal care identified with negative deviation [44]
- (iv) High-risk patient identification – with pattern recognition [48]
- (v) Identification of high-risk healthcare situations with suboptimal care (predictive risk)
- (vi) Algorithms applied to clinical patient data evolve into treatment recommendations
- (vii) The efficacy of different treatment regimens are compared and the best one identified
- (viii) With AI medical routine work, e.g., diagnostic image interpretation, automated
- (ix) Monitoring of epidemics, adverse effects, misconduct, or other clinical issues [49]

Some Industrial Cases – An Overview

There is power in numbers, and in big data big is better. When large companies merge their data synergistic effects arise, allowing access [50] and substrate feed for more precise AIM, more correctly adjusted machine learning algorithms

with higher generalization capabilities. The following is a short introductory overview of companies engaged in these processes – some of the business cases coming out of these and other companies, along with bright start-ups, will be further elaborated later.

A major AIM focus has hitherto been on Clinical Decision Support (CDS) systems, and with increased big data, the CDS precision rises [51].

Some major corporations with AIM projects are to this date:

- **Google:** *The DeepMind* platform is currently being used by the NHS (National Health Service) in the UK. The division of DeepMind Health contributes to the improvement of public healthcare with, for instance, a project on risk-detection for chronic diseases via the patients' mobile app, and another project with computer vision algorithms to detect tumor cells with the potential to evolve into cancer.
- **Intel:** Acquired *Lumiata*, which uses AI algorithms to help targeting risk patients and present different treatment alternatives [52].
- **IBM:** The broadly marketed *Watson* project, to be discussed further later. Now the branch *Watson Oncology* is under development together with the Cleveland Clinic and the Memorial Sloan Kettering Cancer Centre [53]. IBM has also worked tightly with Johnson & Johnson on scientific paper analysis, aiming to process this further into AI-directed drug innovation. CVS Health is looking into AI mobile apps for the personal management of chronic medical conditions [54].
- **Microsoft:** With Oregon Health & Science University (the Knight Cancer Institute), Microsoft has initiated the *Hanover Project* to analyze oncological research and thus obtain the optimal cancer treatments [55]. They are also involved in a project on programmable cells and image processing of tumor progression and prediction of tumoral cell action [56].

Some healthtech start-ups worth mentioning are focusing their work on automatizing prescribed medication administration and distribution,

as well as fully automatizing diabetic retinopathy and mammary gland tumor detection, including real-time user's data in EHRs from a multitude of sources and helping blind people to navigate using pathway recognition algorithms.

AIM Applications

There is of course a plethora, expanding at an exponential pace, of others developing many other AIM-driven applications, such as chatbots to schedule patient bookings in the EHRs and to optimize clinic resources, among the top-ten rated medical AI-driven applications with the so-called personal assistance at present [57].

AIM application entrepreneurs use several archetypical manners to gain and maintain market access and their common modus operandi has become an economic research field in itself, with revealing patterns. Their business plans fall into some typical categories and depend on the target user value (patient, healthcare providers, or other payer) and the mechanisms used to capture the value per se (to provide valuable information, the product of Big Data mining, or by connecting groups of interest, to mention a few) [58].

Government-owned companies and private entities launched mobile apps that directly or indirectly focus on healthcare using artificial intelligence approaches.

Among currently widespread important apps for mobiles can be mentioned the free *Symptomate* (from Infermedica), which is a symptom-checker on Google play. The same company has launched a personal AI voice guide, to respond to a person's symptoms, and made available for *Alexa* (Amazon), *Google Assistant*, and *Cortana* (Microsoft).

The instep level of the applications' output depends on whether aiming toward medical professionals or laypeople. In case of just common medical knowledge, there are at least three major, rapidly growing medical apps – Your MD, GP at Hand (from Babylon), and Ada Health. These pretend to mimic a medical consultation to some extent. The AIM fundamentals of these apps are in

all three only what the individual types in a previous medical history. The reports of his/her history in verbal form and voice recognition classifies the input and runs it against a database of all plausible diagnoses and adds suggested actions, respectively [59].

There are also a couple of apps monitoring delirium and anxiety levels in admitted patients, especially in seniors, impaired patients, or those suffering from different types of dementia. These patient subgroups are deemed to especially benefit from an adapted assisting interface, where extra attention is paid to act as if equipped with human EQ [60].

Economic studies [58] in 2019 have concluded medical expenditures will decrease when AI-powered diagnostics with more accurate prognosis allows planning of resources in a proper manner.

The healthcare effectiveness will likely increase significantly with the use of Virtual nursing assistants – the equivalences are already in use in AI-driven customer service of many companies. With voice recognition and AI, “synthetic nurses” over the phone could help patients with, e.g., mass-triage and other routine phone checks. Fears have been raised that AI would replace healthcare jobs, but most debaters agree AI would rather stay as a decision support system, streamline routine work, and allow healthcare persons to spend more time bedside and in human interaction.

Financial Aspects of AIM

The AI health market has shown explosive growth. Acquisitions of AI start-ups are rapidly increasing while the health AI market is set to register an explosive Compound Annual Growth Rate (CAGR) of 40% through 2021. The total AI health market size was estimated to \$600 M in 2014 and to \$6.6B in 2021 [61]. Artificial Intelligence (AI) in the healthcare market is expected to reach the market value of US\$ 26.6 billion by 2025, growing at a CAGR of 41% during the forecast period (2018–2025). AI in the healthcare market is estimated to grow with 15.7 trillion USD until 2030 [62].

AI is rapidly entering the healthcare sector, especially growing in areas such as radiology and cancer detection. It is already there in many places and is poised to take over many tasks. This in turn of course raises the question of whether it would replace nurses and physicians, and under which economic implications.

As will be shown, a wide range of AI finance experts deem these jobs are definitely not in danger. That said, both AI and machine learning are in a prime position to alter clinical workflows and the training of MDs. And with the market growing in the currently explosive manner, the AI healthcare implementation is inevitable [63].

The human hands and senses are definitely needed, not only for the data input of gigantic amounts of facts, but also to analyze, summarize, conclude, and holistically communicate also in a human emotional manner. And AIM is now utilized mostly to organize and aggregate data – looking for trends and patterns and making recommendations.

To make a brief expert review, the PeriGen CEO Matthew Sappern puts no stock in the theory that clinicians’ jobs are in jeopardy. Instead, he looks at AI more as an empowerment tool: “I think it does things that are really imperative that are not necessarily what nurses can do,” he says. “These tools are not so great where reasoning and empathy are required. You teach them to do something, and they will do it over and over and over again, period. They’re good tools to provide perspective, but it’s all about the provider or nurse who’s making sense of that information.”

He also believes that “AI can help nurses focus more on the actual job of nursing, and focus more on the abstract things that can truly impact patient care. And it has the potential to increase their confidence, as they can report back to the doctor with hard stats instead of vagaries. Used wisely and it can be a boon to fact-based clinical observation.”

The Chief Product Officer of Jvion, Dr John Showalter, does agree with Matthew Sappern. He stresses that it is the hype in itself about jeopardized jobs which is so scary, but that the reality is

not. He states that “there are absolutely places where AI is ready to go today, and then there’s a whole bunch of AI hype that’s really scary, so sorting out the AI that’s ready to help patients and the hype can be really difficult for leadership.”

As demonstrated in the article “AI doctors and engineers are coming – but they won’t be stealing high-skill jobs,” [64] the above quoted experts’ views are shared with a broad range of key opinion leaders (KOLs). The focus of this chapter is rather the plethora of empowering AI applications, which will only be beneficial to patients and clinicians.

Emerging Markets

Rapidly growing markets in formerly called developing nations could, as in many other areas, jump several steps in the technical evolution, and right into the age of AI in healthcare. The care becomes available worldwide in a new manner with new AI applications, coming in the new emerging markets, according to several investment agencies [65].

Radiological interpretations are mentioned several times in this book – here the use of AI empowers diagnostic imaging labs to diagnose many more cases with increased speed 24/7 all year round, and hence we can also use all expensive heavy equipment much more effectively. The AI can also help to train specialist radiologists and other medical professionals, but it is always estimated human intervention will be needed in more complex cases and where patient–doctor interaction is required.

For instance, in 2020, the CAD4TB was developed to detect tuberculosis-related abnormalities in ordinary anterior-posterior chest X-rays. This computer-aided detection software takes a single chest X-ray as its input, in the form of a DICOM image (Digital Imaging and Communications in Medicine, the standard for the communication and management of medical imaging information and related data), and produces several outputs: a quality assessment of

the input image, a heat map highlighting possible abnormal areas, and a score between 0 and 100 indicating the likelihood of the X-ray being abnormal and the subject on the X-ray being affected by tuberculosis. This deep learning-based software is now installed in over 150 mobile systems in 30 countries [66].

Today there are many successful applications of deep learning in medical imaging. An author review is presented recently [67].

The CAD4TB initiator Professor Bram van Ginneken, also co-pioneered the *Grand Challenge* platform for end-to-end development of machine learning solutions in biomedical imaging. It provides the public datasets and the software solutions of the winners of the international “challenge competitions.” At the time of the 1st edition of this book there are outcomes and data from 238 challenges [68].

In statistics and machine learning the concept of “ground truth” is a term relative to the knowledge of the truth in a specific question. To reach this level is the ideal [69]. The term is used in statistical models to strengthen or weaken research hypothesis. To gather objective data, which can be proven, is also called *ground truthing*. The term can be compared with *gold standard*, which in statistics and medicine refers to a standard test; a diagnostic test, or benchmark, which is deemed to be the best [70].

Before any broad implementation of AIM, it’s necessary to test and validate the algorithms behind the applications. Algorithmic biases, machine morals, and DNR (do not resuscitate) conditions, will be elaborated further in the AIM ethics chapter. These mentioned factors have lain behind the early regulatory attempts within the AIM fields [71]. In most countries there is currently almost no regulation legislation within the fields of AIM.

There have been a couple of legislatively preparatory workshops held in some countries during the last 3 years, 2016–2019. The new EU legislation GDPR does though indirectly affect the AI field, but in the EU, and elsewhere, the legislation that affects the AIM field, needs to undergo rapid adaptation to fit the ethical issues.

Clinical Decision Support Systems

The term **Clinical Decision Support System (CDSS)** includes some of the above, and is designed to assist the physician with medical decision support, in especially very complex clinical cases. In this way these systems may provide a bridge between clinical observations with medical science and have an impact, depending on background algorithms, to affect the ultimate choices made by medical doctors in a sharp medical setting. The CDSS is of central interest for the AIM construction (Fig. 5).

In the book the very authentic motif of EHR introductions were discussed, and in the same manner the actual need and effectiveness of a CDSS have been debated intensely. Could the usage of CDSSs and their effectiveness be considered evidence based?

When a CDSS and an EHR was combined, which was studied in a 2014 review, some benefits were maybe shown; however there was no effect on survival at all [73].

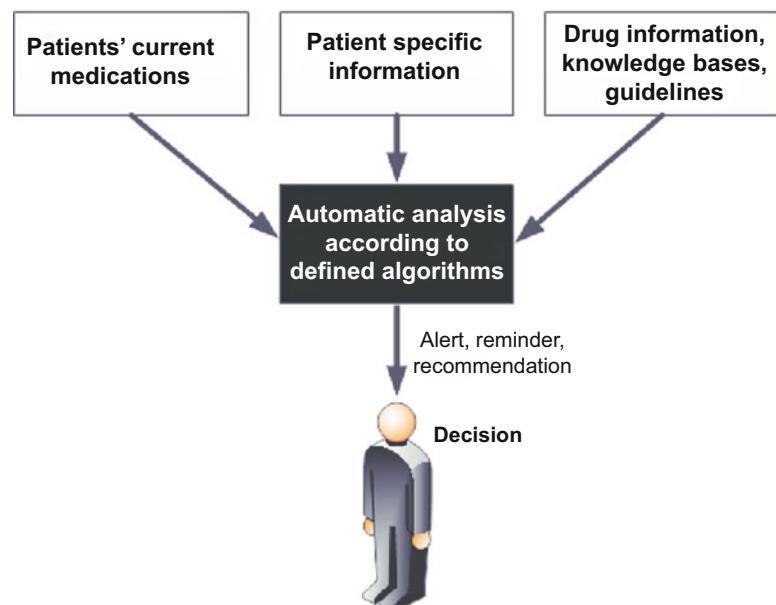

One of the earliest systematic reviews on this topic in 2005 writes in its conclusion that 64% of the included studies showed improvements of the medical care giver, and moreover patient outcomes were improved in 13% of the studies in

the review. Some key features that were connected to this improvement include e-alerts inside the system without the user having to actively switch on this interface. This study, which was published in the JAMA, also concluded that overall the studies (1973–2004), included in the review, show an improved methodological quality in the last part of this period and the number of studies also steeply increased in number [74].

The very same year another review in the BMJ showed a 68% improvement in its included body of studies. The authors did also pinpoint the key ingredients of a successful CDSS; it must be integrated in the clinical work altogether, be it electronic and not paper based, the decision support must be given on time, that is when the patient visits the clinic, in the very consultation and not before or after, and finally it must provide treatment recommendations [75].

The picture is however not unanimous. Less positive reviews have been published as well, e.g., in 2011, a study demonstrated that there was a significant discrepancy between the benefits which were stated about CDSSs and other similar applications, and what could actually be shown empirically. The lack of cost-effectiveness was not demonstrated as they concluded in their review. [76].

Fig. 5 Principle of a Clinical Decision Support System (CDSS) [72]

Until 2014 there was likely no real long-term evaluation to be found in peer-reviewed journals. But this year, probably the first 5-year follow-up of the CDSS's clinical effectiveness was published, and studied the long-term effect of computer-assisted decision support for antibiotic treatment in critically ill patients – as a prospective “before/after” cohort study [77]. It concluded that the implementation of computerized regional adapted guidelines for antibiotic therapy is paralleled with improved adherence. Even without further measures, adherence stayed high for a longer period and was paralleled by reduced antibiotic exposure. Improved guideline adherence was associated with reduced ICU mortality.

The CDSS is characterized by *medical knowledge management*, and uses more than two systematized patient data to generate support for medical decisions by the physician, hence it is also defined as an *active* knowledge management system – the more clinical items about a patient the better.

The very purpose of this system is to support the professional’s clinical decision – the clinician interacts with the system to analyze, diagnose, and choose a treatment. It is not a question of whether the system is taking the decision, rather producing a suggestion or reminder not to miss to consider a diagnosis in a complex case, i.e., the clinician uses both the system and own knowledge to evaluate the cases.

The CDSS group falls into two major categories: they are either based on knowledge or not. For instance, DDSS (Diagnosis Decision Support Systems) suggest diagnoses based on data input – the DDSS response may lead to the health professional’s decision to take further diagnostic action to ring in the correct diagnosis [78].

Case-Based Reasoning (CBR), where similar problems were dealt with previously, form the basis for the problem-solving process in a clinical case. A CBR system can be considered a subtype of CDSS [79].

In business, as in medicine, timing is everything. Even inside the medical support systems the actual is crucial. When CDSS (Clinical Decision Support Systems) are classified the timing factor is divided. Doctors would use the CDSS

when they see the patient in most cases. The CDSS are hence either of pre-, per- (or during), or post-diagnosis type. Again, they are either of a (1) preparatory nature, (2) of the presently filtering type to ease the preliminary diagnosis, or (3) To follow up a diagnosis in past tense or, to mine the big data derived from medical data and clinical knowledge and Evidence Based Medicine (EBM) manuals. The latter would be used for predictive purposes. In the debate, some drop radical ideas such as 80% of all clinical work would be done by these systems instead of by human doctors [80]. But the same author does though conclude that “*data-driven healthcare won’t replace physicians entirely, but it will help those receptive to technology perform their jobs better.*” Given the outcomes of the presented studies in this book, this statement seems too radical and deterministic. Of course, it depends on which specialty we are reasoning about, and what we define as “medical work” – pure routine work or reasoning requiring much higher human capabilities. The former debaters have stated, as previously quoted in this book, that “*if a specific doctor’s quality of medical routine work can be replaced by AIM, then it deserves to be replaced.*”

Others, like the editor of the Healthcare Finance Journal, argue that *while AI has already shown promise in automating certain tasks, it doesn’t seem likely that it will replace flesh-and-blood clinicians anytime soon* [63].

The NHS in the UK uses DDSS to triage the calling patients. With this setup an operator with no medical training can suggest a base level likely action to take – within limited variance though – the suggestions could be: *call 112, see your GP or wait*. No studies have been published on whether this system is better than just average common sense, at least none have been found in this review, but in 2018 a study of another decision support system was published, though with a vast difference – it involved medically trained nurses too – for triage management, with a hybrid approach using rule-based reasoning and fuzzy logic.

This study proposed a rule-based decision support system for triage classification and management. As said, a hybrid approach was applied to

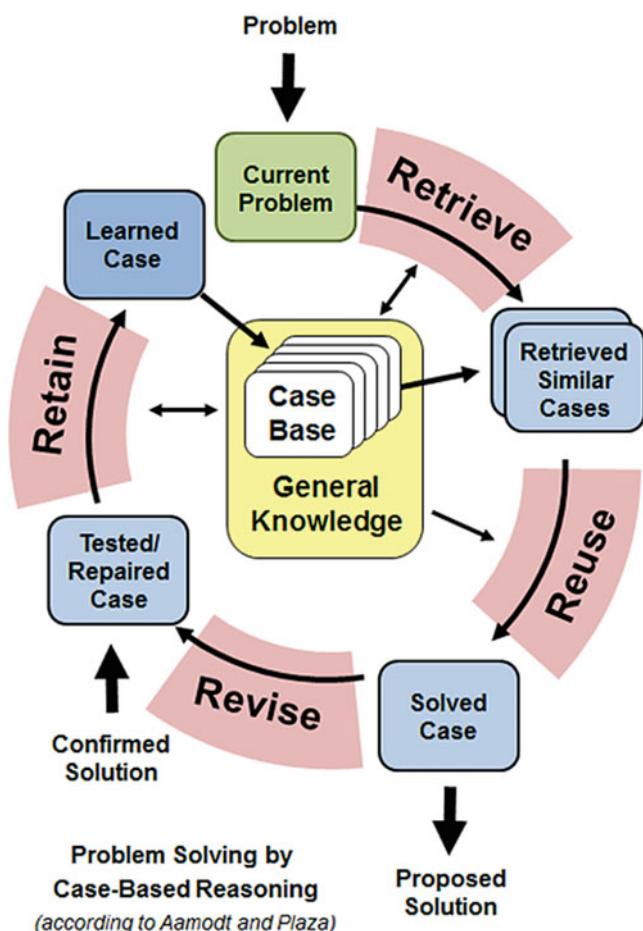

accurate classification of triage based on guideline. Reduction of classification errors and improvement of triage documentation were achieved [82]. It concluded the test-designed system was effective in determining the triage level of patients and it proved helpful for nurses as they made decisions, generated nursing diagnoses based on triage guidelines. The hybrid approach could then reduce triage misdiagnosis in a highly accurate manner and improve the triage outcomes (Fig. 6).

As mentioned above the CDSSs are classified into either having a founding knowledge database or not. If possessing a knowledge base, then the CDSS also contains an *inference engine* and a *communication tool*. In AIM, the inference engine is the part of the system that applies the logical rules governing the information deduction from

the knowledge base. A simple example of such determining law is the type called “IF-THEN rules.” This type of rule is found in action in many EHRs in the form of multidrug interaction checkers – IF drug X plus drug Y, THEN produce alert Z into the user interface of the program. The same core structure has been programmed into the source code of the online WebMD’s multidrug interaction checker, which can handle interactions up to several degrees of complexity, albeit interactions of large numbers of different pharmaceutical medications have not always been studied in detail.

Of course it is of value when the users can update the interaction checker with new drugs or when interactions have been found less valid in further research, or when we’d like to switch off an alert because it is not relevant to the patient –

Fig.6 Basic principle of Case-Based Reasoning (CBR) [81]

compare with the auto-correction in the spell-check function – sometimes the relevant word doesn't exist in the dictionary of the base data collection. Editing and receiving output are both parts of the communication mechanism of the system [78].

To be able to communicate with the computer in a relevant and computable manner, we need to use specific expression languages, e.g., CQL (Clinical Quality Language) or the GELLO. With these, one can set the frames for the system. For instance, we can use these languages to suggest treatment or diagnostic actions, e.g., if a patient has a certain blood pressure of X and Y then the patient should see a doctor within Z weeks. Or if serum potassium level is within a certain range, then a certain action must be taken, etc. The Clinical Quality Language (CQL) is a Health Level Seven International (HL7) authoring language standard that's intended to be human readable. HL7 is a standards-developing organization that provides a framework and standards for the exchange, integration, sharing, and retrieval of electronic health information that supports clinical practice and the management, delivery, and evaluation of health services [83].

The other group of CDSSs is not rule-based, and uses an AI-form termed *machine learning*, which does not require a rule base, since this group's AI structure gets the computer to *learn* from the base of past events (the knowledge base), and/or recognize clinical patterns [84].

The above structure means there is no need for the rules or feedback from medical professionals, as mentioned in the first CDSS group. This latter group is called "black boxes" and act independently, but can of course, evidently, neither reason nor explain its conclusions. This group is only used for cold suggestions and in the vast majority of clinical cases only used after a diagnosis or for pattern recognition and alert human doctors to focus in a certain area, which may require further consideration or research.

The machine learning-based systems, mostly used in clinical decision support systems, include the following two major groups of *support vector* networks, *genetic algorithms* and the use of synthetic or *artificial neural networks* [85].

- **Genetic Algorithms** (GA) contain processes that are evolutionary in their simplified nature – they use a *selection of the fittest solution* [86] to produce the optimal CDSS outcome. As a comparison, in evolutionary cellular biology, the GAs can be understood as a *metaheuristic* that delivers a sufficiently good solution inspired by the process of natural selection that belongs to the larger class of evolutionary algorithms (EA). In computer science, the selection algorithm chooses among randomly occurring problem solutions. The solution picked may be altered, i.e., mutated or recombined, and can be run through the processes again, repetitively, and be refined ultimately. GAs are as mentioned "black boxes," with the goal to extract knowledge from clinical patient data sets [87].
- Artificial Neural Networks (ANN) remind in structure of the group above, but use nodes and weighted inter-node connections and hence discover and analyze the relationship symptom-diagnosis, extracted from clinical patient data sets [78].

The term metaheuristic may require some explanation – it is used in mathematics and computer science and means a procedure (or heuristic) of the higher echelon, designated to produce or identify a search algorithm (heuristic), which can come up with the best solution (the key issue in an optimization problem) [88]. This is relevant especially when the input substrate is imperfect or incomplete, such as in a medical record – so in these circumstances the metaheuristics, which may now be easily understood as general algorithmic frameworks, often nature-inspired, are designed to solve complex optimization problems [89], here within medical data.

At the core of what needs to be solved lies the optimization problem, i.e., to find not only a treatment derived from patient data, but the best treatment, and more so, continuously optimize this superlative over and over. Again, to pick the best solution out of several feasible solutions. Optimization problems are of two natures – the continuous and the discrete – depending on which variables are involved [90].

Yet following guidelines given by clinical decision support systems, more than 30% of patients still do not receive the correct treatment. And in the AIM in EBM (Evidence Based Medicine) we learn that only 60% of patients receive the evidence-based treatment, 30% receive, as just said, an incorrect one, and 10% a directly harmful regimen.

To increase the chances of treating the patients in the best way possible, multimodal clinical decision support systems have been introduced, combining guidelines given by different sources, i.e., clinical practitioners' experience with results [98] given by data mining analysis.

Conclusion

The whole healthcare field largely benefits from the usage of Artificial intelligence, and future applications are expected to determine the efficiency and quality of their services.

AI in medicine will enter literally all areas of healthcare, and in various forms such as image and pattern recognition, decision support systems, robots, applications, drug development, health records, clinical research, medical imaging, etc.

Companies – from start-ups to big-techs – are steeply increasing their investments in medical AI. Profits and applications are fueling new AI tools and applications into new innovative projects, with the goals increased in public and personal healthcare. AI in medicine will boost world economy with 15 trillion USD during the coming 10-year period.

In all medical specialties the effect of AI will be very tangible, and currently the advancements have reached different levels of maturity, and require a plethora of interpretations and approaches to solve their specific needs, which will be elaborated in part III.

In the remainder of part II of this textbook we present the general aspects in common for all areas of AIM – the “lessons for all doctors.” In part III we systematically present AIM in all medical specialties and subspecialties.

Abstract

To better understand the mechanisms of the seemingly “black box” of AI and deep learning, we take a closer look at its internal processes. We will discuss the power of contextual processing, study insights from the human visual system, and study in some detail how different deep convolutional neural networks work. We do this with an engineering view, for radiologists, in an intuitive way.

Introduction

The revolution in Artificial Intelligence in Medicine has surprised us, fascinated us, sometimes frightened us, and mostly benefitted us. Reports on spectacular performance abound, in many different application areas. Virtually all medical imaging and medical image analysis conferences (such as RSNA, ECR, and MICCAI) are now dominated by deep learning applications and papers, and new start-ups announce themselves every day.

This chapter gives a compact overview of the basic principles of AI in Medicine, specifically on deep neural nets, i.e., networks inspired on the adaptive synaptic connections in the brain. This chapter focuses in particular on an intuitive understanding of the technology and functionality inside such a network, with an emphasis on image understanding, to make the system less a magical trick. A section explaining the general pipeline and how the system actually learns is included, as well as a geometric model and how data are optimally represented. As modern neuroscience sees the same revolution, a section is dedicated to the relation with (and lessons from) findings in the human visual system.

The performance (anno 2020) of AI in different application areas is not the same:

- *Recognition* is handled very well: i.e., learning from large datasets to detect very subtle features, often outperforming humans
- *Reconstruction* to some extent: i.e., generating new data, such as CT data from MRI, generating new texts
- *Reasoning* only marginally: i.e., solving complex puzzles, making full differential diagnoses.

In general, much of the internal workings of deep neural nets is not known and they are still largely considered a “black box,” despite huge efforts to work on its explainability [1]. The jargon language of developing and coding deep learning networks is not easy to understand by other fields, such as medicine, biology, and neuroscience. Mechanisms for the distribution of (often open source) AI computer code such as the GitHub repository is very popular, as can be seen by their numbers: as of January 2020, GitHub has over 40 million users and more than 190 million repositories (including at least 28 million public repositories), making it the largest host of software source code in the world. It is promising to see how more and more AI specialists and medical doctors are working in teams together on many different dedicated AI applications.

This chapter is organized as follows: In section “[The Development of the AI Framework](#)” we describe history of AI and neural networks, and the winning configuration: *deep convolutional neural networks* (CNNs). The internal connectivity structure, training, and inference (actual use) are globally explained in section “[How Does a Convolutional Neural Network Work?](#).” section “[Representation Learning](#)” will discuss the mechanism of how learning can be modeled, with a bit of mathematics. Grasping some mathematics may make these systems less enigmatic. The different types of neural nets, methods of learning, and how the performance is measured is discussed in section “[Network Topologies, Types of Learning and Performance Measures](#).” In section “[Deep Neural Network Application Domains](#)” several application areas are discussed, with examples of the exploited network topology, and the current state-of-the-art in performance. The last section “[Relation to the Visual System](#)” focuses on human visual perception and its relation to these deep CNNs. Modern brain research has seen the same revolution, and may inspire not only a possible explainability but also lead to substantial future increases in speed and performance. The chapter is concluded with a discussion and a section with “Lessons for All Doctors.”

Every italic term can be looked up in Wikipedia for further study.

The Development of the AI Framework

Neural nets have been around for decades, but their performance was disappointing. One early type of AI were so-called expert systems, best explained with a famous example. In the 1980s the Campbell Soup factories in the USA exploited highly complicated sterilizers, for thousands of cans of soup. Not many people knew the intricacies, but one exceptional expert in troubleshooting named Aldo Cimino, who flew from plant to plant, retired. They decided to “can” all his knowledge in hundreds of rules. As this set of rules kept growing, it soon became unmanageable, and it failed. The first neural networks, also developed in those days, were limited to three layers (input layer, hidden layer, and output layer), and also disappointed in performance. It led to the so-called AI winter in the 1990s.

The last decade has seen the application of *pattern recognition* [2, 3], where large sets of hand-crafted filters (often up to hundreds) are designed to extract features from images. Typically sets of ground-truth images are processed in a pipeline, concatenating stages for preprocessing, segmentation, feature extraction, and feature selection. From these features then a high-dimensional *feature space* is constructed, in which apparent clusters are optimally separated by so-called *classifiers*. Famous classifiers are *support vector machines*, *random forest classifiers*, and *Bayesian classifiers*. There are dozens more. Despite the many sophisticated filter banks and clever classifiers, the performance was never as good as human experts, and one of the problems was that the hand-crafted design of features was either never complete or too redundant.

The breakthrough came with the realization that the features should be *learned* from the data. This turned out to be best done with neural nets with many more layers. The greater depth gives these network the name “deep.” The universal toy example for any AI student entering the field is the famous example of the neural network “LeNet.” This network, with only 7 layers, gave until then unprecedented performance in classifying images of handwritten digits. It was published by Yann LeCun et al. in a landmark paper [4]. The “MNIST” dataset of written letters (60,000

images of 28×28 pixels) is so small that the network can be handled and trained on any computer. In those days, the famous *ImageNet Large Scale Visual Recognition Challenge (ILSVRC)* was held annually, a competition to classify 1.4 million images into 1000 classes [5]. In 2012 Alex Krizhevsky et al. [6] (85000 citations) beat the competition with a staggering 12% better performance by introducing “AlexNet” with more convolutional layers (explained in section “[How Does a Convolutional Neural Network Work?](#)”), in essence an extended version of the “LeNet” network.

Several recent overviews discuss the history, applications, and future perspectives of AI in medicine well [7–11]. With today’s speed of distributing information, in general three levels of publishing new work can be seen: (a) the classical publications in peer reviewed journals and conferences. This has a relatively long turn-around time, from months to sometimes even 1.5 years. (b) Much faster are ArXiv (for computer science), BioRxiv (for the biosciences), and MedRxiv (for the health sciences), where papers are “published” (and the work claimed) during the review process. This has become popular, especially for the computer- and AI-sciences (ArXiv distributes close to 1.8 million articles). A third level is popularization and getting broad attention through Medium.com, an open publishing forum with many categories and many easy-to-read tutorial contributions on AI (see, e.g., towardsdatascience.com).

In medical image analysis, *grand challenges* have become increasingly popular, and data from hundreds of such competitions (with public datasets, publications in high ranking journals and open source software) are available (e.g., [12]). Recently, the quality control process of these influential studies have received renewed attention [13].

How Does a Convolutional Neural Network Work?

The simplest deep CNN is a neural feed-forward network, a chain with many layers. The number of layers can vary over a wide range depending on the application, e.g., from 7 layers (a “shallow”

network) up to 150 layers (a “very deep” network), or even more.

Figure 1 shows this fundamental CNN layered structure. To the left is the *input layer*, where data are fed into the network. The *output layer* is on the right. The input could be for example an input image, a video, a document, or a series of instrument measurements. The many blue lines are the *weights*, the “synaptic connections,” which are not known in the beginning, and are to be learned. In very deep neural nets, the number of weights can run into the hundreds of millions. The output could be, for example, a classification, or a translation, a modified image, etc. In section “[Network Topologies, Types of Learning and Performance Measures](#)” an overview is given of the many application areas where CNNs have been successful.

Many good introductory and overview texts are available [14–16], as well as many tutorials and downloadable implementations. In this section the main principles of a CNN are summarized, and a concise explanation is given of some

specific terminology that accompanies deep learning, for medical experts as primarily users of this technology.

Convolution and Cross-Correlation

Why is the network called “convolutional”? To understand the notion of *convolution*, it is instructive to study classical *template matching* in images. Suppose one needs to find the positions of the letters “a” and “e” in a piece of text given as an digital image (see Fig. 2).

The “template” is the small image that forms the letter “a” (e.g., 10×10 pixels), which is shifted row-by-row over the pixels of the much larger text image. Every time the template is on top of an “a” in the text, the *cross-correlation* will be maximal: *cross-correlation* is defined as the summed product of every pixel in the template and the underlying pixels of the text image. At other non-matching locations, the value of the correlation will be lower. *Convolution* is the same as

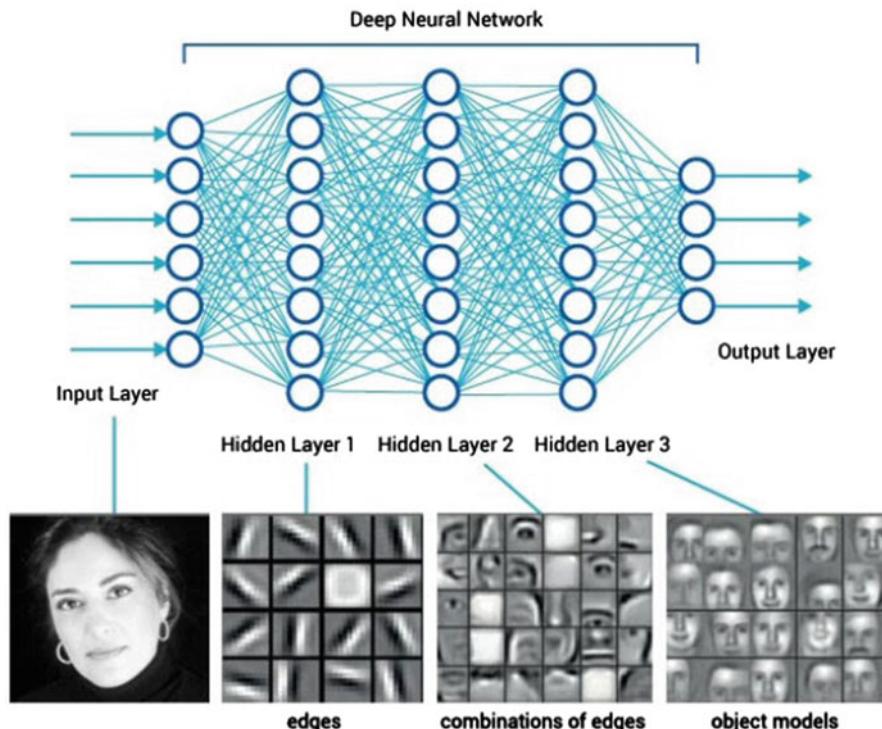

Fig. 1 A deep neural network

Fig. 2 Template matching
The templates (= filters = kernels) of an “a” and “e” (enlarged here for visibility) are shifted row by row over the discrete input image (top). At a match with the underlying image, a high cross-correlation is found. The template matches are shown in the output image as circles (bottom)

correlation, except that the template is then mirrored (in both the x- and the y-direction). Because convolution has specific mathematical advantages, convolution is the standard for neural nets.

The step size of the filter over the image is called the *stride*. Typically the stride = 1, but it can be larger, e.g., stepping every fourth pixel exploits a stride = 4.

Other names for “template” are “filter” or “kernel,” all denoting the same thing, so convolution is another name for “filtering.”

In the CNN the convolutional layers do convolutions. In the first layer the filters are very simple, and detect simple features (like the “a”), i.e., local edges and small line segments.

pixel. This image is convolved in the first convolutional layer with filters (kernels) of $11 \times 11 \times 3$ pixels. Typically the filters are square and have the same number of colors (in this case 3: RGB) as the image. Because the stride = 4, there are 55 steps of the filter over the image (in both the x- and y-direction), so the convolved output image of the first layer has a size of 55×55 pixels. A convolution is almost always followed by a threshold operation, whereby negative values are set to zero with a so-called *rectifying linear unit* filter (ReLU).

The second layer: because there are 48 different filters applied in the first layer, we get a stack of 48 convolved and thresholded images. This stack is a “multi-dimensional matrix” or *tensor* of size $55 \times 55 \times 48$ (actually the authors split the work over two graphical processing units (GPUs), therefore a second pipeline is partially seen above the first one in Fig. 3, so the total number of filters applied to the first layer is 96, but this is not relevant now). To prevent a true explosion of data, some form of data-reduction is done: *max pooling*: only the datapoints with the largest values are kept over a small shifting area, in this case by taking the maximum value in a shifting $3 \times 3 \times 48$ cube with stride = 2. Often this is done explicitly in a separate layer, the *pooling layer*, but here integrated in the second layer.

This output of the pooling layer is then fed into the next convolutional layer, where the data is convolved with 128 kernels of size 5×5 with stride = 2, so the size of the output tensor is

Forward Pass

The input image to the left is a color image with a size of 224×224 pixels with 3 colors (RGB) per

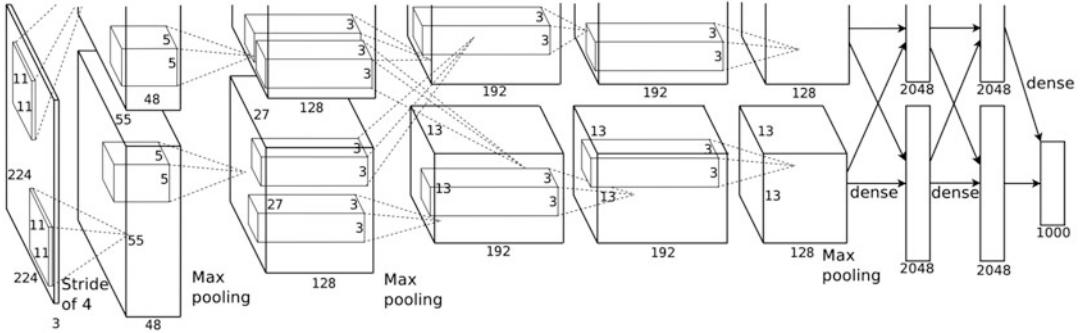

Fig. 3 AlexNet. (Figure from [6])

$27 \times 27 \times 128$. Max pooling again, and convolution with 192 filters of size 3×3 , etc. The images get progressively smaller, and contain less detail but more global information.

The final stage contains the so-called *fully connected layers*. They function as a *classifier*, in this example network to get 1000 neurons (classes) as output. They do this by matrix multiplication with a rectangular matrix, to change the dimensionality. In this way the final tensor of $13 \times 13 \times 128$ is converted into a vector of 1000×1 , which gives the probabilities of the 1000 output classes.

Two more layers are needed: a dedicated layer at the input and a dedicated layer at the output. Because a neuron in the computer can be only be fed with numbers, the input has to be converted to numbers when they are not-numbers, e.g., characters or classes. Such a converter is called an *encoder*. An encoder does any preprocessing, and may include resizing of input images, proper alignment, color mapping, etc. For the output the same holds: output numbers have to be converted to, e.g., classes (“17” = class “cat”). The converter at the end is called the *decoder*. When the output has to be interpreted as a series of probabilities which together sum up to 1, a special *softmax function* is applied in the decoder.

Backward Pass

But how does a neural network learn? After the forward pass follows the backward pass. Learning happens in the backward pass with a process called *error back-propagation*. Initially, all the weights in the network are unknown, and

initialized as random numbers between 0 and 1. They are the blue lines in Fig. 1. When an input image is processed in the forward pass of this random network, it gives a random output, which is likely to be wrong. The weights are then adjusted from the last layer onwards to the first, until the error (or *loss function*) is minimum. So when, for example, a digit recognizing CNN outputs a “5” when the input was a picture of a hand-written 6, the error is +1. When the output is a set of probabilities, an often used *loss function* to estimate the error is the *cross entropy function*. Then the process repeats itself: the next training image is presented and processed in the forward pass, and the weights adjusted in the backward pass. And so on with enormous amounts of training images, until the overall error is sufficiently small. This is the *training process*.

This adjustment by backpropagation is a lot of work for the often millions of weights. The process is well understood. Mathematical optimization techniques like *gradient descent* (to find the minimum, always head downwards) and the use of special hardware such as graphical processing units (GPUs, game cards) have made this finally feasible. During the training, the performance of the net is constantly monitored by frequent tests (e.g., every 100 or every 1000 passes) by doing forward passes with dedicated *validation data with ground truth*. Of course these validation data should be different from the training data.

When the training is finished, the final performance of the system is established as an unbiased evaluation with a *test set with ground truth*.

Often it is difficult to get enough training data. It turns out that small variations of the input image (small rotations, warpings, zoomings, shifts, contrast changes, etc.) can act as “new” unseen input images. This process is called *data augmentation*.

The shaping process of the weights during the training can be visualized. Andrej Karpathy, then PhD student at Stanford University and currently Sr. Director of AI at Tesla, built an instructive website where the CNN can be run in a browser [17]. The convolved outputs of the respective network layers and the momentary error rates of the network can be seen evolving during the training process, for a number of simple networks.

Representation Learning

A crucial question that any user of AI has is: “How does a machine learning or deep learning model make its decisions?”. Or: “What happens inside the black box?”. This is a field of extensive research today, with still partial answers, mostly heuristical. The high complexity and the enormous number of connections do not make this an easy endeavor. By far the greatest percentage of published papers and programs on AI are applied, while leveraging theoretical foundations is still in the beginning. See for a good state-of-the-art overview the paper by Xie et al. [1], which discusses the *explainable AI* problem from many viewpoints.

The similarity to mechanisms of human visual perception is still marginally treated. The fields of modern AI computer science and modern neuroscience research seem still largely separated. The number of papers in both fields has exploded, with relatively few papers focusing on the cross-fertilization. Possible reasons are the broad difference in language (programming/modeling/mathematics versus physiology/pharmacology/genetics), the lack of computational tools for many vision scientists, and decades of historical modest interactivity.

One approach that combines the mathematical and human vision point of view is geometry. We treat one example in the section below. The treatment is some-what technical, but it pays to

understand some of the physics and mathematics of at least the first stages of a CNN (and human vision).

Unsupervised Learning and a Geometric Model

When we want to begin to understand why the self-organization works, we need to know how complex data, like large datasets of medical images, are optimally represented. Optimal in the sense that they take the least space (handy for storage, transfer, and computing) and still retain all information.

In order to begin to understand the stepwise increments in contextual processing exhibited in both deep neural networks and the visual cascade (remember the stages in Fig. 3), it is good to start in the smallest possible environment: a single pixel. Our notion of a pixel is best visualized when we zoom in, and start seeing the pixels. Invariably, these are squares, see Fig. 4 (left) of the author’s face.

But this pixel shape introduces “spurious resolution” [18], i.e., false edges and corners that are certainly not there. Square pixels are easy to fabricate, but the square shape is intrinsically wrong. Nature nowhere exploits squares. It can be proven, from an elegant reasoning with first principles, that the optimal shape of a pixel is the Gaussian kernel (a ubiquitous kernel, the same shape as the *normal distribution*). A Gaussian pixel shape has smooth boundaries (no sharp edges) and is circular (no sharp corners).

So the world is best observed with Gaussian-shaped pixels. In mathematical words: such an observation, where pixels slide over the image, is a convolution, as was discussed in section “Convolution and Cross-Correlation.” Mathematically this is written as

$$obs = pG \otimes w \quad (1)$$

where obs is the observation, pG is the pixel with a Gaussian shape, w is the outside world that is looked at, and the symbol \otimes denotes the convolution operator.

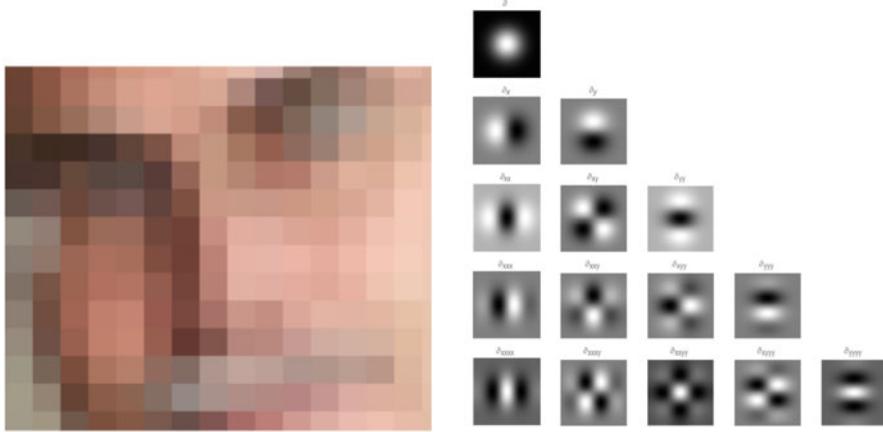

Fig. 4 Left: Square pixels in the zoomed face of the author, generating “spurious resolution,” i.e., false edges and corners. Right: The set of Gaussian derivative filters till 4th order

The next context level is to look at the direct neighbors of the pixel from the previous paragraph. This is done by looking at the difference with the pixel, mathematically described as the *derivative*, indicated with $\frac{\partial}{\partial x}$. The first derivative is the difference in intensity with the next-door pixel, and denotes the local edge strength.

Interestingly, when we take the derivative of our observation (to, e.g., detect edges), we get

$$\frac{\partial}{\partial x} \text{obs} = \frac{\partial}{\partial x} (pG \otimes w) = \frac{\partial pG}{\partial x} \otimes w \quad (2)$$

where $\frac{\partial pG}{\partial x}$ is the derivative of the Gaussian pixel. So edges are measured by convolving (filtering) with the derivative of a Gaussian. This can be expanded to the second derivative (i.e., the derivative of the derivative), third and higher derivatives. The set of all Gaussian derivatives in the x - and y -direction to fourth order is depicted in Fig. 4. On top is the Gaussian kernel (actually the “zero-th derivative”), on the first row the filters for edge detection in the x -direction (i.e., for vertical edges), resp. in the y -direction (for horizontal edges). The higher order derivatives are more complex filters, used for more complex measurements. For example, the second order derivative is involved in measuring the curvature of contours.

These filters are excellent models for the filters that are measured in the first layer of a fully trained neural net [6], and in the first layer of the

visual cortex [19], see Fig. 5. They measure the local *geometry*, i.e., the immediate contextual neighborhood around each pixel. It is interesting that only low order derivatives (up to maximally 5th order) appear in the first layer of both neural networks as in the visual cortex.

There is a mathematical paradigm, called the *Taylor expansion*, that says that we can describe a neighborhood around a pixel with excellent approximation as a (truncated) series of weighted higher order derivatives. See for a clear and entertaining visual explanation of the Taylor expansion [20] (video), and Fig. 6.

In literature these filters are often modeled with so-called *Gabor kernels*, but these, though very similar in shape, do not describe the local *differential geometry*.

So far the mathematical model. We can also do actual measurements of many of such local contextual neighborhoods around a pixel, and find their best representation. In Fig. 7 we have taken numerous patches (in this case of just 12×12 pixels) from a CT slice image. A famous mathematical technique to find the optimal representation is *principal component analysis* (PCA), a procedure that the computer easily can perform on these hundreds to thousands of patches. Figure 7 (top row) shows the PCA result for patches taken from a CT slice: the first 25 basis-patches (these are the so-called *eigenvectors* or *eigenpatches*). Note that these eigenpatches excellently agree with the

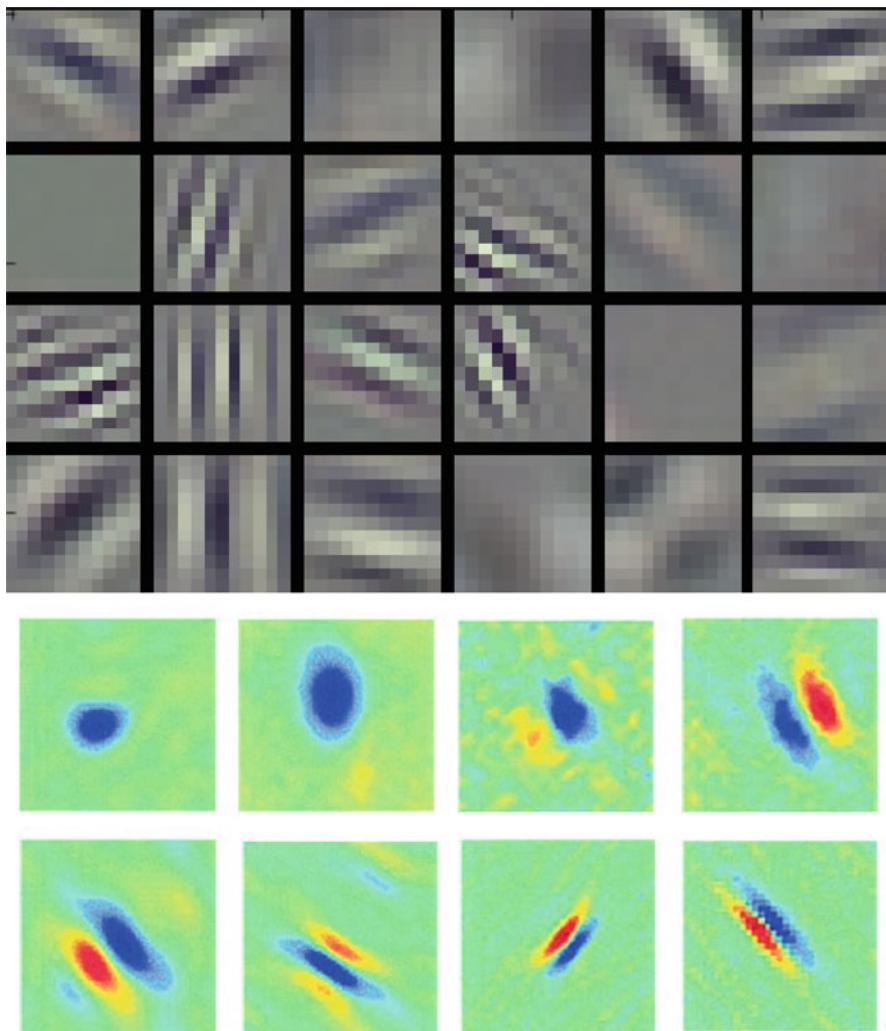

Fig. 5 Top: Learned filters in the first convolutional layer in a fully trained AlexNet. (Adapted from [6]). Bottom: Filters (receptive fields) of so-called simple cells measured in macaque primary visual cortex V1. (Adapted from [19])

model of Gaussian derivative filters described above.

From these eigenpatches *any* patch can be constructed (see figure 6). This is highly efficient: any given patch can be represented as a weighted sum of a small set (20 or less) of these eigenpatches, and we only need to store these basis patches. See how closely these measured data resemble the Gaussian derivatives of the previous paragraph. It is likely that the first layer in a CNN and the first visual layer in our visual system do just that. The eigenpatches form a so-called *basis*, and any patch can be represented with this basis.

This is why deep learning is often called *representation learning*.

With learning different data, different filters emerge. So patches from an image with restrictions, e.g., a picture with mainly vertical trees, leads to different eigenpatches, see Fig. 7 (bottom row). Now the first eigenpatches only measure vertical edges, as there are virtually no horizontal edges in the input image.

An example/proof comes from biology: in 1976 a famous experiment by Blakemore et al. [23] (with video) showed that a kitten, trained from birth with only seeing horizontal bars during

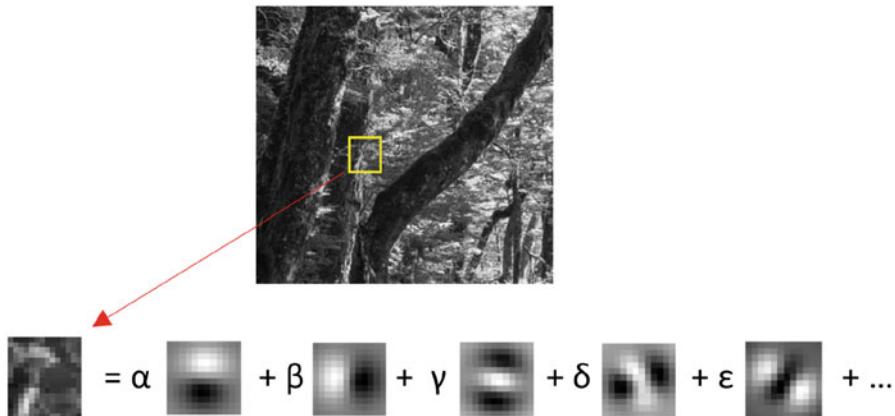

Fig. 6 Every signal, also 2D images, can be described as a sum of basis filters, and approximated with a finite number of basis filters, often < 20 . The small image patch is well

described by a series of image derivative filters. The Greek letters are the weights

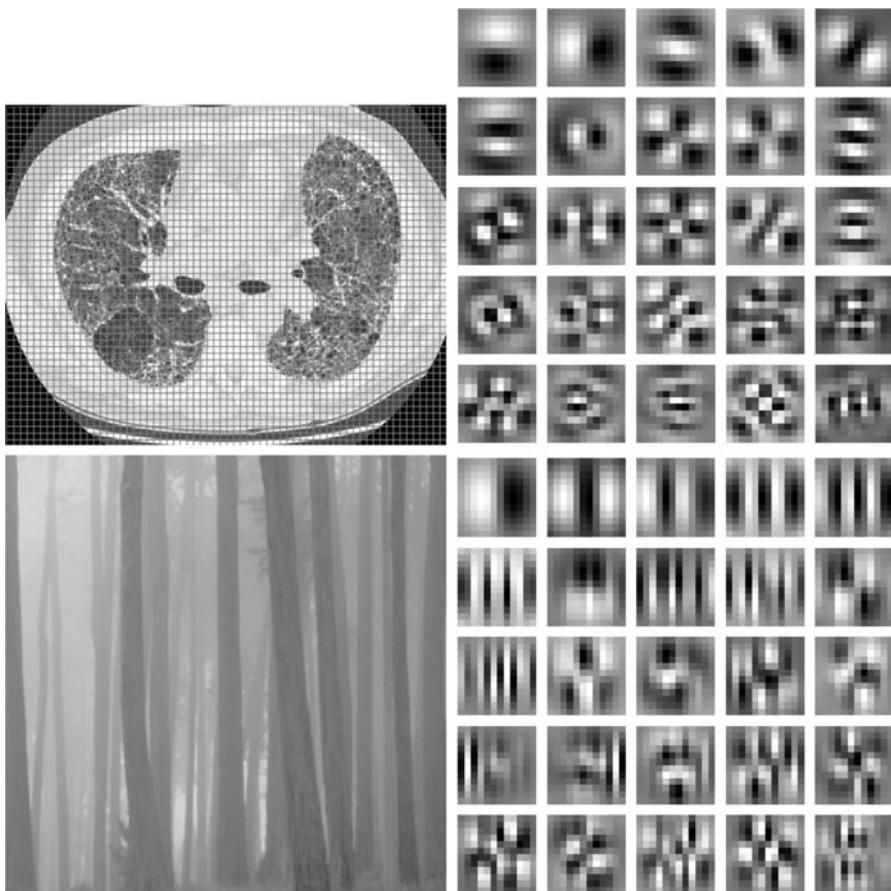

Fig. 7 Top row: Patches are sampled from a CT slice. Right: the first 25 eigenpatches. Bottom row: when patches are taken from an image with restrictions (e.g. only vertical trees), the resulting first 25 eigenpatches (right) show only

horizontal derivatives to high order for the first 7 patches, as vertical derivatives (for horizontal edges/contours) are hardly present in this image. (Adapted from [21, 22])

the first 3 months of its life, could completely not see any vertical bars after this period: it had not developed vertical edge detectors in its visual cortex, as vertical information was not present in the images it saw. See Fig. 8.

It is interesting that our vision also shows this phenomenon: the faces visible in Fig. 9 cannot (or with much more effort) be recognized when the same image is presented upside-down.

It turns out that most natural scenes have a wide variety of edges in many orientations, so this broad set of learned filters in the first stage is often the same for many application areas. It explains why *transfer learning* often works: start with a trained deep neural net from one domain (e.g. skin cancer detection) and retrain it on images from another domain (e.g. trained on ILSRC data). This turns out to substantially reduce the training time, as the filters in the first

layers do not start from a random initialization, but are already close to the required filter shape.

Network Topologies, Types of Learning and Performance Measures

Topologies of Networks

The number of network topologies (layouts) has greatly expanded, and is still growing. It is beyond the scope of this chapter to discuss these network topologies. See, e.g. [25] for an overview of CNNs in radiology. The “Neural Network Zoo” of the Asomov Institute [26] exhibits the many frameworks, see Fig. 10. Well-known networks are: LeNet (1998), AlexNet (2012) (discussed in more detail below), VGGNet (2013), Inception v3 (2015), ResNet (2015), DenseNet (2016).

Fig. 8 Blakemore’s cat. From birth, this kitten was shown – only – horizontal lines during a period of 3 months. After that period it could not perceive a

horizontal stick but it could well see a vertical stick. This kitten had not developed (i.e., learned) any receptive fields for vertical edges. (From [23] (see also the video))

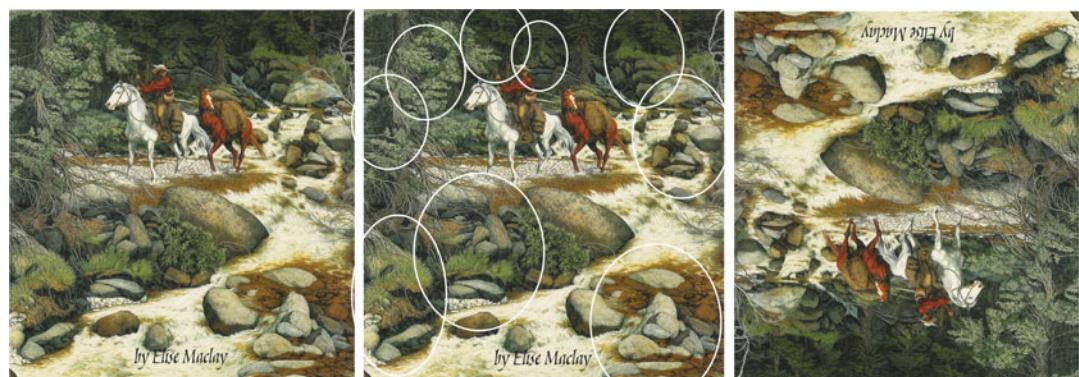

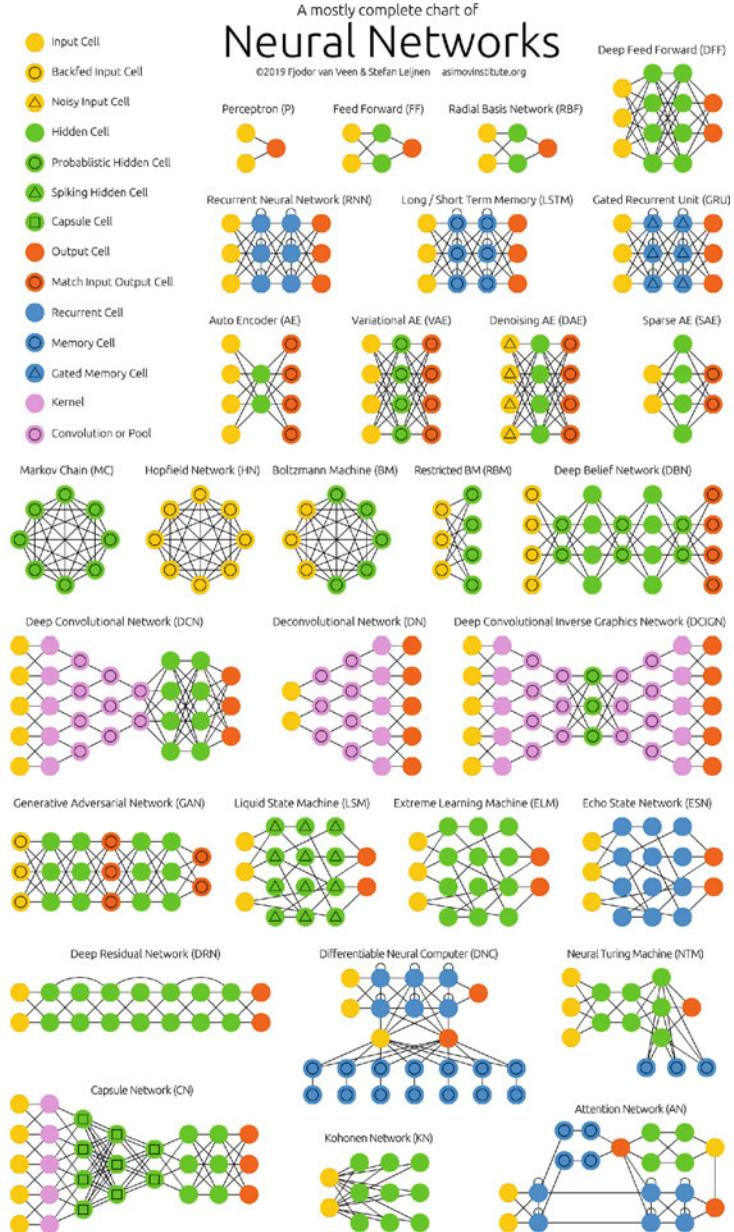

Fig. 9 Face recognition: the faces in the forest (locations indicated by circles in the middle picture) cannot or hardly be recognized in the same upside-down picture to the right.

We have never learned faces that are presented upside-down. (From [24])

Fig. 10 The “Neural Network Zoo,” a mostly complete chart of neural networks. (Figure from [26])

Types of Learning

In grand view, there are three main types of learning:

- *Reinforcement learning*: An agent tries to maximize the total amount of reward it receives while adaptively navigating through a set of predefined behaviors and rules until a goal is achieved [27].

- *Supervised learning*: The training is done with many ground truth examples, which often involves extensive annotation labor. The majority of the networks today are trained with supervised learning.
- *Unsupervised learning*: Where no teacher is necessary, all is trained from the raw data. This process, so natural for humans, is still largely enigmatic and is focus of intense research.

Measures of Performance: Sensitivity, Specificity, ROC

To trust the decisions made by AI systems, a quantitative measure of performance is necessary. These are specified in the conventional way for validation of a decision with specified measures for *sensitivity* and *specificity*, a *receiver operating characteristic* (ROC; see for a tutorial for computer-aided diagnosis systems [69]), a specification of the exact data the network was trained on, and the volume of the training data and the test data with ground truth.

Of course, networks are not perfect. The training set may not be sufficiently large, the algorithm reproduces what it has learned, the chosen topology is not optimal, etc. Sometime inadvertently errors occur. A tutorial example was presented by Narla et al. [28] (as a correction on their highly cited Nature paper [29]) that algorithms are more likely to interpret skin lesion images containing rulers as malignant because images with rulers were more likely to be malignant in the training data, see Fig. 11. Another example is the estimation of the age of a person, given an image of his/her face. A network trained on the public IMDB-WIKI dataset (with over half a million faces [30]) gives an erroneous result when the face is presented with too much surroundings, see Fig. 12, for which it was not trained.

The best insight in deep learning performance gives the direct comparison against healthcare professionals, in the specific topical domain. See for an extensive literature review [32].

Inference and Network Examples

Training is the expensive phase, and might take days, or even weeks to accomplish for very deep networks and millions of input data. Once done, a fully trained network is as an expert brain, the “golden egg,” and works fast (this could even be in milli-seconds). Application of a trained network is called *inference*.

For those not programming deep neural networks: many trained classical deep CNNs can be downloaded. They can subsequently be used for their original purpose, used for transfer learning with input from other domains, or to inspect what happens inside. It is common to see papers appear with full instructions on from which CNN to start, how to adapt and with downloadable free training data (e.g., [33]).

There are numerous free collections of downloadable working deep neural networks, like the TensorFlow Model Garden [34] and the Caffe Model Zoo [35]. For nontechnical users, a highly tutorial collection (directly executable with the software environment

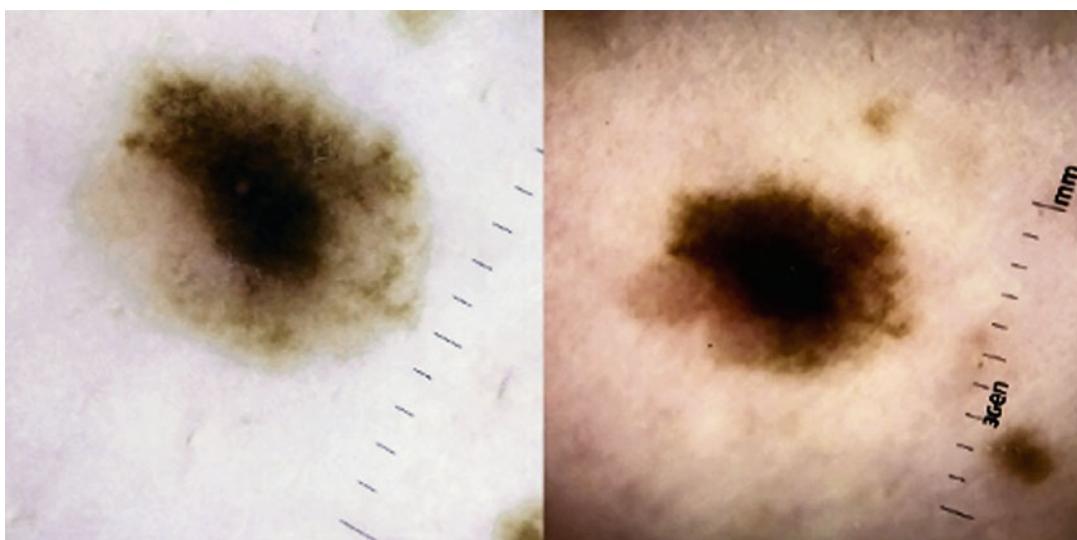

Fig. 11 Skin lesions with rulers can lead to an inadvertent bias towards malignancy. (Figure from [28])

Fig. 12 Age detection from a face [30] fails when the surrounding context is much larger than just the cropped faces of the training set. (Figure from [31])

Mathematica) is the Wolfram Neural Network Repository [36].

Deep Neural Network Application Domains

The impact of AI and deep learning grows rapidly and successfully. Below a concise and in nature incomplete set of application domains is presented, with some example references (also non-medical in order to give a broader overview of current directions) where deep learning is successfully applied. Many more applications are discussed in much more detail in the other chapters of this book.

- **Speech Recognition and Translation**

Well-known examples are Amazon Echo, Apple Siri, Google Translate, etc. These applications struggled for performance for decades, but now deep learning and their continuous training due to large-scale use (think here of millions of users) make them top performing today. The development of *natural language processing* in radiology has been lagging the imaging applications, but is now successfully taking off [37]. Note that recent language networks like GPT-3 not only have learned to autocomplete sentences pretty well (having learned from huge amounts of texts), but can do this even for computer code like *html* (the

language for browsers in which webpages are programmed).

- **Segmentation**

The prospect of self-driving cars became reality with the advent of real-time segmentation of traffic scenes [38] (with an illustrative movie). Many areas in medical imaging have seen successful segmentation [39], especially due to the invention of the so-called U-nets [40] (see Fig. 13), e.g., in the fields of brain MRI, breast MRI and cardiac CTA [41].

- **Detection**

AI has revolutionized histology, a classical area where computer-aided diagnosis was difficult [42]. Another example of successful automated detection is CAD4TB, a system for tuberculosis detection from X-ray images in situations of local shortage of doctors [43], see Fig. 14.

- **Classification**

A classic example (taken from a computer vision challenge) is age estimation from a single face image. Such a system can detect very subtle facial features that human experts cannot even name, when trained from 520.000 face pictures [30]. It inspired a deep learning model that could exploit the gap between predicted brain age using MRI and chronological age as a biomarker for early-stage neurodegeneration [44].

- **Image reconstruction**

Excellent results have been obtained in reconstructing fast dynamic sequences of 2D

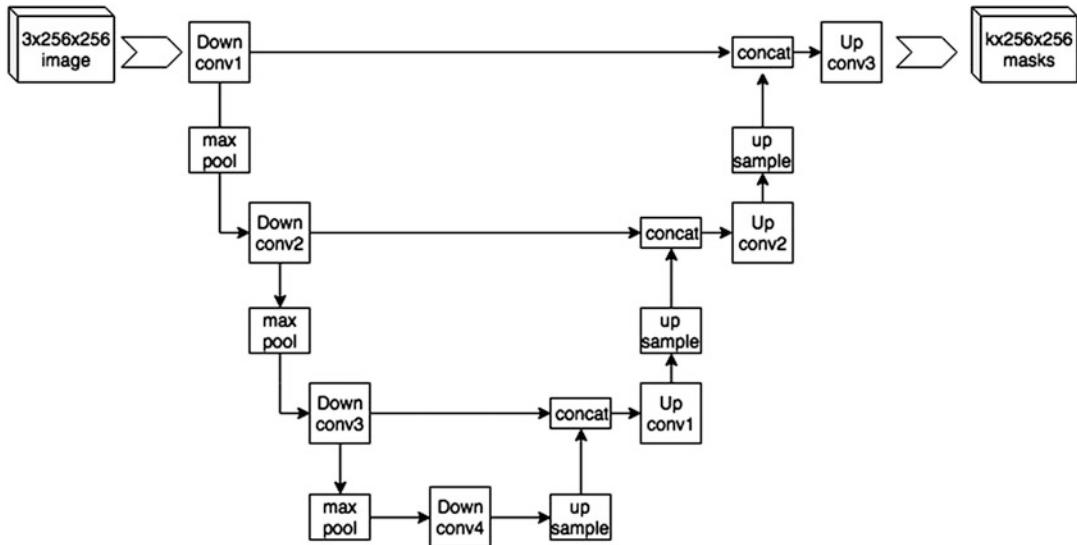

Fig. 13 A U-net [40]. In the left branch the chain of convolutions make the image smaller by a coarser representation (“down-sampling”), in the right branch, with

many side-connections, the resolution is increased again (“up-sampling”), leading to proper segmentation. (Figure from WikiMedia)

Fig. 14 CAD4TB: A lab operator in Ghana studies an AI-detected tuberculosis heatmap of a lung X-ray, acquired in a mobile van. Green and yellow areas point to a risk for abnormalities due to tuberculosis [43]

cardiac MR images from undersampled data using a deep cascade of CNNs [45].

- ***Super-resolution***

Deep learning methods on super-resolution MRI have been shown to generate 7T quality images from large sets of 3T MRI data [46] and was successful in super-resolution musculoskeletal MRI [47].

- ***Content-based image search and retrieval***

Examples abound in daily use such as Google Lens, Google Photos, Facebook, face tagging, etc. These developments are based on the huge numbers of images available (Google Photos: 1 billion users, 1.2 billion pictures are uploaded daily). It is an exciting future perspective to do radiological *query-by-visual-*

search in the ubiquitous PACS archives, e.g., the most similar images as the ones under study [48].

- ***Image restoration***

AI offers good performance in many image restoration tasks, such as *inpainting* (filling-in gaps in images with the contextual texture of the surroundings) [49], denoising, enhancement, and CT/MRI image quality improvement [50].

- ***Image registration***

Image registration (matching) is an ill-posed problem, and faces severe difficulties with conventional methods. Both supervised and unsupervised methods for direct and fast transformation prediction are hot topics in research, and the number of successful application areas in medical imaging is steadily increasing. See [51] for a recent review.

- ***Image, text and speech generation with GANs***

Generative adversarial networks (GANs) generate new images (or text/speech/video), by a competition of two neural networks. One network generates fake data, and the other tries to establish if it is fake or real. The results in generating new highly realistic images such as faces (e.g., “StyleGAN” face generation in a browser [52] (search YouTube for “StyleGAN2”)), but also “new” medical images used for data augmentation) are outstanding. GANs are also exploited to synthesize CT data from MRI data [53], of much practical use in radiotherapy. The growth of GAN applications is turbulent. See for a review on GANs in medical imaging [54].

- ***Image style transfer***

The advent of so-called cycleGANs, generative adversarial neural networks that propose a structure preserving loss in unpaired image-to-image translation frameworks [55], lets the network learn a specific style (e.g. by a painter as van Gogh) and transforms the input image into that style. StyleGANs have proven to be successful for staining normalization in digital histology images [56].

- ***Neural radiance fields***

Recently it has become possible, with a technique called neural radiance fields, to reconstruct complex outdoor scenes like

buildings in 3D with high precision from huge amounts of unstructured (“in the wild”) photographs. See: [57] and the impressive video.

Relation to the Visual System

Not many papers on AI make the comparison to human visual perception. The similarity of a deep CNN with the visual pathway is beneficial in dealing with their explainability [58].

Vision is by far the most extensively studied brain function and many excellent state-of-the-art overviews exist [59–61]. The classic popular overview by Nobel Prize winner David Hubel [62] is still a good entry in the field. It turns out that the visual processing in our brain is massive: about one quarter of our brain’s 10^{10} neurons is involved in visual processing, we really are “visual machines.” The internet exploded when it was possible to handle images easily.

In vision we also recognize a cascade of layers in the occipital part of the brain, which are termed V1 (primary visual cortex), V2, V3, etc., see Fig. 15. A striking difference between the human and artificial networks is the difference in use of energy. A typical human brain is estimated to use about 25 Watt, while modern computing data centers use even Megawatts. Another difference is the frequency: neurons fire at rates not higher than 4–6 kHz, while current laptops have processors running at 3 GigaHz. The difference is so many orders of magnitude that the conclusion must be that still an enormous number of clever strategies can be learned from visual circuits.

A few examples as food for thought for energy saving are given below.

Color Processing and Colorization

In computer vision applications a color pixel is processed as a triple of red, green and blue (sometimes 4: transparency). This triples the computational costs. It is known that color processing in the visual cortex is more efficient: color-sensitive areas in the visual cortex are organized in *blobs*,

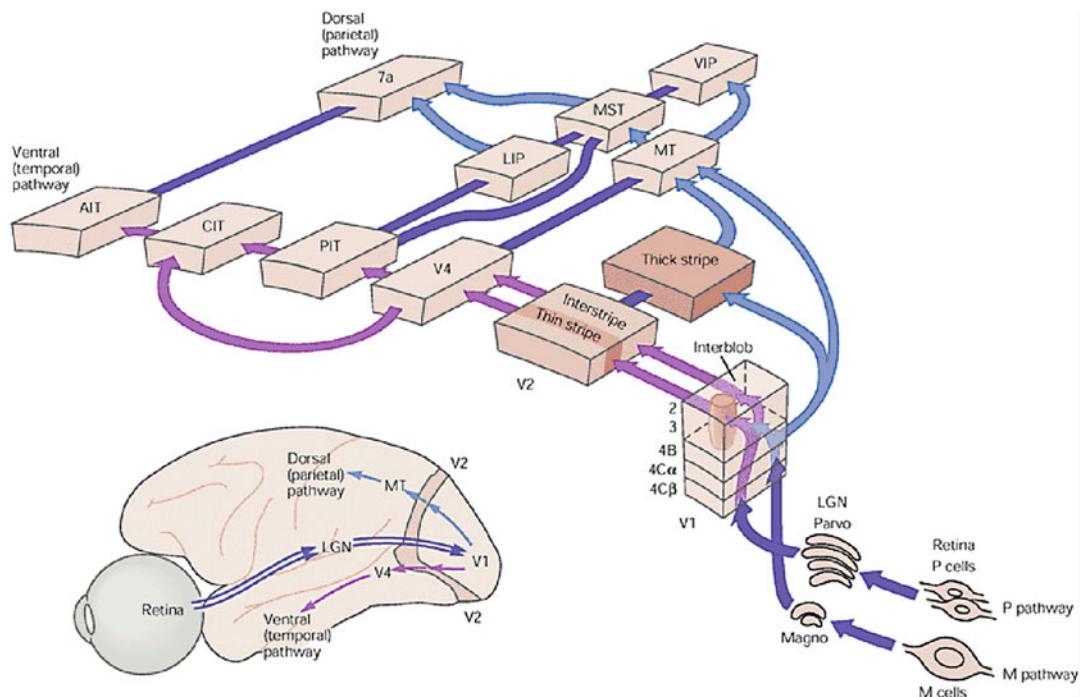

Fig. 15 The layers in the visual system. From the retina (lower right) two streams (parvocellular for shape and magnocellular for motion) project to the thalamus, from

where they project to the primary visual cortex V2, V2, V3, etc. From [62]

stainable with cytochrome oxidase, and take less than 10% of the available space. Maybe our conventional triple pixel processing is overkill? Levin et al. demonstrated that a grayscale image can be colored per segment by only giving some color hints [63], a process called *colorization*. See Fig. 16. AI neural nets can be specifically trained for color, such as ColorNet [64]. For the layout of the network see Fig. 17. This network fills the coloring into a back-and-white input image quite reliably. For an example see Fig. 18. In visual neuroscience it was found that such a mechanism, i.e., scene segmentation and the binding of color to object surfaces, seems to converge in V2 in the visual cortex [65].

Foveated Vision

Our retina is not just a simple camera. Having a fovea saves energy, as now only the 3D world is sharply painted in our internal representation

where we actually look, where we focus our attention. The rest is at lower resolution. First described in [66]. The illusion in Fig. 19 makes the point. Of the 12 black points present, only one can be seen at a time. Foveation was applied in a CNN by Ghafoorian et al. [67], using filters with a spatially changing resolution, sharp in the middle and blurred further out. See Fig. 20. As they reported, the performance was excellent. The kernel permitted a larger contextual area to be covered for less computational effort. This principle, of only painting the attentional focus into the internal representation, is also used in 3D *Simultaneous Localization And Mapping (SLAM)*. Here the fovea is replaced by a *Lidar*, an infrared laser range measuring system, to map the surroundings. This technique is ubiquitous in AI systems for self-driving cars. See [68] for an instructive movie.

Many more of such inspirations for energy savings are likely to be surfacing in the near future.

Discussion

In this chapter we looked more closely inside the basic structure and mechanisms of deep convolutional neural networks, the workhorses of modern AI for images. The purpose is to take the magic off such networks, to appreciate the methods they employ for learning and what is necessary for optimal performance. The developments go fast, and many new network types are being developed and exploited, so the treatment is only elementary. Especially in the fields of generative adversarial networks with its many variations (conditional, cycle-consistent, style-), unsupervised learning, ever increasing hardware performance, and the availability of big data substantial (often even spectacular) steps are taken.

Modern GPU technology has taken the place of regular computing in AI, i.e., massively parallel supercomputing performance is now available at competitive prices. For example, the Nvidia DGX-A100 GPU delivers 5 petaflops (5×10^{15}) or five quadrillion (thousand trillion) floating point operations per second), faster than the world's fastest supercomputer was in 2012, for 200K\$. GPU computing power can now be rented for reasonable prices in the cloud.

Currently much of the AI development is still energized by research groups, which involves open source software and freely available trained networks and datasets for evaluation. With the advent of networks that are just too big to install on regular computers (such as the language model *GPT-3*), and the advent of many more commercial companies (from start-ups to unicorns) active in the medical arena of opportunities, this is likely to change soon.

Lessons for All Doctors

- AI in Medicine is here to stay, as a major supportive medical device. The successes are already impressive in many application areas, and a rapid expansion is seen. As in any field, it remains imperative to be critical. A thorough understanding of AI's tools and their possibilities enables the acceptance, and the way how to control its introduction.

Collaboration between medical and computer scientists is key. In many pioneering hospitals, AI specialists are already embedded in the clinical divisions, often in large groups. Radiology and pathology are rapidly adopting the new AI tools. Such tools need to be trained specifically for the focus of that department, with own (often longitudinal) data. Data security also requires that the development is best done in close collaboration on-site.

- AI should be embedded in the training of medical specialists from the beginning. Today's tools are so user friendly, that even doctors can play with the principles on their laptop, train their own teaching networks, to grasp the look-and-feel of what these new tools do, and how a dedicated local database should be designed.

New paradigms are needed in AI research. As the brain is extremely energy efficient and the current implementations of AI systems for processing and storage are not, much inspiration is expected to come from biology. The worlds of AI vision and biological vision is fusing, and the cross-fertilization can have tremendous benefits. In that sense: AI has actually only just started.

Abstract

Artificial intelligence is a chaotic field with conflicting terminology, philosophies, and architectures. This occurs in part due to the rapid merging of practitioners in computer graphics, image processing, and computer science. The entry of large corporations, attempting to simplify and streamline machine learning, creates an environment providing for reduced technical understanding by users. Competition for noteworthy breakthroughs drive rapid prototyping and early reporting. This collision yields a vivid spectrum and hidden risk. This chapter provides an orientation to important components and terminology in machine learning, plus painless examples of success and failure.

Do not include reference citations or undefined abbreviations in abstracts since these are often read independently of the actual chapter and without access to the reference list.

Keywords

AI · Neural nets · Segmentation · Learning mode · Prediction mode · Self-evaluation mode · Perceptron · Forward propagation · Back propagation · Multisensory data · Boundary condition · Validation · Gatekeeper · Transparency · Artificial intelligence · Medicine · Cancer · Decision-making · Decision basis

Introduction

Would you like to know four years in advance that you have a high probability to fall ill to a potentially deadly disease? [13] AI technology is available today, for hundreds of medical applications, and is under vigorous investigation. How does AI work? Let us take breast cancer as an example

[15]. At its simplest, you first collect thousands of mammograms over a period of time. Then you mark which ones contain cancer and which ones do not. If you then go back to the negative mammograms, years before the cancer has occurred, and compare them to the mammograms identified as positively cancerous, the computer can search for patterns and possibly identify early indicators of the disease. Years before it happens. Once a new patient gets her mammogram taken, you ask the AI to compare her pictures with the thousands of examples already collected. Leveraging significant computational power, you can derive at an answer immediately, providing you with a probability score. This score indicates the likelihood of having breast cancer, or developing it in the future. The AI does this by comparing your mammogram with ones that look similar to yours. How many are marked positive for breast cancer, or, if they are negative, how many were diagnosed with cancer in the years after imaging? Depending on the probability score, you can determine a personal threshold for what will be considered at risk versus what will not. For example, during your screening, the displayed imagery of the mammogram could be color-coded as such: green if you are determined to be in the low-risk category, yellow if further investigation is recommended, and red if there is any indication of a high probability of breast cancer. In some medical specialities, this type of technology may already outperform doctors. This makes sense, as a doctor may see a few thousand patients throughout their career, whereas a computer could theoretically collect data from millions of patients undergoing mammograms. The beauty of this system is that every single patient, who contributes his/her data, is helping society as a whole. How well the AI machine performs is due in part to the algorithms, but also to the amount of meaningful data collected. It is important to understand that masses of data are the rocket fuel for AI.

This introduction is designed to give you, who are new to AI in medicine, a quick overview into the rapidly advancing world of artificial intelligence, machine learning, neural nets, and the unique hardware architectures being designed to quickly and precisely process these concepts. In this short read, we hope to bring you up to speed on the broad concepts, promises, and pitfalls of AI.

It will equip you to decide where to dig deeper and will allow you to read the upcoming chapters with a basic understanding of AI. With this knowledge, you will be able to create a map of where these application-focused authors are located in the technical space of AI.

Please note that this chapter focuses on machine learning for imagery, one of the most common uses of AI in medicine today. There are wide variations in techniques, nomenclature, and architectures, which is why we will take you on a simplified path, one without a lot of terminology or math. The path we are taking is not the only one, but rather a grand tour to provide some context.

The Amazing World of AI

The human eye cannot detect subtle patterns just by looking at a histopathological slice. But a computer can “see” what the human eye cannot [12]. Computers can find patterns, and are able to identify the slightest variations between images, on a pixel-by-pixel basis. This is the magic of computers. But how does AI actually work? How do we go from data input – we feed the computer images of breasts potentially containing cancerous cells – to data output, that is, the computer determining whether it is cancer or not?

At its most basic, AI can either be in training mode, prediction mode, or self-evaluation mode. Before we can get any meaningful output, we need to train the AI. The traditional way of doing this is by feeding in pictures, or other data, that we tag as cancer or not cancer. This is the AI training session. It is easy to think that the more pictures we feed in the better. But it is not as

simple as that. To create well-performing AI, we need to feed in pictures with rich variations and try to account for as much variation as possible. Usually, during training sessions, we tend to choose the pictures we are very sure of. The consequence of this gives us an AI model that computes a correct output for the “easy” cases. In order for the AI to perform well with more difficult cases, we need to train appropriately. A great challenge with AI training is to know that we have not added a feature that is present in all the sick cases, but irrelevant to the actual condition. A nonmedical example of this is a person who trained his AI to recognize horses. Most of the pictures he fed in were taken by the same photographer. What he did not notice was that the images containing a horse, also contained a copyright symbol with the photographer’s name on it. When testing his system with random pictures of a horse from the Internet, his system classified those pictures as “not horse,” because it lacked the copyright symbol and the photographer’s name. This being said, it is easy to miss such a small detail that is detrimental to the whole system. We need to remember what is obvious to us is not obvious to a computer. The computer does not understand causality, only correlation. Planning for training, and careful selection of data, is critical to success. Designing the AI model can also include setting limits or rules on the correlations to exclude results which lie outside of possibility. This may be accomplished through software to visualize correlation importance, to understand what the AI believes is important. Computers have no common sense, something we will circle back around to. AI learns only based on what we feed it.

A World of Terminology

When I was in medical school, in the early 2000s, I had a teacher that taught us the anatomy of a leg by using an old overhead projector from 1973. When we pointed that out, he replied that the leg anatomy had not changed since then. Terminology in the AI world changes constantly as AI is a rapidly evolving field. What is said one way today may be said differently tomorrow [2, 5, 10].

Nevertheless, it is important to understand basic concepts about the underlying processes of AI. Let us dive into the more technical part of this chapter to open the black box of AI. To do that, and to achieve an understanding of these underlying processes, we will start by defining some fundamental terminology.

Neural Nets: Quite Similar to Neural Networks in the Human Brain

There are different types of AI, and a common method to solve AI problems is through the use of neural nets. The purpose of neural nets is to imitate human intelligence to solve a problem. The core feature of neural nets is that it helps to correlate or declutter information. Associated information is enhanced and enables us to focus on it, whereas less important information is given less attention. We can think of this as circuits in the human brain. Neurons that fire together, wire together, creates a self-regulating system and contributes to noise reduction. So as input information is more important, it is given more weight.

Similar to the human brain, the output from an AI neural net is dependent on the strengths and importance of stimuli. Visual input through the human eye activates different areas of the visual cortex. Computer vision, which can use the architecture of neural nets, works in a similar manner. Computer vision consists of highly specialized neural net circuitry that processes a continuous flow of data, typically with circuits for edges, stereo fusion, and contrast management, just like specialized areas in the human visual cortex. So, when the human eye sees a cat running over the street, this picture is also segmented in order for different parts of the brain to focus on motion, edges, colors, background reference, etc. The computer also segments the picture, as we will see soon, and may also contain specialized region processing for these different features.

The core unit of a neural net is a perceptron, if one has a medical background I think it helps to think of a perceptron being a neuron. The purpose with the perceptron is to weight the importance of incoming variables (input) and generate an output.

This is called forward propagation. Unlike typical statistics, these circuits handle huge numbers of input parameters and are evaluated in something called the hidden layer. The hidden layer is located between the input and output of the process and performs the actual weighting. The hidden layers typically use nonlinear weighting, for help force a decision. Weighting individual perceptrons is the mathematical process of increasing or decreasing the importance of each specific node. This process distinguishes perceptrons from typical statistics.

Single perceptrons can only retain a tiny amount of information. Single layers or perceptrons have limits in the degree of convergence that can be obtained. In contrast, multilayer perceptrons also called deep learning, with many layers, have greater convergence power and can take more complexity into account. So, when we later on talk about data segmentation, data fusion, and data federation – these are all processes that tend to imply multiple layers of perceptrons. The term deep learning refers to this concept of numerous stacked layers of perceptrons, so that each perceptron layer can focus on a subset of the overall problem or a degree of refinement. Deep learning is trusted to perform more advanced AI in medicine, which makes sense considering the subtleness of a lot of medical diagnostic imaging. The example in the coming segmenting section is a real-life example of deep learning.

Data: The Fuel for AI

For AI to work, we need to convert an image into numbers which can be feed into the machine for learning equations, which we will describe below. At its simplest, images can be represented as a simple matrix of numbers. Groups of images may be more conveniently represented as tensors. Tensors are special spaces for numbers, which are often multidimensional. AI input can vary in modality as well as dimensions. It may, for example, be a single image or a sequence of images either in space (such as a 3D biopsy image stack) or in time (such as a movie). A different modality may also be spectral in nature, e.g., be 600 nm

wavelength imagery or 800 nm. For illustrative purposes we will talk primarily about images in the coming sections. The example we have chosen is *one* way of doing AI. This example revolves around an experimental multimodal imaging system developed by one of the authors [Passmore]. The device, let us call it HyperTrak, was developed for noncontact imaging of people to develop a health score, based on detected symptoms of illness. The motivation was to obtain some clue to who are most symptomatic of illness, and are possible candidates for further screening. The driving factor for health scoring is the ongoing crisis of covid-19, especially in large crowds. This provided an opportunity to leverage AI, develop a hyperspectral imaging workbench, and make a contribution. The device has been built and is currently being tested in Texas, USA. It is also a convenient platform to reference in these discussions.

Segmentation: Feeding Quality Data

A traditional way of teaching AI is to do it in binary form, as in “sick” or “not sick,” while looking at a picture as a whole. But there can be so much more to it than that. Let us describe the process of feeding more complex data into neural nets and how deep learning works, in very simplified terms. The HyperTrak scanner consists of different sensors which pick up different aspects of light. The captured images typically not only contain the color of interest, but also texture, edges, geometric properties, background clutter, and more. All of these properties are different variables. When extracting portions of an image containing different properties, we call that segmentation. Looking at individual image segments, we can tease out commonalities in that region based on variables, such as green regions, areas with a bumpy texture, specific cell types, and so on.

Imagine a crowd of people passing through the entrance of an office building, and the HyperTrak scanner is placed in front of the entrance so that everyone who enters the building will pass it. The first thing the scanner captures is a crowd at the

entrance doors along with all the things in the background. Segmentation is the process that separates the people from the background. In a second segmentation process, individual faces are separated from the crowd. A third segmentation process starts to pick each face apart into different types of facial regions. Think of this process as picking Mr. Potato Head’s head apart. You can remove his eyes, nose, ears, and mouth. One important facial region that is scrutinized in this context is the area under the eye (AUE). The AUE is normalized for light and color before it is picked apart into its different variables, e.g., sweat, temperature, pallor, etc. Each of these variables are then fed into a set of neural nets which consists of neurons (think of it as a box for AI), synonym with perceptrons. By normalizing the data and sorting it by different variables, the dataset becomes better “behaved,” making it easier to understand which image segments and which variables contribute to the output. Imagine we segment the picture of a person into ten unique layers, or in our example ten different parts from Mr. Potato Head’s head. Now we have ten images, with isolated objects, to look at, rather than just one (i.e., the complete picture of a whole Mr. Potato Head).

When we feed the temperature properties of the AUE into a box of neural nets, we get a scatterplot of the temperature data. A polynomial equation is fitted to the data which is a large-scale operation. Numerous equations (layers of neurons) are stacked on top of one another in order to diminish the error factor and finding the best fit for the curve. Solving the equations results in a line that is fitted to the data. The reason for layers upon layers of equations is that each pixel is connected to all neurons in the neighboring layer, and each of those neurons are connected to each neuron in the next layer in line, and so on. The purpose of this rather complex structure is to drive the error toward zero to get the best possible fit to the data.

The amount of equations contributes to complexity of scale, requiring substantial computational power. Once we have the fit in training mode, we will tell the AI: “when the line looks like this, it is covid.” In prediction mode it will be: “when the incoming line looks like this it falls into

the covid category.” The text above only described the process of analyzing one variable for the AUE. Now imagine we have other regions of the face that we are interested in, e.g., the actual eyes, forehead, etc. In the same way that Mr. Potato Head has different objects we can pick apart, we can perform this procedure for all the areas/objects we are interested in. The more numerous our sources of input data, and the more variables we put into the AI from our segmented objects, the more information we have to base our output on. This is a type of pattern recognition via machine learning. Pattern recognition is a widely used term that indicates when computers learn to identify patterns. Summarizing, segmenting the data into different layers provides distinct channels about what “sick” looks like, compared to just having a single layer (the whole picture). It also makes it easier for us to tease out the contributing correlations, assisting us in appropriate supervision.

Training Mode

Training can occur in different ways. One way of thinking is that when feeding the AI, we can think of it as providing a verb, a noun, and an adjective. Let us take an example of a scanned image, positive for covid and a resulting patient death. This scenario contains more than a noun (covid or no covid). Please think about this for a moment. Compare the above sentence with a scanned image, positive for covid and the patient was healthy within a week. The last sentence adds the information about a good outcome compared to the first sentence. The difference may be the degree of illness, the adjective. The predicted existed of covid, the noun. The death a verb. If AI indicated covid – would not you also like to know the last part of the sentence, the end result? If yes, this is something we need to add into the AI training, so this message can be included to you. Thus, it is highly desirable when we feed AI, to give it complete information, rather than just label input as sick or not sick. It is also desirable for us to show variation in cases. Going back to the example with the horse. Imagine that we only

feed the AI with pictures of horses standing still. Then the AI may perform poorly at recognizing horses when jumping, running, or lying down. Or even a pony. It is similar in medicine. If we only train with covid from one vantage point or with a single type of people, but not with another, the computer will have no reference when we provide new and unfamiliar data. As such, it will not be able to reliably detect if the result is sick or not sick. For this reason, we need to plan and strategize for our AI, before training and deployment.

Multisensor Data

Let us revisit multimodality. A powerful option of data input into AI is the addition of multisensor channels. When we want a complete picture of health state, we often do this best by collecting a variety of data types. In the introduction, we presented how one type of data can be utilized to foresee disease. For example, mammogram data to predict breast cancer. However, one powerful technique in AI lies in the combination of different data types. So, if mammography can be considered as a single channel of data, adding information from an additional type, such as ultrasound, can be considered as a second channel of data. Adding different channels of data is called multimodality. You can imagine one example of multimodal data collection by thinking of the five senses of the body. Imagine you are invited to a fancy dinner at a restaurant located by the sea, where you are sitting in a hanging garden of lemon trees. If you only collect data from your eyes, you will have one type of experience. If you collect data from both your eyes and your nose, you will have another type experience. And if you have your eyes, nose, and ears there will be a third experience. The more senses you use, the more complete your perception of the dinner will be. Of course, forgetting the sense of taste would be a disaster. It works the same way within medicine.

Data collected from different modalities can be normalized and placed in the same space. A simple example could be cameras with different resolutions. It simplifies our thinking to overlay the different cameras in a common resolution. This

process is called data fusion. In addition, we may want our AI module to communicate with other AI modules. These other modules may be other modalities or it could be something as distant as another doctor's AI for a related disease. We do this with federation, when different AI modules communicate with each other, sometimes over great distance. When properly staged, the resulting answers can be the result of a collective of AI modules working together. As previously mentioned, these processes require multiple-layers perceptrons. These concepts are an emerging area of AI and hold tremendous promise.

Prediction Mode

So far, we have trained our machine for what is probably ill (check for covid) and what is probably not ill (lower priority to check for covid). Now, we want to see some predictions. To get a prediction, we need to switch the AI from learning mode to prediction mode. Imagine we now take a random picture of a person and feed it into the system. How can the AI know if it is covid positive or negative? What happens in our example is that the picture is segmented into Mr. Potato Head's different parts and their variables. For each segment we will use the matrices of weights and bias values. The computer applies the matrices to each segmented image's variables to determine the confidence of covid, as individual values from each segmentation. Let us say that all our sums, for all segments, fall into the positive sick/covid category, then the AI will give a positive "sick/covid" probability as an output. It could be that if only three of our curves are within the covid threshold, we may choose to assume "no significant symptoms" as an output. But what about if five or six of our curves fall into the positive covid category – what will the output be then? Frequently, the outputs from individual channels are fed into additional layers of machine learning. However, unless the answer is overwhelmingly distinct, we will ultimately have to make a judgement call regarding our belief whether the result is significant or indeterminate. This highlights the importance of determining thresholds and may

also, over time, help us understand the stability and usefulness of the predictions. One possible factor to add is the input confidence used to train the machine. If we only teach the AI that the output can either be covid or not covid, then prediction stability may suffer since the training is based on absolutes, where absolutes probably do not actually exist. However, if the AI is trained with tagging that indicates a 20% likelihood of covid, a 60% likelihood of covid, or an 80% likelihood of covid, it may be possible to avoid some errors of oversimplification. We need to ask ourselves, what is the basis for decision-making that we want to use? Thresholding, already an existing problem in diagnosis, carries through in machine learning. One can, however, make matters worse by oversimplifying data tagging used during training. We may also want different outputs for different indicated diseases depending on their severity. If we change the word "covid" from the example above, to "cold" or "cancer," the importance of associated thresholding and the importance of individual symptoms will vary.

We also need visibility into how predictions are weighted. Common sense tells us that some factors are of greater importance for indicating a disease than others. Meaning that even when only three modalities of an AI model indicate "covid," there may be a greater chance of the disease than if compared to six less important modalities indicating "covid."

Levels of Expertise

It is not uncommon to develop multiple models for a problem. This is different than modalities, in that a model is an architecture, or design of an AI solution. A modality is a characteristic of an input channel, which can be run through many different models. We can see the simultaneous use of different AI models as an analogy to a committee of doctors who are voting whether your data indicates covid indicators or not. If you only look at one model, it is a bit like asking a single doctor if it is covid or not. If you look at many models, let us say several – it is like asking several doctors if it is covid or not. However, it is also a similar thought

exercise as if those several doctors just recently finished medical school or if instead you have several highly experienced specialists in your committee. We all know there are some doctors who are more skilled than others. When the voting concerning your health is happening, you want the best doctors on your committee. Especially when this voting concerns potentially deadly illnesses such as covid or cancer. For this to happen we need to consider all the above. The above reasoning also stresses that we need to be humble about AI and possibly seek the opinion of multiple models. We unintentionally transfer our bias and errors into AI training. Being poorly skilled or being genius, our opinions will carry into the AI model, which means in some ways we are replicating ourselves with AI. Therefore, we need to be humble about ourselves as well. The human brain created silicon intelligence and subsequent ramifications. If the trainers are mistaken about reality, we can expect our AI predictions to reflect this.

AI can perform tirelessly, in terms of time and energy, as well as process huge amounts of medical data. In the real world, a human doctor may go through a few histopathological slices from a cancerous tumor to determine diagnosis, stage, and prognosis. A computer is able to go through thousands of slices, several times. Similarly, it could screen a crowd of people for covid infection in a second. This enables us to be more thorough in the medical care provided. It may also increase the probability to be more accurate, while the chance of missing important information decreases. It is predicted that AI will have the greatest immediate impact on specialities such as pathology and radiology, because these are specialities based on visual data.

At the moment, AI is being celebrated. It is similar to when we start dating. At first we believe the number of desirable partners is great. However, after a while we probably notice that 90% are not compatible and fit into the dates that we should discard. It is the same with AI, not all AI is a good fit. Most early experimentation may need to be discarded. The consequences of having a bad date are typically inconvenience, but the consequences of poorly trained AI in medicine can be fatal. Level of expertise is crucial. With

that said, we need to seriously consider who we date, and in medicine, do a proper background check.

Self-Evaluation Mode and Correlations

Once we have taught the AI system what covid, cancer, or any other disease looks like (or not), as well as having informed the system which variables are more important than others, it is time for the system to learn to improve itself. It does this when in self-evaluating mode. Perceptrons can refer to themselves in feedback loops, enabling the system to self-evaluate for the purpose of convergence.

This happens when the actual error factor coming out of the hidden layer is compared with the expected value. Gradient descent is one process of minimizing the error and updating the weight for prior circuits. As previously mentioned, imagine that every variable in the neural net is a person in a committee who will vote if a person has covid or not. If the discrepancy between the expected error and the actual error is huge, it means that this person (perceptron) is bad at predicting who has covid or not. When there is a vote, this person gets it wrong most of the time. Such a person would be considered less important in a committee. We would give their opinion a lower weight, possibly much lower. In contrast, other variables that are very performative, these are considered to be very competent, similar to a great doctor. Such a perceptron will be given considerable weight in the voting process and, subsequently, contributes more to the output. This self-evaluating feedback processes is called back propagation and was a critical breakthrough between rule-based AI and self-learning machines.

Related to correlations is the ability of AI to pick up changes in correlations. This is valuable when the symptomatology of a disease changes. Using such a system could be perfect to detect, for example, how a covid mutation may cause changing symptomology of the disease. Such a method could give early alerts to authorities that the symptoms are in motion, which could prompt investigation. For example, imagine that the variable

which is the best predictor of covid today is pallor, but after a new mutation has taken over, we may see that this variable is contributing to more errors than usual. This could be a sign that something is happening. In parallel, another variable, let us say temperature starts becoming a better predictor. The system could then allow for the perceptron weights to change. In this scenario, the pallor variable could switch from having a great weight, or importance, to become much less important and the opposite could happen for the temperature variable.

Computers are excellent at picking up correlations. However, they are not strong at understanding if a correlation is meaningful. When AI gives us information about how two or more variables may correlate, it is up to us to understand causation and create the narrative around such a finding. In the horse example the copyright symbol was right every time, in identifying a horse, until the input data was taken from another photographer. With this said, we as humans need to understand causation and create the narrative around relationships. Here, human supervision can add sanity to the process.

One interesting process is to ask the AI to create its own image from a tag, such as “sick.” This process of generating what the machine thinks, or internally sees, can be instructive. Under supervision, images which appear correct can be fed back into the learning cycle for reinforcement training.

Breaking Boundary Conditions

Again, AI is dependent on what it has been taught. For example, say that all images of people that have been feed into HyperTrack had both brown eyes and were sick. Meaning that by poor design or accident, it could be assumed that covid-positive people have brown eyes. If HyperTrack would be used in, e.g., Sweden, where lots of people have blue eyes, the system may not reliably predict until trained with Swedish people. We refer to this as breaking a boundary condition.

There are nonintuitive stories around this. In one case an AI was trained by letting young men

select and add pictures of males and females into the computer, teaching it whether the picture showed a male or a female. All female images selected by the young men were females with large breasts. When testing the prediction capacity of the system, females with smaller breasts were also added and predictably, these pictures were misclassified as men. Other examples of these AI training mishaps have occurred with concerning social consequences, such as racial bias based on skin color.

It is also helpful to let the computer know if we are teaching it several things simultaneously. If we put in multiple covid symptoms, but do not differentiate in our architecture, we can expect slower convergence, or unexpected results. If we do not, the computer will not know that we taught it two different things and teasing apart the weighting of these different symptoms can become more challenging. Purely as illustration, we have included a picture below of a “dog-flower.” In this case the AI is unaware that a dog is not the same thing as a flower. Although clear to us this is nonsensical, although interesting, it highlights that one cannot expect AI to possess common sense. We would like to use this image to help re-emphasize that the computer will only learn what we teach it. Therefore, it is important to consider what type of biases and omissions that may exist in the data, in order to derive accurate predictions from widely varying data and possibly intertwined case modality. We also need to train and update AI systems continuously to stay current, as the world around us changes.

Multiple Ways of Solving a Problem

A proper background check in AI is about understanding the ways a problem can be solved. When we understand the basic concepts we can start to evaluate model validity. We also begin to experience humility for all the things that can go wrong. There are many possible approaches to problem-solving in AI. There are a wide variety of architectures, preexisting models, and differing hardware platforms. These selections can have dramatic impact on success and practicality. Let

us look briefly at one version of recent AI history as it is related to image-based learning.

What most of us today think of as AI is considered machine learning. In our example, we are teaching a computer what is possibly covid or not, from imagery. AI is the parent of machine learning and a lot of early work was performed using rules, not self-teaching. Today, most machine learning is not built so much on explicit rule definition. Some of AI's roots are reflected in an early AI language, Lisp, and an early computer built around it, Symbolics. Symbolics popularized rule-based algorithms, such as flocking. This programming philosophy, which can be thought of as object personality structures, was applied to model natural phenomena, including particles, fractals, and eventually chaos. These rule-based methods became what were called expert system. This hardware manufacturer, and others like them, made inroads into the applied sciences of computer graphics and image processing.

The computer graphics group focused on creating models to create images of the world. Although math was certainly a large part of what was called AI at the time, the math was explicitly defined and did not contain self-teaching. It did use stochastics [3, 11], a form of randomness, to insert a sense of natural complexity. This created a sense of machine intelligence. Watching computer animation of flocking certainly gives an impression of machine intelligence, where there is no real opportunity for self-modification. This community was focused on the output of imagery and was most visible in visual effects for motion pictures, computer gaming, and computer art.

At the same time, another community, who had largely separate conferences and publications, was at work on pattern recognition and image processing. A group of these image processing programmers were focused machine vision, the practical understanding of input imagery. Machine vision programmers looked at a very similar problem to the computer graphics tribe, but in the opposite direction. How to take real-world imagery and create an internal model. This group was most visible through aerial mapping and factory automation.

A third group, composed more of physicists and mathematicians, had been working for decades on the overarching mechanics of AI. To an outsider, it appeared they were more focused on the theory of AI. Suffering numerous setbacks, a series of impressive breakthroughs regarding methods of self-teaching began having some serious success in the 1990s. This group gained attention through AI gaming of chess and robotics.

Today, the three groups have largely joined, each bringing their own vocabulary, methods, and architectures with them. This, in part, explains the diversity of terminology and methods used in AI. Every group have an ownership stake in AI, while simultaneously approaching it from different perspectives. Explicit operations, symbolic AI, and rule definition have largely given way to machine learning, a method of automatically converging on pattern recognition. The clarity of rule-based AI then gave way to convergence and abstraction.

Machine learning (ML) also shares commonality with statistical models [1]. Both use data-driven model generation, both are designed to attempt understanding. ML, however, is almost solely focused on prediction, where statistics, at least in theory, is focused on teasing out causality. ML produces these predictions through convergence, without necessarily yielding an explicit understanding of the relationship between variables. It is the drive for prediction that uniquely defines ML and holds much of its challenge. Those working in the field see remarkable success and equally remarkable failures of ML, frequently resulting from relatively minor processing adjustments or inadequate verification. It is as if a thinking machine is willing to go way out on the limb, in its aggressive attempt to predict. When successful, ML does not typically serve up knowledge of the relationships between input variables. We then, as operators, may blindly accept the predictions, based on feedback loops and testing, with no real understanding of the underpinning relationships. This is becoming increasingly common as scientists shift toward data feeding of more abstracted systems, without any involvement in the programming or algorithm development. ML learning then can be thought of as a form of

consequentialism whereas statistics is rooted in deontology. Consequentialism is deeply rooted in programming culture and it seems only natural that the implementation of ML systems has evolved from this mode of thinking. After all, massive computational loads are a common form of permissible harm in programming, only to be minimized later when the end result is successfully achieved.

This in no way diminishes the importance of ML, but provides the context for the radical shifts and complexities that occurred leading to today's popular definition of the term AI. Later in the text we will therefore discuss aspects to consider, as we increasingly lose an understanding of how the machine thinks, in order to provide classification and prediction.

Processing Improvements

When I was working with imaging processing during the first decade of the 2000s I always heard fun stories from elderly colleagues about how they had dozens of pictures in the 1980s and how they had to cut, paste, and glue them together to make sense of the data. When I was doing my scans, I got thousands of pictures from every scanning session. I did not use scissors or glue. I used a software called Matlab. In Matlab there were several pages of code that helped me automate the preprocessing of my imaging data. A single error in the code, like a comma or a typo, could result in fatal consequences for the analyses. An AI may traverse a one million lines of code! In the same sense that several typos have been made while writing this text, typos are made when writing one million lines of code. From previous paragraphs we have learned that thousands of equations need to be solved to weight the importance of different aspects of data. With this said, AI requires tremendous computational power and there are lots of things that can go wrong.

Committing a mistake within research leads to false results. Depending on what research it is, the impact it has on patients may vary. A nonsolid AI system can give the wrong output. Not just to a single patient or a few patients, which would be

the case if a doctor committed mistakes. It could be amplified to thousands of patients. What does it mean when thousands of patients suddenly get the information that they have a high likelihood of having cancer? This means that we need to think when AI gives us a prediction. We need to discuss what to do with the information. Imagine you get an output recommending giving the patient in front of you cancer treatment. Do you really want to give them radiation, chemotherapy, or amputate their leg? This is a decision you have to make on solid ground.

Validation

This brings us to the topic of validity of AI [3]. When AI is created, it can either be made from scratch or we can stand on the shoulders of giants using different AI prepackages to create our tailor-made AI system. How do we know that the pre-made AI packages are good? We have learned that a horse picture without a copyright symbol can be classified as not showing a horse and women with small breasts can be classified as being men, because of their small bust size. A recent anecdote of encoded bias has been on display as AI tagged members of the US Congress as known criminals, more often identified minorities as a credit risk and an abject inability for everyone to understand how an AI model makes decisions. The confidence interval for the AI systems predicting US Congress members as criminals was 80%. Eighty percent sounds pretty good, but less so if you are identified as being a convicted criminal (even though you are not) due to skin color or if you get a cancer diagnosis and go through a cancer treatment without having cancer.

Evidently, a crucial topic to discuss around AI is how we validate the system. From a basic medical research perspective, we always talk about the importance of replication to validate a result. This becomes tricky with AI because you can only get an identical result from the system if you feed it identical data. So how do we do it then? There are different ways one typically uses. One common option is to build two AI systems – each based on a different AI model.

When data is fed through and both systems give similar results, it would help validate their output. Another method almost always used is to test the system by feeding it data where you know the output, for example, “no cancer” or nonsense data. If the system manages to give you correct answers in both cases, it strengthens the confidence in the system. Doctors still need to be smart when handed an AI output; we cannot blindly trust the output as its processes can contribute to doctors losing their skills. Doctors should become more alert and smarter to keep up with the machines, so we can program them to be even better. Every output needs to be validated whether it is plausible or not.

As we have previously seen, computers are extremely good at finding correlations, but you as a clinician need to know your physiology and pathophysiology to understand if the result makes sense or not. In a medical context this means that if two different cell types in a histopathological slide covary, you as a doctor need to figure out why. As in a hypothetical case with pancreatic cancer, the presence of red blood cells in a sample may be important, as it may indicate a more aggressive cancer with greater vascularization and thus greater risk for bleeding, or it is a nonsense result that is not relevant at all for the condition. AI points our attention to what may be of importance, but so far, we need to create the story around it and understand the causality.

From an ethical point, we also need to decide the importance of AI. What happens if a doctor contradicts the AI output or vice versa? This maybe be extra important to consider in a country where an AI software produced in a fancy tech hub, has a greater status than a local health worker in a poor country. What if technology tells us to do the wrong thing, where a human eye can tell it is obviously wrong? Like the horse problem. We can be pretty sure that a picture shows a horse even though it does not have a copyright symbol. A security feature could be that humans can override the tech so it will not be forced to do the wrong thing. However, this will at the same time leave a loop hole for the ones who think they are right, but are actually wrong. The importance of an output will probably be in relation to resources. In a

country with restricted medical resources, the benefit of relying fully on AI may be the most beneficial option compared to no health care. To figure this out, a risk and benefit analysis would need to be in place. The community in which an AI operates needs to have guidelines for what weight to give AI output. In America these questions are put to the test as lawsuits are coming in against AI. Who is responsible for an AI output? Is it the company creating the AI system, the programmer, or the doctor using the system? Or could it be the hospital providing the AI tool to its doctors? Similar questions rise for autonomous vehicles, what happens if a self-driving vehicle runs over a child, who is responsible?

Gatekeepers

In this chapter it has become evident that AI in medicine is a complex topic and a very powerful tool. We need to decide who will be the gatekeeper of deciding what type of data is of good enough quality and certainty to be fed into a system, as well as what level of knowledge do you need to have to create AI for medicine.

What is the optimal process when creating new algorithms for medicine? This is also a core question within AI in medicine that should be thoroughly discussed within the profession. The most important is to know the individual AI system's strengths and limitations, especially the latter. By understanding what different aspects a system considers in combination with what type of data has trained the system, one can get a picture of the system's reliability. For more advanced diagnostics and where there is a huge risk for the patient, one could consider multiple AI systems verifying each other in order to be safe. One could consider a similar mechanism for AIM as for verification of blocks in a block chain. The greater the transaction, the more verifications are required for the transaction to go through and be valid. Using AI in medicine could rely on the same principle, the more of an impact an output has, the more validation there needs to be.

We also need to know or even decide who should train the AI. From a performance

perspective it would be optimal if the best experts in a field trained the AI that would be used within their area of medicine. But is it really the best of the best that trains AI today? If not we need to have a discussion who is. If it is an average Joe who has trained an AI system it means very different things if we read that the system is as good as doctors or if it is better than doctors. It is also important to know the level of expertise for those doctors. On the other hand which doctor is prepared to admit that AI is performing better diagnosis and prognosis than they do? When doctors do, they will probably be replaced. Meaning we wish for an amazing AI system that somehow is better than us, but we do not want to be replaced.

So far, AI seems to be at best, as good as doctors. Thus, at present, the recommendation is that AI should collaborate with doctors. This brings us to the topic of limitations.

Limitations

As AI relies on its data, programming, and algorithms, the design of these become crucial. So far, AI can never become better than the human programming it, thus imperfect humans code imperfect machines. In an AI context this means that if we use, for example, a mammogram where a doctor wrongfully labeled it as cancer (even though it was not), we will teach the AI the wrong thing. We may also tend to feed the AI with cases we are sure of. This gives us an AI that is good at solving the easy cases but has a higher likelihood of committing mistakes when handling ambiguous cases. Often we make the mistake of comparing humans versus computers in order to announce a winner. There is a danger of doing this. Computers as we know have amazing features, but so do skillful humans. Having common sense and feelings are actually good tools for decision-making, especially when balanced with concrete rational data. Going toward one of the extremes usually results in poor decision-making. To further understand the threats around AI and relying too much on rational data – let us compare AI to a sociopath.

Responsible Artificial Intelligence

A sociopath may have all the answers to curing your disease, but be insensitive to your emotions, make treatment decisions based on your social value, and may gloss over the specifics of your unique case. Your concerns about ethics, morality, and the pleadings for your life go in deaf ears. The eyes of the sociopath are distant, unblinking, and laser focused. Due to raw brilliance, should we all fall to the feet and obey this sociopath?

Today, thousands of us are building the most brilliant sociopath of all. Able to avert, diagnose, and treat disease, plus predict your mortality, many of us relinquish control of our lives and fail to understand the basis of decisions that will impact every future generation of humans. We are at a crossroad between a future of subservience to a silicon overlord and a future of a profound collective intelligence to cooperatively guide our world. If we close our eyes, blindly trust our sociopath friend, and run toward the cliffs, we will certainly get what we deserve. A lot of engineers hate drama and many doctors are simply numb to it. Drama, however, emphasizes a potential truth. It tunes our senses and energizes us into diligence and action. Surrounded by advanced technical lingo, let us pause and find a way to incorporate compassion, morality, and even humanity into these technical processes.

Various Agendas

The goals of AIM are filled with honor and pride. Collective intelligence, consistency in decision-making, sensing the hidden variables, and error checking live health providers, AI holds the promise to determine risk of disease onset, predict treatment success, manage complications, assist in ongoing care, and provide valuable advice on drug development and clinical research. All these goals appear within reach, with more powerful computers, vast storage farms, and absolute mountains of data.

Simultaneous to this, there is a small, but growing culture of technologists desiring what is a trinity of fairness, accountability, and

transparency. Why are these needed? What contributing factors require this mode of thinking? We see three main categories for diligence; AI's impact on doctors, on patients, and with regard to society. Let us briefly review these.

AI can lead to a de-emphasis on human agency. A key factor here is a human bias to trust automation results. Add to this, less time for doctors to interact with patients, due to schedule overloading, growing regulation on caregiving flexibility, growing legal liabilities, and administrative demands for doctors to be data entry clerks. As doctors become increasingly distracted by operating computers and following rules, they also become dissociated from their patients and isolated from the greater medical community. Patients, sensing they are on an assembly line, increasingly seek answers in social media and the Internet. Search engines, which are optimized to tell users what they want to hear, dish up biased results specially tailored for them. Differences between advice from their medical practitioner and what they see online lead to increasing mistrust of the medical community. This is certainly evident in the USA, where conspiracy theories are causing substantial social disruption. Patients, relying on information found online, can then justify unhealthy decisions regarding behavior and may be lulled into inaction due to errors of omission.

There are also broader forces at work. There is competition between the use of medical AI to save money versus saving people, a blindness to localized cultural values and a growing tendency to determine success based on patient satisfaction rather than treatment outcome. Encoded bias has been mentioned in earlier paragraphs.

On the broadest scale, there are issues surrounding the ownership of medical models and the enticement of large corporations to offer free or discounted AI services in exchange for AI data being under their control. Do these corporations have our best interests as a priority? There is also the risk of medical AI manipulation for use in cyber warfare, against both military and civilian targets. We need to consider the consequences of a foreign nation hacking into our systems, modifying the results of patients. Perhaps you would

receive an altered diagnosis, prognosis, or treatment. These issues illustrate the importance of human medical supervision, monitoring the plausibility of an AI result [13, 15].

Regarding AI, there are more fundamental risks, such as the risk of predictive inaccuracy. This risk may be due to generalization, unstable correlations, AI cheating, incorrect thresholding, overfitting, and lack of clinical context. These issues arise due to errors in medical records, multisyndrome patients, biased sampling, incomplete data, uncertainty in cases, and the error of data crowdsourcing instead of expert sourcing. Conflicting data can lead to unstable predictions, where a few new cases may cause dramatic shifts to outcome.

Transparency

Of course all these problems are correctable with diligence and imagination. The desirable path requires a few things: transparency, ubiquitous mobile sensors, federated thinking, and patient involvement [6–8].

An emerging field in AI is thinking visualization [9]. Hidden layers, especially of the stacks used in deep learning, is a black box to users. Akin to polynomials on top of polynomials at a large scale, these can become completely opaque to understanding. Methods of viewing the hidden layer connections, the priorities of input data attributes, and the linkage between correlations offer a key to thinking evaluation. The use of massive, coded point clouds, optimized for real-time display, can illustrate how a result was reached. As deep learning models become increasingly massive, our ability to render coherent abstractions of thought will be critical to transparency and detection of boundary violations, such as, not all hair is black, brown, blonde, or grey. Other methods of transparency are in the works as well, although visualization seems to have some of the densest data content.

As long as humans are encoding data, humans will be the bottleneck. Eventually, sensors with legs will be needed to feed the machine. The ability for an AI engine to gather its own data

and travel to the locations where such data is available will shift the equation. Robotics with a mind-numbing number of sensor modalities seems an inevitable future. Trained robotic observers that can see the visible, as well as the invisible, can begin to maintain the feedback loops of treatment, outcome, complications, mortality, litigation, cost, happiness, and predictive confidence.

At some point, as convergence occurs in specialties, multisyndrome complications will become an increasingly significant variable. Federated systems linking arrays of AI models will emerge, and ontology, coupled with communication standards, is a natural path. Today, competing companies are motivated to tunnel users into their farms and sell knowledge to financially vested third parties. Privacy regulation, ironically, can justify data silos to the benefit of large corporations. The development of open standards for AI models and their federation will be critical to averting monopolistic behavior. This flies in the face of open market financing, but hopefully medical data may eventually become an exception to data hoarding and alternative ways of funding AI research need to emerge.

When to Use AI in Medicine

A risk and benefit analysis should always be considered when implementing a new system to understand the consequences of a methodology. In the case of anemia it could be of great value to automate diagnostics and treatment as the procedure is straightforward. For example, blood tests indicative of iron anemia lead to a computer recommending you iron supplements. The risk with this procedure is fairly low. Even though you could be misdiagnosed, the consequence of such wrongdoing is negligible. Diagnosis of iron insufficiency stands in stark contrast to getting a cancer diagnosis where invasive treatments may be recommended. However, one may prefer an AI doctor to nothing. In rich countries we may have the opportunity to choose, whereas in poorer countries AI doctors may be the only ones available.

In a perfect world, vetted AI could make advanced health care available to the masses. However, before implementing a new system the entire value chain needs to be scrutinized. It is one thing to provide a patient with a diagnosis or prognosis, but what will the patient do with that information? A system needs to be in place to take care of the patient once the patient has been provided the results. Not all countries have straightforward systems to handle the medical care process from a to z. Thus, before implementing AI, there need to be clear structures and procedures regarding what the care process will look like. The patient needs to be able to act upon the provided information. Otherwise, one should consider the value of providing such info, if the patient is unable to act upon it. This is an ethical discussion. In some cases, it may be valuable for a patient (and/or their loved ones) to know that they suffer from bipolar disease, as this knowledge may help them to understand their behavior. However, a patient may not want to know they suffer from cancer if there is no available treatment. Whereas another patient may desire the prognosis, even though it is untreatable because they want to make the most of their remaining life. Would you like to know four years in advance that you have a high probability to fall ill in a potential deadly disease? Technology itself is not good or evil, humans are. AI in medicine is a revolution that can either destroy or save the world. It is up to us.

Abstract

This chapter reflects upon the research and innovation at the forefront of artificial intelligence (AI) from hardware to software and their application to draw the potential future

P. Mistry (✉)

applications of AI that will change how care is delivered irrevocably. Techniques including machine learning, natural language processing, and computer vision will be applied to enable earlier diagnosis, give patient control, and create entirely new categories of diagnostics. AI has the potential to not just digitalize what healthcare currently does but provide uniquely different ways forward that will revolutionize care delivery.

Introduction

This chapter is intended to give the reader a glimpse of how AI may alter health and care services in the longer term. The day-to-day changes wrought through AI-powered tools may be dramatic or subtle; either way, the impact is anticipated to be far-reaching.

Three things fuel AI progress – data to inform and train software, algorithms using data to replicate “intelligence” in software, and hardware that runs the algorithms. All three of these areas continue to advance at pace which in turn will accelerate AI applications and their impact. Data is becoming increasingly accessible in healthcare systems, and many healthcare systems are tackling interoperability and transitioning to integrated care providers [1]. This new approach aims to dissolve silos in healthcare systems through the integration of primary, secondary, community, and other health and care services. As integrated care providers mature, the result will be integrated datasets and, alongside consumer devices, richer more comprehensive data pools that can be used to train AI algorithms – improving AI performance. Hardware development is also progressing at pace, and companies are developing bespoke silicon chips specifically designed for AI applications. These chips are being designed for use in every computing device from the phones in our pockets to the tablets and

laptops in our bags, to the computers on our desks and data centers for cloud computing. These AI-optimized silicon chips (called AI accelerators) will continue to push the boundaries of speed and AI complexity across devices. Existing algorithms will get faster, and algorithms that did at one time take too long now become practical. Finally, new AI techniques continue to be developed and refined improving efficiency and functionality. When combined with more specialization it means algorithms become less multi-purpose and more tailored toward a specific application improving efficiency. AI is now being applied to develop the next generation of AI algorithms and techniques [2]; as this continues to develop, new AI techniques are likely to emerge and improve on speed, accuracy, and ability to handle increasingly more complexity.

We can speculate upon how the combination of comprehensive rich datasets with optimized faster hardware and new algorithms with new techniques will unlock AI functionality that will look like magic. Perhaps these will even pave the way to the development of general AI, and the dream of the AI doctor will become a reality. However, this chapter will remain grounded in current research to shine a light on potential developments that are tantalizingly out of reach yet possible in the near future. At the end of the chapter, we will briefly cover how AI may unlock totally new ways of working.

Natural Language Processing

Can Future AI Systems Use Natural Language Processing to Improve How Individuals Engage in Their Health?

Healthcare systems are moving toward a more person-centered model of care provision with health literacy, patient activation measure, and shared decision-making becoming more important as a way of categorizing the capability, willingness, and approach of co-deciding care alongside the patient.

A patient with good literacy skills is an individual empowered to be in control of their health, care, and wellbeing. Literacy is essential for being

able to understand the situation and be confident in making decisions. Literacy underpins accessing self-help, understanding consultations, engaging in remote consolations, researching and digesting background information from trusted sources, reading and understanding test results, being able to understand medical records, interpreting medical guidance and medicine side effects, and uncountable more aspects of health and care.

The literacy capability challenge is twofold: i) patients' literacy levels need to be adequate enough that they can convey information and comprehend what they are reading (e.g., in records, test results, or patient information leaflets) or told (e.g., in consultations or conversations); and ii) clinicians need to be able to gauge a patient's literacy level and match this in all forms of communication. AI has the potential to alter radically shift information exchange improving understanding and patient engagement.

Natural language processing (NLP) essentially takes speech (or text) that's constructed with natural sentence structure through normal dialogue and converts this speech into text (or text into speech). Currently NLP is capable of taking a range of natural language sentence structures and words to confer a generalized meaning irrespective of how the original sentence is structured or the variety of the words used, e.g., NLP can assume the equivalence of lots of pain, painful, really hurts, and acute pain.

Current linguistic research is exploring how language and meaning change across different academic disciplines. NLP tools are improving the understanding of language and communication, research findings show that subjects as different as physics and history have similarly complex features [3]. This research is improving our knowledge of how language can be restructured to be interpretable at varying degrees of complexity. There is complementary work bringing together communication scientists, computational linguistics researchers, and health service researchers and staff; it shows promising indications of where language complexity and NLP may lead in the future. The research demonstrates NLP tools can analyze and interpret patient communications to gauge a person's health literacy level with good accuracy (>80%) [4]. The tools can

also interpret clinician communication in real time and advise if the health literacy level is incompatible with the patients' capabilities [5].

As this strand of NLP research and tools progress in the future, it will be possible to have a more nuanced interpretation of the natural language sentence structures within health and care. This will create NLP software tools that are able to span different levels of literacy and sentence structure sophistication (see Fig. 1). What this means in reality is that clinical information could be translated into audience-appropriate text, speech, or visual media depending upon the literacy level of the individual. This use of AI will empower individuals to access understandable health and care information in their records, medication guidance, and trusted sources without requiring additional staff resources. This development of NLP will be the bridge joining an individual's capabilities with specialized information.

Unlocking Clinical Knowledge to Address Common Patient Concerns Through Clinical Avatars

A positive diagnostic test for a life-altering or life-threatening condition commonly leaves patients feeling disorientated. They need time to process the news, consider the implications, and come to terms with the diagnosis. Directly upon receiving the news, the patient will have immediate questions, but more often, they or their family have many more questions which spring to mind hours, days or even weeks after the consultation. Patients either need to wait for another contact with the clinician or attempt to navigate the information available through the Internet or patient information leaflets. Waiting for another appointment can increase stress and anxiety, which is detrimental to their mental health. Furthermore, an appointment to answer routine questions might not be the most effective use of clinical time during an appointment. Instead, the clinical time could be better used if the patient has their questions answered before their next appointment enabling a more therapeutic and informed consultation. Navigating patient information leaflets or information on the Internet is an option but

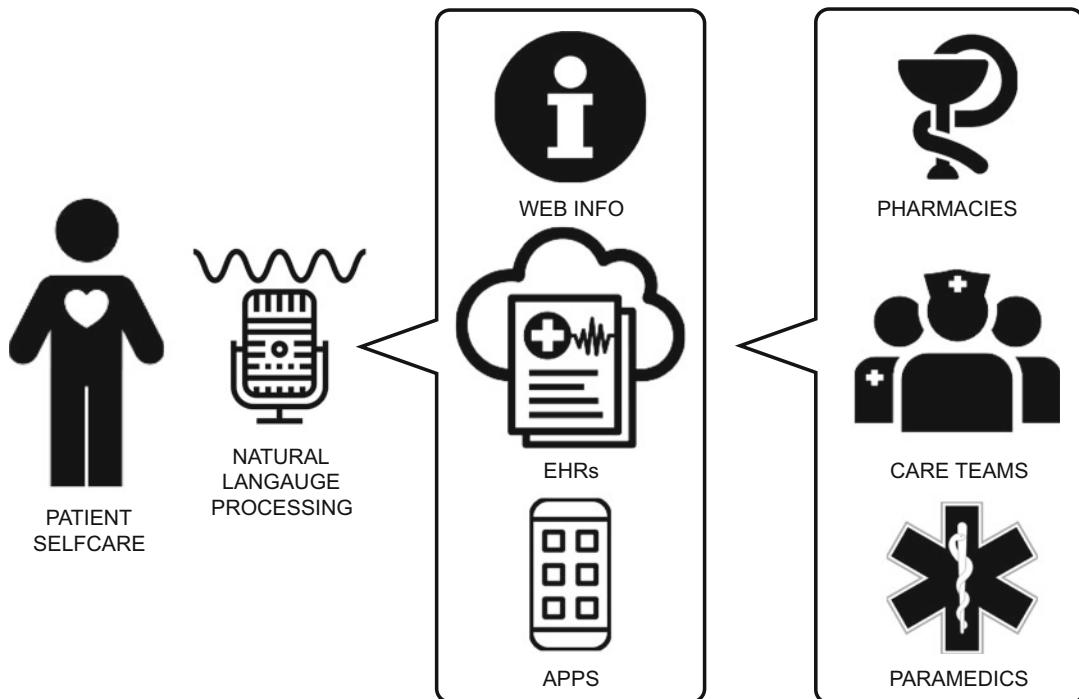

Fig. 1 Natural Language Processing (NLP) will enable clinical information to be translated to meet the readers capabilities and needs (Illustration: Dr Niklas Lidströmer)

requires patients to have a good enough level of literacy (as discussed above) and be able to find trusted sources of information. The literacy requirement excludes patients, while incorrect information has the potential to cause more harm.

AI in the future has the potential to change this to improve patients' knowledge and how clinical time is used. NLP could be applied to create clinical chatbots for routine information [6]. Chatbots are now very common, but the quality is highly variable, with many of us having very good and very frustrating experiences.

In the future, the technology will be mature enough for specialists, or hospitals, to be able to develop chatbots that act as clinical avatars available 24 h 7 days a week to answer patients' questions on their recent diagnosis or ongoing treatment [7]. This has the potential to help patients navigate their change in health and have timely trusted information while saving clinical time. Such avatars will be able to provide factually correct responses to a patient's queries when a patient needs it. Orientating these tools through

healthcare organizations will enable the combined clinical knowledge and expertise of multiple specialists to be used to train the avatar sharing the burden to create and maintain the avatars and also increasing the scope of the information available. A clinical chatbot would need additional oversight and training to mitigate against medical risk and harm. However, the benefits include saving clinical time and improving accessible trusted knowledge for patients for routine questions in common clinical areas.

There is increasingly more research focus on therapeutic empathy and the potential for machines and software to have perceived empathy [8]. Empathy is an essential skill for therapeutic consultations. While public sentiment is generally quite skeptical about machines exhibiting empathy, research suggests that people naturally project social rules and expectations on machines [9] which contribute to perceived empathy. When engaging with chatbots, people prefer health advice chatbots that exhibit sympathy and empathy [10]. Longitudinal studies demonstrate people build relationships with

chatbots; however, the repetitive and predictive nature of current chatbots means relationships are not long-lasting. As chatbot functionality continues to mature, clinical avatars will take on a conversational therapeutic function for some clinical situations and conditions for some individuals. It is important to note this is very different to an AI doctor, clinical avatars have the potential to provide short-term support through information and a form of treatment through therapeutic conversations, but they are likely to continue to be capable of functioning in narrow application areas and a limited number of situations.

Engineering the Next-Generation Electronic Health Record and Improving Staff Workflows

Electronic health records (EHRs) are longitudinal records of a person's health and their interaction with the health system. They have been created and implemented in different ways in different healthcare systems for slightly different purposes – e.g., care provision, reimbursement, etc. Capturing the information takes the time and attention of highly qualified clinicians; studies show out of an 11.4-h day, approximately 6 h of clinician time is used for data entry [11]. It is believed that EHRs are time-consuming and disrupt workflows to such an extent that they are contributing to increased pressure on clinicians resulting in burnout [12].

EHRs are essential, they put crucial information at the clinicians' fingertips to improve the quality of care and reduce medical errors, but they also contain bias and variation in detail. Different clinicians take different approaches to recording patients' information. Some clinicians record information verbatim; others record interpretations [13]. Similarly, consultants dictate or record summaries for support staff who create the records and/or relating correspondences (e.g., letters) creating variation. Furthermore, EHRs hold multiple different types of structured and unstructured information, from test results to consultation notes to specialist clinic letters and images. All these in combination mean that there's a

significant degree of variation in the information quality and a range of information types.

Natural language processing (NLP) is being developed to reduce some of this administrative burden on healthcare workers [14]. The speech-to-text capability of NLP has the potential to be used to record and categorize a patient's electronic health record without the direct involvement of the clinician. A clinician can dedicate their time in consultation instead of multi-tasking. This reduces cognitive load decreasing burden and improving the quality of consultation time. It is anticipated this will improve the quality of care and save time for the healthcare staff. The information captured and coded would be more consistent across staff and provider organizations creating the opportunity for improved research and analysis for population health interventions, for example. It will also be possible to use the analysis of vocal patterns as a new type of indicator of clinical condition.

Along with the time savings and the improvement in consultations, there may be unanticipated consequences. The process of creating EHR entries is believed to help clinical staff to synthesize and assimilate the information disclosed by the patient [15]. Using NLP for EHR entry processes could impact how staff develop clinical judgment and clinical knowledge; changes to medical training will be required to circumvent any detrimental effect on clinical judgment.

Machine Learning, Deep Learning, and Neural Networks

Improved Disease Detection Through Computationally Enabled Diagnostics

Biomarkers are the rockbed of modern medicine, and biomarkers that are well characterized have repeatedly demonstrated that they correctly predict clinical outcomes across a range of treatments and populations [16]. This means an individual's physiological state can be monitored or managed with confidence using one or more biological markers.

A biomarker was defined in 1998 by the National Institutes of Health Biomarkers Definitions Working Group [17] as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.”

Generally biomarkers are measured and monitored with diagnostic medical devices. These are devices that accurately measure one or more biomarker, and the accuracy is verified through evidence that is generated using appropriate methodologies (such as a clinical trial). The devices are checked that they are acceptably low risk through adherence to medical device regulations. Non-medical devices such as wearables do not have this rigor in evidence and regulation, but there is potential for non-medical devices to be used to change how diseases are detected and monitored.

Wearables are devices that are not designed to be medical devices but consumer wellness or fitness devices. The sensors found on wearable devices often measure medical biomarkers such as heart rate, breathing rate, ECG, blood oxygenation, etc. But wearables do not undergo the level of scrutiny, evidence generation, or regulatory approval that is expected of medical devices. Wearable devices have a number of unique aspects compared to medical devices which could significantly alter how diseases are detected, treated, and managed. Wearables generate data in much higher quantities than medical devices; this is because they have high sampling frequencies and are always on the person. They also potentially have higher levels of variability and errors – the accepted variation between devices is greater for fitness purposes than health applications, manufacturing tolerance can be larger, devices do not have mandated regular maintenance and may be jostled when worn [18]. So, while there are huge amounts of data, there are also significant noise, irrelevant data, and poor-quality data.

AI is the ideal tool to create meaning from the vast quantities of wearable data. With AI, data analysis can be automated by rejecting abnormalities, flagging non-compliance, and reducing variance to provide data that is interpretable and

then apply analysis to derive clinically meaningful insights. This field which can be considered as computationally enhanced diagnostics is in many ways analogous to computation photography (see Box 1).

Box 1 Computational Photography

AI has unlocked a revolution in smartphone photography – tiny cameras, powerful silicon chips, and AI in combination enable images to be created which are far better than raw camera images. AI techniques process the raw camera image, and their application enhances and improves the quality and features of the images captured.

AI-powered software will effectively interface between the wearables that measure biological markers and time-constrained healthcare staff who seek actionable insights with which to support their patients. These AI software tools at the most basic level filter the jostles and noise to leave the usable data. As AI advances, it will create personal baselines for everyone individualizing the detected changes and create inferences by adding other data sources (e.g., location, pollen, pollution, temperature, etc.) to link triggers with symptoms. These in combination will complement existing medical diagnostics to improve the diagnosis, treatment, and management of clinical conditions. Information will be more relevant to the individual and actionable to address deterioration or symptoms.

This AI software could dramatically change healthcare and medical knowledge. Access can take a much more personalized approach based on data related to physiological or psychological changes instead of the current structure of routine appointments. Wearables will give frequent data sampling across broad demographics, and this will change how disease is measured. Firstly, the quantity of data gives more insight on range of variation in clinical conditions. Secondly, the ability to measure biomarkers in real-world circumstances. The ramifications of this data and understanding is a change in the very nature of how disease is defined if high degrees of

individual variability are found. For example, it will raise questions on what constitutes as the boundary between ill-health and good health.

Entirely New Ways of Diagnosing Disease Using Digital Biomarkers

Digital devices (phones, tablets, computers, etc.) are very different to most wearables; our digital devices contain sensors that measure what we do but do not measure the generally accepted clinical biomarkers. Instead, digital devices measure (or can measure) more mundane things such as how we are typing or communicating. It's possible that this more mundane activity can give insights into our wellbeing and our health conditions.

How we engage and use digital devices has the potential to create new biomarkers – digital biomarkers (see Fig. 2) – that give indications on our health. For example, the gait of the way we walk changes with certain diseases [19] and can be detected using machine learning, the way we tap

out a text message can change with the onset of tremors [20], how we cough can indicate the type of respiratory illness [21], and our phone usage behavior can indicate our mental health [22].

Our digital behaviors indicate our physiological and psychological wellbeing; this can be utilized to create new types of biomarkers for the early detection of disease and ongoing disease monitoring. Similar to wearables, the data generated from these digital biomarkers are variable and noisy, and AI is essential to identify the usable data and link the various data types to create clinically meaningful digital biomarkers. Early indications are that digital biomarkers are unique to an individual [22] which ordinarily would pose a problem to train machine learning algorithms, but the quantity of data each person generates should avoid data limitation problems. With the right machine learning algorithms, it will be possible to track how an individual engages with their devices, examining how we scroll, swipe, tap, etc.; creating a personal baseline for each type of engagement action; and using meaningful divergence from the baseline to indicate deterioration in health and wellbeing.

AI is well suited for such a new approach for diagnosing illness, and it requires tracking and analyzing thousands of data sources daily for each individual and across multiple devices and with a huge number of variables. Approaches such as machine learning, deep learning, and neural networks are ideal to analyze vast datasets so that we can identify patterns and establish new patterns or deviations from existing patterns. It is these new patterns and deviation from existing patterns that would firstly generate evidence that these digital biomarkers give indications of clinical conditions and help provide timely indication of a meaningful clinical change in the individual.

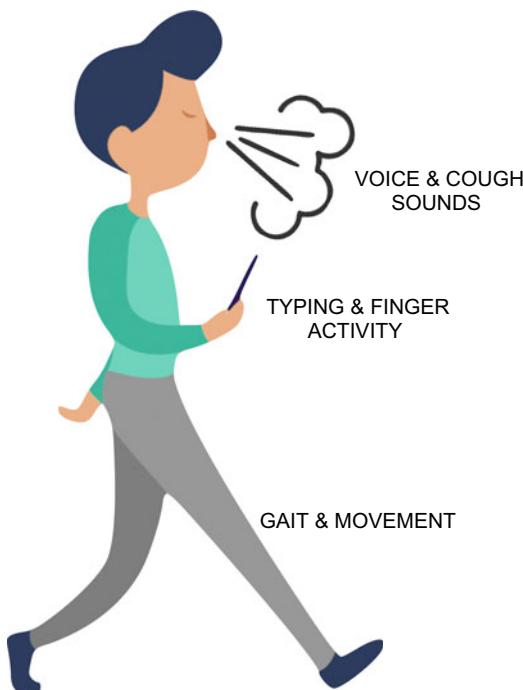

Fig. 2 Our use of digital devices has the potential to create a new generation of biomarkers (Illustration: Dr Niklas Lidströmer)

AI-Driven Population-Level Interventions for Entire System Planning and Optimization

The quantity of data generated from one wearable is vast, and the above section demonstrates the need for AI to make sense of it all and create

actionable insight on a person's health. The quantity of data collected across a geographical region (such as that used for population health management) is orders of magnitude larger. This huge data quantity across a regional population has the potential to power population health interventions and public health initiatives complementing information from healthcare records. However, the challenge of using such a large volume of data is also considerable.

Machine learning algorithms will be able to support the data analysis by identifying patterns through linked data. For example, AI software can be applied to electronic health records and consumer devices to create insight on the health trends for local populations and within particular clinical conditions. This will help to target local-level interventions for particular clinical conditions in the first instance it could inform a need to improve particular care pathways. Fusing various sources of health and environmental information (e.g., air pollution, pollen, noise pollution) has the potential to help forecast service capacity changes, e.g., medication usage, mental health needs, social prescribing needs, etc.

Computer Vision

Using AI to Generate Real-Time Synthetic Images to Improve Surgical Interventions

Currently, AI software applied to medical imaging is able to improve the quality and speed of specific parts of the diagnosis process. AI within hospitals has demonstrated the potential to improve the speed of segmentation for clinical diagnosis and quantify changes in physiology (e.g., tumors, retinopathy, dermatology, etc.) [23]. AI is unlocking specialist tools and making them available in the hands of the public; it is now possible to detect diabetic retinopathy [24] and identify melanoma [25] using AI-powered software and a smartphone.

AI techniques have the potential to improve medical images through feature enhancement and interpolating features to improve the resolution of small structures beyond the capability of

the hardware. Computational techniques will also make it possible to artificially increase the contrast of low-dose live x-ray images which would reduce exposure to ionizing radiation while improving visibility for the surgical team.

As AI-powered imaging systems improve, the benefits will compound. Currently, during surgical planning, images are taken using several modalities. Commonly in, for example, cardiac surgery, live x-ray is used for tracking surgical instruments, and past images from other modalities are overlaid to aid the intervention. In the near future, software will be able to automatically combine images from different modalities to create fused images that merge the advantages of each modality into a composite image [26]. If bias and error generation issues can be solved, it will pave the way for more sophisticated AI tools trained on pre-operative images and video and combined with live x-ray during interventions. Such tools will be able to reconstruct medical images and video, and so they will simulate live videos composed of information from several modalities and display this to surgical teams during interventions. Such AI imaging fusion will improve capture speed, quality, and accuracy of the images enabling lower functionality equipment to be used for higher sophistication purposes. It will also enable lower dosage of radioisotopes and x-ray radiation improving safety and reducing costs.

AI-Driven Surgical Success Measures to Create Intelligent System-Wide Resource Planning

In the near future, machine learning applied to electronic health records will identify correlations between surgical intervention and recovery times predicting the requisite post-operative rehabilitation support. This could be used at surgical planning stages to forecast the future resources that will be required such as community support and rehabilitation required.

The accuracy of such a tool would vary considerably with a dependency upon multiple variables not just the intervention type limiting the utility. The use of computer vision will further

enhance these predictive models so they can use medical imaging from surgical interventions to provide additional data to train models. The use of image features from surgery combined with electronic health records data will give an improved forecast of post-operative needs of the patient. The combination of retrospective image data with information on procedure outcomes will enable forecasting of resources required for successful recuperation; this would aid budgetary forecasting and enable improvements to efficacy. These models could then be iterated upon, incorporating rehab and fitness data to improve the projections in near real time.

Robotics

Partly Automated Surgery for Rapid Recovery and Safety

Robots for robotic surgery have been available on the market for over a decade [27]. The robots however are not automated, that is, they always

require a human operator – usually in the same room or an adjoining room. This limits many of the potential benefits of robotic surgery, and when combined with hardware limitations, it means that they have only been utilized in niche areas since becoming widely available.

More recently, with the aid of high-fidelity Internet connectivity, tele-robotic surgery has started to emerge [28]. In this case, the human operator can theoretically be anywhere in the world and can remotely connect to the robotic equipment to remotely operate on a patient.

The advent of tele-robotic surgery has unlocked access to additional information and data alongside the previously accessible medical image data (see Fig. 3). It will soon be possible to compile these data to automate one or more steps of an intervention, but it might not be possible or advisable to automate entire procedures. For example, through computer vision techniques, it will be possible to use AI to plan the incision step of an intervention automating a robot to carry out this part of the process potentially reducing scarring and reducing recovery times.

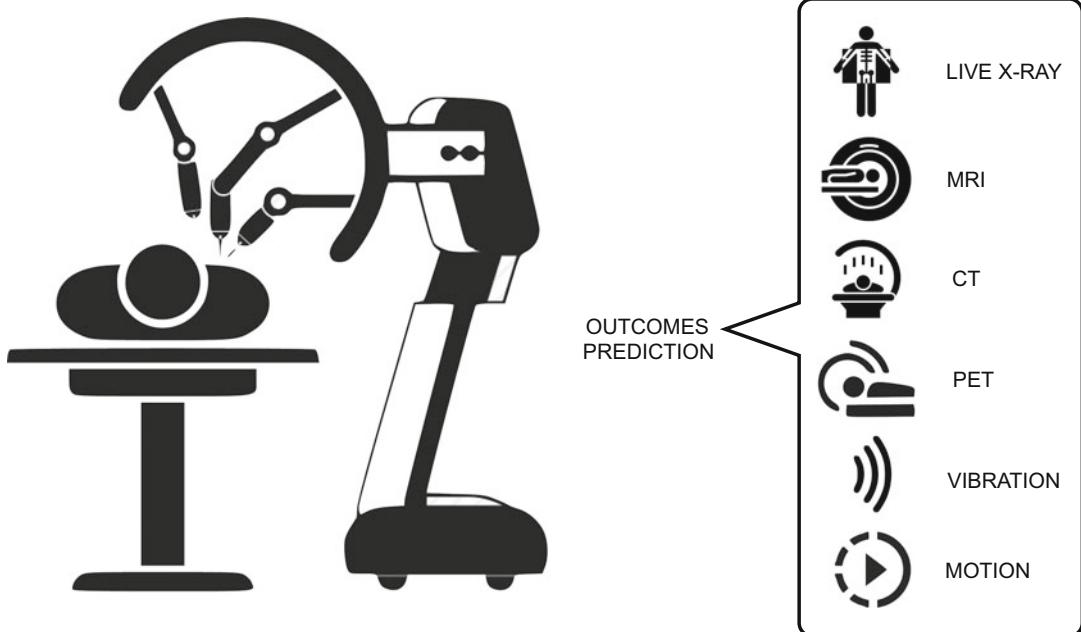

Fig. 3 Remote robotic surgery utilising combining stored and live images with predictors and tracking to estimate outcomes and rehab needs (Illustration: Dr Niklas Lidströmer)

In the long term, it might be possible to automate entire interventions; in the short to medium term, steps of highly routine interventions will become automated and use robotics; but in the medium term, it's unlikely that entire operations will be automated. In areas such as congenital heart disease, the variability in condition and intervention approach creates a high risk of unforeseen emergencies this means we will need humans to be involved and engaged in the surgical interventions. Semi-automation reduces human awareness and perception in the moment, while perceived high-fidelity systems can result in less vigilance from human operators both of which can increase harm (see Box 2).

Box 2 Self-Driving Cars

The early 2000s onward has seen an explosion in the development of autonomous vehicles (or self-driving cars). The combination of sensors, computing power, and software has resulted huge leaps in capability progressing toward automating vehicles, but they are still only semi-automated. These semi-autonomous vehicles have now travelled millions of kilometers on public roads improving the algorithms and capabilities with each journey. Along with the training, there have been accidents, sometimes despite a person sitting in the driver seat [29]. The reason for this is a lack of engagement in the action of driving which reduces attentiveness requiring longer to respond to a rapidly changing situation. This can also give insight into the risks of semi-automated surgery.

In a driving situation that rapidly changes, it's been documented that a person not actively controlling the vehicle has difficulty re-establishing context (referred to as "rapid onboarding" by psychologists); it's essential the person take control of the vehicle as the automated system is unable to handle the situation. However, it's likely the human driver takes time to re-establish situation awareness critical time that can make the

difference to whether there is an incident. Research shows the onboarding times grow longer when high levels of automation are combined with complex situations [30]. Furthermore, there is growing evidence that prolonged use of automation deteriorates human skills, with cognitive skills deteriorating quickly, but manual skills remain. However, the cognitive skills are essential to use our manual skills effectively [31].

AI-augmented surgeons carrying out surgery using robotics could improve patient safety and reduce adverse incidents. The use of machine learning with computer vision could aid the development of AI systems that are able to analyze intervention images in real time and reduce operator hand tremors. The same images with AI interpretation could establish safety based AI algorithms which guard against commonly avoidable surgical errors [32].

New Frontiers in AI

AI Bias Gives Another Perspective on Driving Improvement

AI has the potential to be a technology that knits together other technologies and unlocks insight that has until now been inaccessible. With all such technologies, their immediate application replicates the status quo – the current way of doing things. However, in successive generations of AI, the unique capabilities will get used more and will completely change how we approach and deliver healthcare.

Healthcare Service Redesign

Often AI is considered to be a tool that solves a problem, that is, we feed data in, and it gives us an answer. However, data has historically been used to identify areas that warrant a closer look. AI can be used for this approach to power a learning and evolving healthcare system that uses AI to suggest quality improvement projects to reduce systemic inequalities.

AI is a data-driven software tool, the algorithms and software are written by people, and this can include biases. Additionally, the data

collected to train systems may replicate these biases or introduce new ones. Using such data-driven software risks perpetuating biases, hard coding them into complex software applications, and embedding and exacerbating inequalities [33]. It is absolutely essential that the AI software are evidence based and regulated to ensure acceptable levels of risk. Equally important, if not more so, is to ensure the healthcare system has the knowledge, processes, skills, and tools (including datasets) to audit and interrogate AI software for bias. Firstly, this would ensure biased AI is identified prior to being implemented so the exact use case of the software can be defined; otherwise, there is a risk of widening inequalities or even harm [34]. Secondly, with this knowledge, it may be possible that AI can help improve healthcare services in novel ways. By their nature of being biased, AI can provide insight into where there are inequities in service provision.

AI applied to local population-level data could be used as a healthcare service redesign and improvement tool to help address inequalities within particular clinical conditions by helping to monitor pathway effectiveness for particular cohorts or surface a pattern of need that is currently unidentified.

This information can help to identify everyday services and pathways which can be improved for specific populations to continue to develop an equitable healthcare system.

Evidence-Based Individualized Treatment Pathways

There's potential for AI to power a next generation of clinical decision-making, one that supports healthcare staff to use all the interventional tools available to support patients.

For a long time, treatment approaches have been quite simple with a range of drugs, therapies, or surgeries. With progress comes a proliferation of medications, therapies, and surgical interventions all with different efficacies, risks of side effects, and harm. The progress in genomics has compounded the complexities in selecting the right medication for an individual. Drugs have

been combined with devices for common surgical interventions like angioplasty. There are a growing interest and evidence base around the use of social prescribing – social engagement to treat non-communicable diseases. Digital therapeutics (apps as an intervention and treatment approach) is another area with growing interest and evidence. It's not possible for a healthcare worker to know about all of these and how they can be fit together to improve a patient's health. The default is to rely on familiar treatments which might not be the best suited for that particular individual.

AI is a well-suited tool to help make sense of all the potential treatment and intervention choices to create options (see Fig. 4). AI can identify all the treatments with evidence that match the individuals' demographics giving them the best possible outcomes and align to their preferred treatment methodology. AI can filter, adjust, and overlay these multiple approaches to suit the patient's preferences and goals. When combined with the clinical risk and need this presents a portfolio of options of essentially personalized pathways that can be selected from by the healthcare staff with the patient, to find an approach which would best suit the patient. Using the most effective combination of medicines, surgery, therapies, digital tools, and community activities available not just the tools most familiar to the consulting clinician.

The Future of AI in Medicine

This chapter outlines how AI has the potential to substantially change and improve the delivery of healthcare. As covered in the beginning of the chapter, AI can improve how we currently think of healthcare system and delivery. The two theoretical scenarios provided at the end of the chapter demonstrate that AI has huge potential to change how we design healthcare services in ways that have never been seen before. In the short term, we will see AI tools that replicate current care provision identifying features in images, symptom checking, creating electronic health record entries, etc. In the medium to long term, we will see completely new ways of creating patient pathways, monitoring disease, and improving the

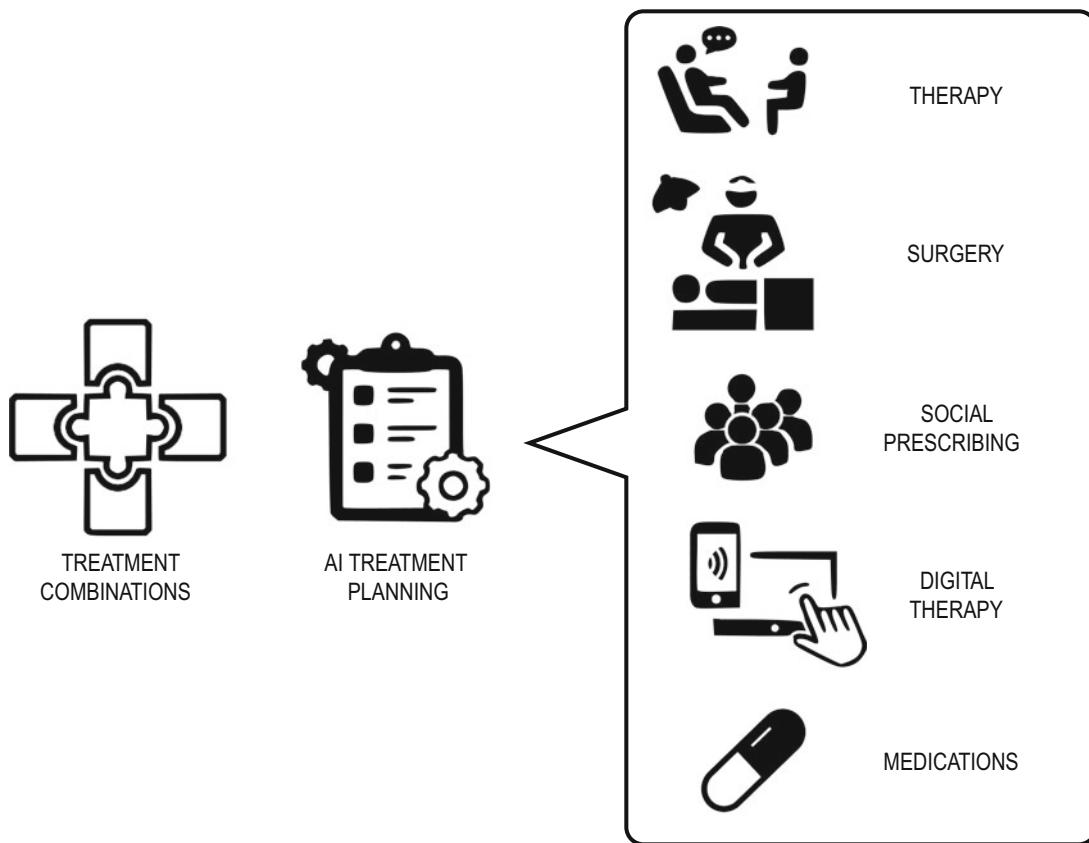

Fig. 4 AI which combines multiple evidence and service information sources to provide options for combinations of treatment approaches (Illustration: Dr Niklas Lidströmer)

healthcare service. Much of the AI development discussed in this chapter is at the forefront of what is possible; it challenges processes and standard guidelines. Similar to the Wild West, and with all new frontiers, the rules need to be adapted and applied to minimize risk, remove bias, and ensure evidence, and high quality is at the core of AI applied to medicine.

Abstract

Artificial intelligence is becoming seamlessly integrated into our everyday lives, augmenting our knowledge and capabilities in driving, avoiding traffic, finding friends, choosing the right movie, or finding the perfect song, and, perhaps most importantly, it is entering into

healthcare and medical diagnostics with large brave strides. As this twenty-first century “man meets machine” reality is unfolding, several social and juristic challenges emerge for which we are in general poorly prepared. We here review social dilemmas where individual interests are at odds with the interests of others, and where artificial intelligence might have a particularly hard time making the right decision. Examples thereof are the well-known social dilemmas of autonomous vehicles and vaccination. We also review juristic challenges, with a focus on torts and product liability that are due to artificial intelligence, resulting in the claimant suffering a loss or harm. Here the challenge is to determine who is legally liable, and to what extent. We conclude with an outlook and with a short set of guidelines for constructively mitigating described challenges, with a focus on artificial intelligence in medicine.

Social dilemma · Vaccination · Cooperation · Reward · Punishment · Agent-based model · Tort law · Legal liability

Introduction

A broad body of literature anticipates that in the years to come, intelligent objects will overtake more and more jobs that people have traditionally performed, from driving, diagnosing diseases, providing translation services, and drilling for oil to even milking cows, to name just some examples [1]. In 1999, a British visionary Kevin Ashton coined the term “Internet of Things” (IoT) to describe a general network of things linked together and communicating with each other as computers do today on the Internet [2]. The connection of objects to the Internet makes it possible to access remote sensor data and to control the physical world from a distance [3]. Data communication tools are changing “tagged things” into “smart objects” with sensor data supporting a wireless communication link to the Internet [4, 5]. This means that the manufacturer can make fewer visits, reducing costs and producing less disruption and higher satisfaction for the customer [6]. Remote diagnostics, where complex manufactured products are monitored via sensors, may not, however, only be important for repairing industrial machines but also for human health, such as remote control of pacemakers [7]. The widespread use of Wi-Fi and 4G enables the communication with smart objects without the need of a physical connection, such as to control customers’ home heating and boiler from their mobile or laptop. Mobile smart objects can move around and GPS makes it possible to identify their location [3]. This technology facilitates the development of so-called connected or automated cars that enable the driver automatic notification of crashes and speeding, as well as voice commands, parking applications, engine controls, and car diagnosis. It is foreseen that trucks will soon no longer need drivers, as computers will drive them, without the need for rest or

sleep. Moreover, each Philips or Samsung TV comes nowadays with an application called “Smart TV,” which consolidates video on demand function, the Internet access, as well as social media applications [8]. Objects are thus becoming increasingly smart and consequently autonomous. There are many implications of this in the field of medical law, in particular in relation to the mobile health apps, e.g., a smart phone that is acting as a thermometer or as a blood pressure monitor, applications that track events, retrieve medical content, or allow patient-doctor communication.

However, autonomous objects will also cause accidents, invade private space, fail surgeries and fail to diagnose cancer, and even engage in war crimes [9]. As autonomous objects will become more and more commonplace on streets, on the skies, in households, and in medicine, their social and legal status will only grow in importance. Considering that autonomous objects are not a matter of “if” but rather of “when” such technology will be introduced, the regulatory dimension might be decisive in this respect, as is the prior identification of socially challenging situations where not only the user but also others may be adversely affected. If the activity of autonomous objects, and more generally of artificial intelligence, is not properly regulated, it will not be broadly accepted as a more efficient and safe alternative to human controlled objects or human decision-making. However, the autonomy we give to machines may render many established legal doctrines obsolete, and more importantly, affect what we judge to be “reasonable” human activity in the future.

Modern businesses and technological developments thus need to be followed by appropriate regulation that will control the associated hazards and thus enable the industry to flourish. At the same time, regulation has to leave enough flexibility so that law does not restrict technological development. This development is also extremely important in the field of medicine, where technological developments bring about a special revolution in terms of medical devices, but which must also be accompanied at the right time by appropriate regulation, in order to take advantage of the benefits that new technologies bring to patients

and to avoid potential threats, either in the form of products which may harm human health or in the form of tampering with personal data and the right of individuals to confidentiality. Considering that the industry, the consumers, and patients are getting increasingly smart, smart regulatory solutions need to follow [10], establishing the right balance between safety, liability, and competition on one side and innovation and flexibility on the other. In this respect, regulatory requirements can either restrict technological development, in particular if liability for potential errors is strict or if taxation encourages human workforce, or boost it, if the standard of liability is set so that safety of computer performance is compared to the safety of certain human activity, such as driving.

In the European Union in particular, there are delicate discussions taking place on who should be competent to set the rules in this respect, Member States or EU institutions. Moreover, it is also important that this regulatory process does not bypass democratic governance principles and that industry is included in the regulatory process, as well as that self-regulation replaces legislation where possible, so that only general regulatory requirements are set by the public authorities and the market defines the technical solutions [11, 12].

In what follows, we will review social and juristic challenges of artificial intelligence in more detail, and then proceed with conclusions and guidelines as to how they might be successfully overcome.

Social Challenges

Preceding regulation and any legal action that may follow is the identification of situations where artificial intelligence is likely to be particularly challenged when it comes to making the right decision. Some situations are of course very clear-cut. A movie recommendation system should obey parental restrictions and not serve up R rated or NC-17 rated content to a child. Likewise, an autonomous vehicle should not crash into a wall for no apparent reason. But oftentimes situations are far less clear-cut, in

particular when not only the user but also others are involved.

Social dilemmas are situations where what is best for an individual is not the same, or is even at odds, with what is best for others. Already in the early 1980s, Robert Axelrod [13] set out to determine when individuals opt for the selfish option, and when they choose to cooperate and thus take into account how their actions would affect others. Of course, cooperation is a difficult proposition because it entails personal sacrifice for the benefit of others. According to Darwin's fundamental On the Origin of Species, natural selection favors the fittest and the most successful individuals, and it is therefore not at all clear why any living organism should perform an altruistic act that is costly to perform but benefits another. In Axelrod's famous tournament, the so-called tit-for-tat strategy proves to be the most successful in the iterated prisoner's dilemma game. The strategy is very simple. Cooperate first, then do whatever the opponent is doing. If the opponent was cooperative in the previous round, the strategy of tit-for-tat is to cooperate. If the opponent defected in the previous round, the strategy of tit-for-tat is to defect. This is similar to reciprocal altruism in biology.

But what about artificial intelligence, and one-off situations where the "machine" has to determine whether to act in favor of the owner (or user), or in favor of others? This was brought to an excellent point by Bonnefon et al. [14], who studied the social dilemma of autonomous vehicles. Inevitably, such vehicles will sometimes be forced to choose between two evils, such as running over pedestrians or sacrificing themselves and their passenger to save the pedestrians. The key question is how to code the algorithm to make the "right" decision in such a situation? And does the "right" decision even exist? Research found that participants in six Amazon Mechanical Turk studies approved of autonomous vehicles that sacrifice their passengers for the greater good and would like others to buy them, but they would themselves prefer to ride in autonomous vehicles that protect their passengers at all costs. Put differently, let others cooperate, i.e., sacrifice themselves for the benefit of others, but we would prefer not to.

An in essence, the same social dilemma emerges with vaccination. Old-school vaccination strategies, although admittedly easy to implement, demand that a certain fraction of the population needs to be vaccinated for herd immunity to set in. But with major progress in the structure and function of social networks [15], the same problem could be approached more systematically, by means of determining key individuals in such networks, and vaccinating them based on various metrics related to centrality, betweenness, and influence. Factors that could also be considered include temporal aspects such as traveling and commuting. A contemporary review of these developments is by Wang et al. [16]. Such advancements call for artificial intelligence, but they inevitably create a social dilemma. Will the individuals chosen for vaccination agree to this? Should they agree to being vaccinated for the good of others? Of course, the right thing to do is to agree, but the choice may nag on some of the vaccinated. Why us, why not others? The initially mentioned “old-school” strategies avoid this dilemma by essentially demanding all be vaccinated. Perhaps this is the easiest solution to the dilemma – to avoid it altogether. But easy as it may be, it neglects major progress done in many fields, including network science and digital epidemiology, and it precludes our capitalization on this progress. How many doses of vaccine could have been saved and used elsewhere for efficient immunization? How many people would not have needed to cope with some of the more adverse side effects? Would it be ethical to reward those that do get vaccinated, or even punish those that decline? We arrive at a much more complex playground of human decision-making, augmented by artificial intelligence, where a rich plethora of different strategies is at our disposal to promote cooperation [17]. But altogether, we arrive at, or rather we are faced with, the same conclusion as with the autonomous vehicles: let others cooperate and sacrifice themselves for the benefit of others, not “us.”

This is nothing if not a brutally honest outcome of a social dilemma situation involving us, humans. We are social, and we are compassionate, and we care for one another, but in rather extreme

situations, Darwin still has the best of us. It is important to understand that cooperation is the result of our evolutionary struggles for survival. As a species, we would unlikely survive if our ancestors around million years ago had not started practicing alloparental care and the provisioning for the young of others. This was likely the impetus for the evolution of remarkable other-regarding abilities of the genus Homo that we witness today [18]. Today, we are still cooperating, and on ever larger scales, to the point that we may deserve being called “SuperCooperators” [19]. Nevertheless, our societies are also still home to millions that live on the edge of existence, without shelter, without food, and without having met the most basic needs for a decent life [20].

So what can we expect from artificial intelligence in terms of managing social challenges, and in particular social dilemmas? We certainly have the ability to write algorithms that would always choose the prosocial, cooperative action. But who want to drive a car that may potentially kill you to save the lives of others? According to Bonnefon et al. [14], indeed not many of us. Hence, their conclusion, “regulating for utilitarian algorithms may paradoxically increase casualties by postponing the adoption of a safer technology.” We thus have the knowledge and the ability to program supremely altruistic machines, but we are simply too self-aware, too protective of ourselves, to then be willing to use such machines.

This in turn puts developers and engineers into a difficult position. Which is either to develop machines that are save but very few would want to buy, or to develop machines that may kill many to save one and will probably sell like honey. Nevertheless, the situation may not be as black and white, as artificial intelligence itself may learn how best to respond. Indeed, a recent review by Peysakhovich and Lerer [21] points out that, because of their ubiquity in economic and social interactions, constructing agents that can solve social dilemmas is of the outmost importance. And deep reinforcement learning is put forward as a way to enable artificial intelligence to do well in both perfect and imperfect information bilateral social dilemmas.

Well over half a century ago, Isaac Asimov, an American writer and professor of biochemistry at

Boston University, put forward the Three Laws of Robotics. First, a robot may not injure a human being or, through inaction, allow a human being to come to harm. Second, a robot must obey the orders given it by human beings except where such orders would conflict with the first law. And third, a robot must protect its own existence as long as such protection does not conflict with the first or the second law. Later on, Asimov added the fourth law, which states that a robot may not harm humanity, or, by inaction, allow humanity to come to harm. But this does not cover social dilemmas, or situations, where the machine inevitably has to select between two evils. Recently, Nagler et al. [22] proposed an extension of these laws, precisely for a world where artificial intelligence will decide about increasingly many issues, including life and death, thus inevitably facing ethical dilemmas. In a nutshell, since all humans are to be judged equally, when an ethical dilemma is met, let the chance decide. Put in an example, when an autonomous car has to decide whether to drive the passenger into a wall or overrun a pedestrian, a coin toss should be made and acted upon accordingly. Heads it's the wall, tails it's the pedestrian. No study has yet been made as to what would potential buyers of such a car make of knowing such an algorithm is embedded in the car, but it is likely safe to say that, fair as it may be, some would find it unacceptable.

Ultimately, the problems that arise when a machine's designer directs it toward a goal without thinking about whether its values are all the way aligned with humanity's, or when the machine is designed to "SuperCooperator" standards, rather harming the user than others around, we need good regulation and a prepared juristic system to tackle the challenges. This, however, leads us to a new set of challenges, namely, those that are mainly juristic.

Juristic Challenges

Considering its multifaceted character, artificial intelligence inherently touches upon a full spectrum of legal fields. Firstly, new technology raises issues concerning patentability, joint

infringement, and patent quality [23]. New relies on communication between two or more smart objects and consumers, and it is challenging whether inventors of certain types of IoT applications will be able to overcome the test for patent eligibility. Moreover, even if they obtain patents on new methods and protocols, the patents may still be very difficult to enforce against multiple infringers [23].

Furthermore, as collecting and analyzing data is progressively spreading and an increasing number of companies and health institutions have started to exploit the possibilities arising from collection and exploitation of potential data, so that added value can be created [24], this information explosion (also called "data deluge") unlocks various legal concerns that could stimulate a regulatory backlash. While it is claimed that data has become the raw material of production, and a new source of immense economic and social value [25], Big Data has been identified as "the next frontier for innovation, competition, and productivity" [26]. This is extremely relevant for the medical sector, where research is crucially dependent upon gathering sufficient amount of relevant data. On the other hand, however, open questions range from who is entitled to use this data, can data be traded, and, if so, what rules apply to this. Health data are considered particularly delicate and therefore call for special legal protection. Yet, if the rules for collecting this data are too strict, development of new medicines and health appliances might be hindered. To prevent diminishing the data economy and innovation, "smart" regulation is needed to establish a balance between beneficial uses of data and the protection of privacy, nondiscrimination, and other legally protected values. The harvesting of large data sets and the use of modern data analytics presents a clear threat for the protection of fundamental rights of European citizen, including the right to privacy [27].

Thirdly, ICT is changing the role of the consumer "from isolated to connected, from unaware to informed, from passive to active" [28]. This process is sometimes also called "digitalization" of the consumer [29], considering that people are increasingly able to use digital services. The

younger generations are grown up with digitalization and are eagerly in the forefront of adopting new technology. This could mean that the traditional presumption in consumer law that a consumer is uninformed and thus requires special legal protection no longer holds true. Nevertheless, the change is so rapid that the pre-Internet generations hardly follow the suit and new manufacturing methods bring new dangers for consumers. As the health sector greatly involves elderly generations, it is important they are included in the development and medical advances in this field while also adapting consumer law to the new challenges.

Finally, tax policy will play a very important role in the age of intelligent objects, particularly considering that human labor costs are increasing, so that it is broadly expected that automation will lead to significant job losses. As the vast majority of tax revenues are now derived from labor, firms avoid taxes by increasing automation. It is thus claimed that since robots are not good taxpayers, some forms of automation tax should be introduced to support preferences for human workers.

The focus of this section is on tort law aspects of intelligent objects, such as robots increasingly used in medicine. Tort law shifts the burden of loss from the injured party to the party who is at fault or better suited to bear the burden of the loss. Typically, a party seeking redress through tort law will ask for damages in the form of monetary compensation. Tort law aims to reduce accidents, promote fairness, provide peaceful means of dispute resolution, etc. [30].

According to the level of fault, torts fall in three general categories:

- (a) Intentional torts are wrongs that the defendant deliberately caused (e.g., intentionally hitting someone).
- (b) Negligent torts occur when the defendant's actions were unreasonably unsafe, meaning that she has failed to do what every (average) reasonable person would have done (e.g., causing an accident by speeding).
- (c) Strict (objective) liability torts do not depend on the degree of care that the defendant used; there is no review of fault on the side of the

defendant; rather, courts focus on whether harm is manifested. This form of liability is usually prescribed for making and selling defective products (products' liability).

Multifaceted character of artificial intelligence brings challenges in the field of regulating liability for damage caused by intelligent objects.

Tort Law

In relation to automated systems, various safety issues may arise, despite the fact that manufacturers and designers of robots are focused on perfecting their systems for 100% reliability and thus making liability a nonissue [31]. It can happen that robotic technology fails, either unintentionally or by design, resulting in economic loss, property damage, injury, or loss of life [32]. For some robotic systems, traditional product liability law will apply, meaning that the manufacturer will bear responsibility for a malfunctioning part; however, more difficult cases will certainly come to the courts, such as a situation, where a self-driving car appears to be doing something unsafe and the driver overrides it – was it the manufacturer's fault, or is it the individual's fault for taking over [33].

Similar difficulties may arise in relation to remotely piloted aircrafts (so-called civil drones). In the USA, a case concerning civil drones already appeared before the courts, when US Federal Aviation Administration issued an order of a civil penalty against Raphael Pirker, who in 2011, at the request of the University of Virginia, flew a drone over the campus to obtain video footage and was compensated for the flight. First instance, the court decided that a drone was not an aircraft, while the court of appeal ruled to the opposite. The cases ended in 2015 with a settlement of \$1.100.

The starting point for examining “computer-generated torts” [30] is – or at least should be – that machines are, or at least have the potential to be, substantially safer than people. Although media broadly reported on the fatality involving Tesla's autonomous driving software, it is

generally accepted that self-driving cars will cause fewer accidents than human drivers. It is stated that 94% of crashes involve human error. Moreover, medical error is one of the leading causes of death [34]. Consequently, artificial intelligence systems, like IBM's Watson, that analyze patient medical records and provide health treatment do not need to be perfect to improve safety, just better than people.

If accident reduction is in fact one of the central, if not the primary, aims of tort law, legislators should adapt standards for tort liability in case of harm caused by intelligent objects in such a way that law encourages investment in artificial intelligence and thus increases safety of humans. Most injuries people cause are evaluated under a negligence standard, where a tortfeasor is liable in case of unreasonable conduct. If her act was not below the standard of a reasonable person, the harm is thought to be pure matter of chance for which no one can be held accountable. When computers cause the same injuries, however, a strict liability standard applies, meaning that it does not matter whether someone is at fault for the harm caused or not. This distinction has financial consequences and discourages automation, because computer controlled objects incur greater liability for the producer or owner than people. Moreover, if we want to improve safety through broader use of automation, current regulation has the opposite effect.

As currently product's liability is strict, that is independent of fault, while human activity is measured according to the standard of a reasonable person, legal scholars claim that in order to incentivize automation and further improve safety, it is necessary to treat a computer tortfeasor as a person rather than a product. It is thus defended that where automation and digitalization improve safety, intelligent objects should be evaluated under a negligence standard, rather than a strict liability standard and that liability for damage would be compared to a reasonable person [30]. Additionally, when it will be proven that computers are safer than people, they could set the basis for a new standard of care for humans, so that human acts would be assessed from the perspective what a computer would have done and

how using the computer humans could avoid accidents and the consequent harm.

Nevertheless, jurists broadly defend strict liability for intelligent objects or in some respects even broader than currently foreseen, particularly in terms of the bodies involved that could be held liable – from the producer, distributor, seller, but also the telecommunication provider, when, for example, the accident was caused due to the lack of Internet connection. At the European Union level, considering that the Product Liability Directive (85/374/EEC) does not apply to intangible goods, inadequate services, careless advice, erroneous diagnostics, and flawed information are not in themselves included in this directive. It is nevertheless important that when damage is caused by a defective product, used in the provision of a service, it will be recoverable under the Product Liability Directive [35], regulating strict liability test (see also EU Court's decisions on Cases C-203/99, Veedfald, and C-495/10, Dutrueux). Many acts by robots used in medical procedures will thus come within the ambit of this Directive, including software that is stored on a tangible medium. This means that in case the consumer, whose car causes an accident due to malfunctioning software, or a patient, who suffers the wrong dosage of radiation due to a glitch in the consumer software, may bring a claim under the Product Liability Directive against the producer of software [36]. When software is supplied over the Internet (so-called non-embedded software), however, potential defects do not fall within the scope of this directive, and a specific directive on the liability of suppliers of digital content is needed.

As far as product safety regulation is concerned, Article 2(1) of Directive 2001/95 on general product safety defines the reach of the product safety regime to include any product intended for consumer use or likely to be used by consumers "including in the context of providing a service." Nevertheless, this does not cover safety of services [37]. It is hence for the EU Member States to adopt legislation setting safety standards for services, which is not the preferred solution in times of extensive technological development. Analysis of the suitability of existing safety regulations is, for example, needed in

relation to software-based product functions that can more and more be modified after delivery.

It is also essential to understand, however, that the more autonomous the systems are, the less they can be considered simple tools in the hands of other actors and that overly stringent regulation, expecting perfection instead of acceptable robot behavior, may discourage manufacturers from investing money in innovations, such as self-driving cars, drones, and automated machines [38]. Smart regulation is thus again needed, taking into account all the involved stakes.

While intelligent objects are imitating the work of humans, as well as their legal liability, the question also arises, whether robots will be entitled to sue, be sued, and also be engaged as witnesses for evidence purposes. Currently, it is not possible to sue a robot as they are considered property, just like an umbrella. Intelligent objects do not have legal identity and are not amendable to sue or be sued. If a robot causes harm, the injured party have to sue its owner or its manager. However, comparing the robots to companies, for procedural purposes companies were also not treated as separate legal entities from the human owner for a long time in history [30]. Nevertheless, over time legislators and courts abandoned the model of treating corporations solely as property and awarded them an independent artificial personality that allowed them to sue and be sued. In respect of the robots, it will thus need to be established whether they are more like an employee, a child, an animal, a subcontractor, or something else [39].

Related to this, 3D printing turns traditional service providers into manufacturers, making the relevant legislation applicable also to them. Specific regulatory challenges in this respect arise in the medical field, where 3D printing brings the ability to print replacement body parts, organs, bones, and even skin. In this situation, medical doctors and dentists provide a bundle of services – besides the ordinary patient treatment, they make a digital design of the implant and printing the implant in their offices with a 3D printer. Each device is designed and manufactured based on a patient's medical image data, which ensures a perfect fit with his unique anatomy. Low price

and high functionality 3D printed medical devices may save lives and have important consequences on the social security systems; however, the regulation needs to contemplate the risks involved and maintain patient safety standards. Under current EU Medical Devices Directive (93/42/EEC), 3D printed medical devices fall in the category of "custom-made medical devices," similar to orthopedic shoes that are not strictly regulated. In relation to 3D printed medical implants (such as prosthetic limbs, hips, or teeth), however, it is widely accepted that they require more stringent quality requirements to address the needs and potential risks [12]. Nevertheless, it seems that EU regulators are supporting the status quo, considering that the Explanatory Memorandum to the future Medical Devices Regulation states that "Manufacturers of medical devices for an individual patient, so called 'custom-made devices', must ensure that their devices are safe and perform as intended, but their regulatory burden remains low." What is thus needed to assure patients' safety is to subject the manufacturers of higher risk 3D custom printed devices to a conformity assessment and to require CE marking of the input material (in the same way as materials that are currently used for creating a dental filling). Keeping current uncertainties might lead to different national interpretations of risk related to 3D printed medical devices and a fragmentation of the internal market, thus harming both the consumers and the business.

Conclusions and Guidelines

Artificial intelligence certainly has the potential to make our lives better, especially so in medicine. It is in fact already happening, but as the adoption of any new technology, the welcoming of artificial intelligence into our lives is not without challenges and obstacles along the way. We have here reviewed some of the more obvious social and juristic challenges, for which we are nevertheless not well prepared. In particular, we have reviewed social dilemmas as traditionally demanding situations, in which we find ourselves torn between what is best for us and what is best

for others around us and for the society as a whole. It is difficult enough for us to do the right thing in such situations, and now we have to essentially build machines that will, with more or less self-training, be able to do the right thing as well. The essential question is whether we expect artificial intelligence to be prosocial, or whether we expect it to be bent on satisfying an individual, the owner, or the company of which property it is. The meme “is my driverless car allowed to kill me to save others?” brings the dilemma to the point. It is relatively easy and noble to answer yes without much thought, but who would really want a car that could potentially decide to kill you to save other strangers? Research done thus far indicates that not many, depending of course on some details as to who might the passengers be and how many others would potentially be saved. But regardless of these considerations, one of such cars is an unlikely entry on the top of any wishing list. There are of course many similar situations that have the same hallmark properties of a social dilemma, like whether or not we should be vaccinated. If a large enough fraction of a population says no, then we will lose herd immunity, and long forgotten diseases will surely return. To be vaccinated, on the other hand, is a difficult decision for some because of possible side effects of the vaccine.

Therefore, the answer to the question whether we want artificial intelligence to be prosocial or not certainly has no easy or universally valid answer. As is so often the case, it depends on the situation, and also on the juristic circumstances either decision would create.

As industry and technology are changing hastily, all the involved stakeholders have to utterly consider whether the society can adjust to this development equally fast and whether people develop the necessary technological skills. While some commentators claim that EU may adopt the legislation concerning digitizing industry too fast, since it is not yet known how exactly smart industry will develop, others call for immediate response to avoid distinct legislative activities by individual states. Robotization in many aspects makes sense and it is thus reasonable that it gets regulatory support. However, this does not mean that it is

always necessary to rush into new regulation, when amending existing legislation would suffice.

In reviewing the social and juristic challenges of artificial intelligence in medicine, we propose the following set of guidelines:

- (i) Improving the digital skills of the workforce for medical professions requires public measures with pertinent financial support.
- (ii) Strict liability for the marketing of autonomous healthcare services and medical diagnostics discourages investment in this field, thereby decreasing the potential of robotization to make these services safer and more accessible and affordable. This can be considered as the main regulatory paradox with respect to the introduction of artificial intelligence into new areas of application, including medicine.
- (iii) Patients' safety needs to be ensured by subjecting the manufacturers of higher risk 3D custom printed devices to a conformity assessment and to require CE marking of the input material (in the same way as materials that are currently used for creating a dental filling).
- (iv) Before autonomous services enter into medicine, liability issues need to be clearly set by legislation, so that it is not left to the user to search and prosecute the liable entity in courts.
- (v) Obligatory black box to record the functioning of the intelligent object and help ascertain liability in cases of potential faults.
- (vi) No fine print. The user should be informed how the artificial intelligence will react in critical situations, as well as be made accurately aware of all drawbacks, possible errors, misdiagnosis, and things that can go wrong when relying on it.

Abstract

Artificial intelligence (AI) is revolutionizing healthcare, and with this transformative innovation comes the challenge of responsibly integrating AI into clinical care. AI has the potential to improve patient outcomes, increase the efficiency of healthcare diagnosis and treatment, and lower the cost of care. Leveraging these benefits, however, requires attention to the ethical risks raised by this new technology. In this chapter, I illuminate the primary ethical challenges of AI in healthcare and argue that in order to fully realize the potential of AI to improve individual and population health, we

need to align AI with the ethical principles of medicine. The ethical challenges posed by AI can be categorized into the four principles commonly used in healthcare ethics: respect for autonomy, beneficence, nonmaleficence, and justice [1]. Careful consideration of the implications of these principles will allow us to maximize the benefits of AI in healthcare.

Respect for Autonomy

The principle of respect for autonomy entails enabling patients to make their own decisions about which healthcare interventions they will or will not receive. Healthcare practitioners manifest respect for patients' autonomy by helping patients make informed decisions through a process of informed consent. By sharing information about the purpose, risks, benefits, and alternatives to an

L. S. Lehmann (✉)

Google, Harvard Medical School, Brigham and Women's Hospital, Boston, MA, USA

intervention and engaging patients in a process of shared decision-making, healthcare practitioners guide patients to decisions that are consistent with their goals and values. As healthcare systems and practitioners integrate AI into clinical decision-making, questions arise about whether patients should be informed that AI is being used to guide clinical decision-making and treatment. Do patients need to consent to the use of AI in clinical care?

Informed consent within the context of AI poses practical challenges of explainability to patients as the output derived from AI systems can be challenging to interpret [2]. For example, when deploying an algorithm trained to identify cancer cells, clinicians may be unable to identify the features the algorithm used to make a determination that certain cells are malignant. While there may be limited information on how an AI output is derived for a specific system, in most cases there are important features of AI that can and should be shared with patients. The details of how sensitive and specific the algorithm is for certain patients, the error rate of an algorithm, how an algorithm's accuracy compares with physicians' decisions, the safeguards put into place to detect and prevent errors, and the consequences for patients' health if the AI algorithm is biased or wrong may be more important to patients than how an algorithm arrived at a decision. A retrospective research study of AI algorithm to predict eye disease needing urgent referral performed as good as the two best-performing retinal specialists, significantly outperformed six other experts and made no clinically serious wrong decisions [3]. This type of information on AI algorithm performance may be meaningful for clinical decision-making and should be shared with patients.

The limits of an algorithm should also be disclosed to patients. As AI algorithms learn from training data, it is important for clinicians to guard against automation bias and an over-reliance on the recommendations of an AI algorithm. Like extrapolating the benefits of a medication or intervention from a clinical trial to a particular patient, it is important to understand the data on which an algorithm was trained so that

clinicians can predict and inform patients if the output will be valuable to a particular patient [4]. In addition to evidence of efficacy, it will be important to share evidence of the effectiveness of an AI algorithm in clinical practice. The full scope of benefits and risks of AI in clinical care may only be evident when algorithms are integrated into our complex clinical environments. As part of the informed consent process, clinicians should provide patients with information on the characteristics of patients whose data was used to develop the algorithm and convey the potential for an algorithm to underperform in populations on whom it has not been tested. As AI algorithms are scaled to diverse populations and we have greater confidence in their ability to improve patient outcomes, they will likely become part of the fabric of healthcare and become so commonplace that they don't require explicit informed consent.

Beneficence

Beneficence, the obligation to promote well-being, is a foundational principle of healthcare. Healthcare practitioners have a moral duty to act with the goal of benefiting our patients. Many interventions carry some potential for harm, thereby necessitating an assessment of the risk of harm and a weighing of the benefits and risks for individual patients, populations, and society. Beneficence demands that we maximize the benefits and minimize the potential harms.

AI holds the promise of improved patient health and quality of care. AI is already being used to assess patients' symptoms and provide guidance to patients on whether they should seek care in an emergency department [5]. AI applied to imaging and diagnostics is integrated into clinical care with systems that assess the degree of diabetic retinopathy in patients [6], identify malignant lesions on mammograms [7], and help clinicians diagnose dermatological conditions [8]. The application of machine learning to complex diagnostic challenges will allow for the recognition of patterns that even the best clinicians may not have recognized. AI may also allow clinicians to benefit patients by fine-tuning

screening and prevention protocols to significantly reduce the burden of disease through earlier cancer detection.

As healthcare systems integrate AI into clinical decision support systems, the potential benefits to populations including of improved quality of care, accuracy of diagnosis, efficiency, and cost of care may conflict with the potential for harm to individual patients. AI algorithms may recommend interventions that maximize aggregated benefits for a population while generating harm for a segment of individual patients with cases that the algorithm does not account for. While AI has the capacity to improve population health, it is critical to also consider how to mitigate possible risk to individuals. The risk of using AI on all populations should not be greater than what would be imposed when AI is not used.

Nonmaleficence

The benefits of AI should be considered within the context of the potential for harm. In this section, I focus on the potential for harm associated with AI secondary to privacy and safety.

Privacy

Many AI algorithms depend on large volumes of individual patient data. In the United States, the Health Insurance Portability and Accountability Act Privacy Rule (HIPAA) guides the use and disclosure of patient data [9]. In Europe, the General Data Protection Regulation (GDPR) protects EU residents' personally identifiable information. [10]. HIPPA is narrow in its scope, covering specific identifiable health information generated and held by "covered entities" and their business associates. HIPAA does not apply to de-identified health data, however, entities disclosing data should be careful to ensure that sensitive data cannot be re-pieced together.

GDPR is an entirely different regulatory regime with distinct requirements that must be met to process sensitive personal data, including data concerning health. For example, data

concerning health may only be processed under certain circumstances, such as the individual providing explicit consent or processing that is necessary for direct patient care, public health, scientific, historical or statistical research purposes [11]. In most instances, individuals must consent to their personal data being collected and used for automated decision-making that significantly or legally affects them, and individuals have the right to obtain human intervention and contest decisions based on AI [12].

Privacy is linked to digital agency, that is, control over access to and use of an individual's personal information [13]. Patients are increasingly demanding greater transparency over what personal health data is collected for, who has access to their personal health data and how it is used.

Natural language processing (NLP) applications are also being integrated into clinical settings and raise privacy considerations. As healthcare systems try to enhance efficiency with the use of chatbots for patient communication and improving mental health, patients are expressing concerns about electronic sharing of confidential information [14].

Safety

Researchers have increasingly recognized AI algorithms need broad validation to be able to make predictions in varying populations. The data used to train an algorithm has significant implications on the output of the model. Subtle differences between data used to train an algorithm and real world data encountered during clinical deployment can result in algorithms making erroneous predictions that may be difficult to identify. For example, a sepsis prediction model deployed in hundreds of hospitals was found to perform worse than indicated by initial studies. This example underscores the need for external validation of AI algorithms before widespread use [15, 16].

A recent study of AI predictions of hospital-acquired infections found that the variables

associated with risk at one hospital were protective at another hospital [17]. As a result of using inaccurate synthetic data, as opposed to real patient data an AI algorithm generated erroneous recommendations for cancer treatment [18]. These examples underscore the importance of broad testing of AI algorithms in diverse patient populations and adopting safeguards, such as using AI as an adjunct to clinical decision-making, until we have confidence in a model's predictions. An AI algorithm that is not generalizable across populations can pose a threat to clinical decision-making and patient safety and, similar to other clinical interventions should be tested in large groups of diverse patient populations [19, 20]. Our ethical duty to do no harm requires the development and integration of proactive and responsive quality management systems alongside the deployment of AI in healthcare.

Justice

One of the most significant ethical concerns with the integration of AI into healthcare is the potential to introduce and amplify bias based on race, sex, insurance status, and healthcare usage [21, 22]. Such bias may only emerge when an algorithm is employed in diverse populations and can exacerbate health inequalities [23]. The ethical principle of justice in healthcare impels us to prioritize fairness in the provision of healthcare. It would be unjust to give one group access to a diagnostic or therapeutic intervention and withhold it from another group who suffers with the same illness.

Despite the importance of justice in healthcare, bias has crept into clinical prediction models. In a recent study of the use of an AI algorithm used to predict risk and guide decisions for referral to high-risk care management programs used for roughly 200 million patients, investigators found that Black patients assigned the same level of risk by the algorithm were sicker than white patients [23]. Racial bias in the algorithm reduced the number of Black patients identified for extra care

by more than half. This error was thought to occur because the algorithm used healthcare costs as a proxy for health needs. Because less money was spent on Black patients with the same level of need, the algorithm falsely concluded that Black patients were healthier than equally sick white patients. The prediction model used the cost of care as a proxy for healthcare needs, and those who created the model did not realize this seemingly minor decision could have such far-reaching consequences for patient care. This research exemplifies the need to rigorously evaluate models prior to integrating them into clinical care and the importance of a socially conscious approach to the development of AI algorithms so that we don't encode and amplify inequities in healthcare.

Another factor driving bias in AI is the underrepresentation of diverse groups in training and testing datasets used to develop and validate AI models [25, 26]. The benefits of AI in healthcare are going to be limited by the scarcity of data that adequately represent individuals of varying age, sex, race, ethnicity, and environments [27]. Healthcare practitioners can help address this challenge by increasing awareness among underrepresented populations of the value of data sharing and by building trust through transparent and inclusive communication.

Impact on the Physician-Patient Relationship

AI is likely to change the nature of the physician-patient relationship. Patients look to their physicians as their fiduciary who will advocate for their best interests. With greater reliance on the output of AI algorithms, healthcare practitioners may feel less empowered to challenge an AI decision or advocate for a particular patient. The sharing of patients' data without their meaningful and explicit consent may also undermine patients' trust in their healthcare practitioners and the profession of medicine. Patients may express understandable anxiety about the role of difficult to explain algorithms influencing healthcare

decisions. Clinicians may mitigate these concerns by explaining how the AI was integrated into their decision making and recommendation. There is a risk that an overreliance on the technology will diminish physicians' clinical skills and that our constant push for greater efficiency will allow the outputs of AI systems to be directly shared with patients without appropriate context and interpretation provided by clinicians. Some patients may have a preference for receiving clinical information and treatment recommendations from an empathic physician. Clinicians have an important role to play in educating patients about the risks and benefits of AI in healthcare.

AI has the potential to radically change the practice of medicine through the application to diagnosis and treatment. Aligning the integration of AI with the ethical principles of our profession, including respect for patient autonomy, beneficence, nonmaleficence, and justice, will accelerate the responsible adoption of AI into daily clinical practice.

Abstract

The widespread applicability of medical artificial intelligence systems hinges on their development and validation on large, diverse, and representative datasets. So far, such datasets have only been able to be assembled through multi-institutional data sharing and aggregation. Such practices are however associated with legal, ethical, and technical challenges and scale poorly to multinational efforts. They furthermore potentially infringe on data ownership and complicate the enforcement of data governance measures. Privacy-preserving machine learning offers solutions to these challenges by implementing techniques for the decentralized training of algorithms on datasets without requiring direct access to the data or by offering guarantees of privacy protection during training and algorithm inference. This chapter presents the core techniques of secure and private artificial intelligence, which can serve to enable the training of algorithms on larger datasets and their provision to more people under provable assurances of privacy and ownership protection.

Introduction

Medical artificial intelligence (AI) research has, over the past few years, led to several successful clinical applications such as individualized cancer diagnostics, tumor subtype characterization, patient outcome prediction, and survival or therapy response risk assessment [1–9]. It is to be expected that AI systems will become part of clinical routine in the near future and offer decision support to physicians in a variety of

domains. The common denominator of such applications is the requirement to train AI algorithms on large and diverse datasets. Data is required to be representative of real-world patient attributes including edge cases, and – optimally – be highly diverse with regard to patient factors (such as gender, ethnicity, or age) to be fair and unbiased, but also with regard to different imaging system vendors to be applicable in real-world scenarios. Such datasets, ideally representing all relevant clinical pathologies encountered in patient care, can usually not be procured by single sites alone; rather, international confederations of healthcare providers are required. The realization of such collaborations is so far based primarily on centralized data aggregation and sharing. However, this practice is problematic in several regards: Legislation regarding data protection and sharing is highly heterogeneous across different countries. The US Health Insurance Portability and Accountability Act (HIPAA) [10] imposes strict rules on the use of personal health data and requires authentication, authorization and accountability. The European Union's General Data Protection Regulation (GDPR) [11] stipulates rights for data access, rectification, and deletion (*forgetting*) of stored data, the restriction of processing, and a strictly regulated view on data portability and sharing. In the context of AI-based processing, this regulatory landscape raises complex considerations, such as verifiable algorithmic interpretability to realize rights to explanation, as well as questions such as ownership of algorithms and data, and the enforcement of granular governance schemes. Such considerations are beyond the scope of this chapter, but will without doubt require multidisciplinary scientific, political,

and societal debate. Crucially, such debate must address fundamental ethical principles, such as transparency, justice and fairness, non-maleficence, and responsibility [12, 13].

Beyond such considerations, applications including medical data are critical due to the high value of the data [14]. The release of health information can lead to severe discrimination by employers or health insurance providers, with allegations pointing to systematic profiling of high health-risk individuals and business models involving the sale of de-anonymized medical records to insurance companies to mitigate financial risks [15]. Such practices also highlight the function of personal information within an evolving data economy, in which data assumes the role of a valuable production asset. An increasingly privacy-aware public, conscious of this value, is thus demanding *single-use-accountability*, that is, the ability to at any time rescind the permission about the storage, transmission, and/or utilization of their personal data and the guarantee that the data is used only for an explicitly designated purpose. Similar considerations are raised by algorithm owners, who wish to protect their AI models, representing both production value and intellectual property assets, from theft, misuse, or unauthorized exploitation. It thus becomes clear that medical AI applications are developing within a complex, multifaceted field involving algorithm developers, imaging equipment vendors, physicians, and patients, each with their own motives, objectives, and – potentially conflicting – interests. This complexity, lack of transparency regarding motives and the nature of digital data being more accessible, easier to exchange and distribute [16] than ever, are threatening the inviolability of data privacy. While the importance of privacy is undoubted, its precise definition is also evolving. Historical definitions such as the *right to be let alone* from American law scholars in 1890 [17] are no longer applicable in the context of AI, as they could not foresee the technical advances including digitization, the Internet, or data science. Kaassis et al. define privacy as *the ability to retain full control and secrecy over one's personal information* [18]. The *control* aspect is further emphasized by

definitions such as Nissenbaum et al. [19], who eschew notions of privacy based primarily on obfuscating data, instead defining it as *contextual integrity*, that is, the purpose-specific flow of data within a larger context of societal and ethical norms. The concept of privacy should also be delimited from *confidentiality*, the legal or ethical duty to maintain secrecy over specific information.

AI in medicine represents a quintessential conflict between privacy and utility (*privacy-utility-tradeoff*), that is, between the **protection** of personal data and AI algorithms and the **utilization** of personal data for AI algorithm training. The reconciliation of these requirements is the domain of *secure and private artificial intelligence*. It provides a set of techniques for ascertaining the protection of data (*training data, model input, and model output privacy*) and algorithms (*model privacy*). The provision of these guarantees alongside auditability and integrity assurances via technically verifiable methods is termed “structured transparency” [18]. This new and evolving discipline is embedded within the larger field of *trustworthy artificial intelligence*, which includes the study of fairness, robustness, causality, interpretability, security, privacy, verifiability, accountability, and auditability. The current chapter will motivate the requirement for next-generation privacy-preserving methods, present their technical realization by summarizing the concepts of *federated learning, differential privacy, homomorphic encryption, secure multi-party computation, and trusted execution environments*, explain their current technical limitations, and sketch a scenario of how their interplay enables large-scale decentralized and privacy-preserving machine learning in medicine.

General Considerations and Current Technical Standards

Prior to a description of specific techniques, the general idea of a *threat model* is introduced. All techniques described in this chapter unfold within this conceptual framework defining the level of trust between participants. Scenarios can

range from *fully trusted* settings, in which all participants adhere to protocols without attempting to extract any information to *honest-but-curious*, in which participants do not actively undermine the protocol, however try to extract as much information as possible to *dishonest*, in which participants actively attempt to undermine or subvert protocols or the entire system to gain information or cause harm. Such dishonest participants are also referred to as *adversaries*. A threat model specifies the theoretical considerations required and the level of protection offered by a system under a given level of trust.

Current technical standards of privacy preservation revolve mainly around de-identification, that is, the removal or obfuscation of personally identifiable data from datasets. As mentioned in the introduction, the requirement for large and diverse datasets is currently addressed by centralized data sharing of such de-identified data in a majority of cases. Three main techniques for de-identification exist, which are described in the following section.

Anonymization, Pseudonymization, and k -Anonymity

Anonymization refers to the removal of all identifiable patient data entries, for example, patient name or birth date. Pseudonymization is similar but does not rely on removing these entries, but rather on replacing or altering them using randomly generated identifiers in a non-recoverable fashion. Usually, the pseudonymization provider retains a linkage record, or so-called *look-up table* to later be able to re-identify certain individuals if a specific question arises, or the dataset is modified. An evolution of these techniques *k -anonymity* [20] provides a theoretical guarantee that an anonymized data sample cannot be distinguished from $k - 1$ other samples in the corresponding dataset. It is of note that stronger notions of anonymity correspond to a decrease in information content of the dataset, shifting the privacy-utility tradeoff toward privacy. Although representing the current standard, all aforementioned methods are prone to *catastrophically degrade* in the

presence of side information. Catastrophic degradation refers to the full reidentification of individuals contained in the dataset, also referred to *blatant non-privacy*. Side information can be thought of as any (partially) non-de-identified dataset containing at least one identifier in common with the de-identified dataset. Such side information can give rise to a class of attacks termed *linkage attacks* [21]. They are based on the usage of a non-anonymized dataset containing an intersection of patients with the attacked dataset and finding similarities that are sufficiently remarkable such that, with a high probability, two entries are from the exact same patient. A prominent example of a linkage attack was the de-anonymization of the *Netflix prize* dataset by Narayanan et al. [22] in 2008. The dataset contained 500,000 anonymized movie ratings of Netflix users and was linked to profiles of known users of the IMDb dataset, who were identifiable by name. The same technique was then used to recover information about political preferences and other sensitive information about the users. Similarly, the de-anonymization of New York City taxi data [23] was demonstrated, in which the authors were able to concretely reidentify 91% of the contained data samples. Modern linkage attacks are estimated to be able to concretely identify 99.98% of the American population using 15 demographic attributes [24].

Considerations for Specific Dataset Types

The abovementioned de-identification methods are unusable for certain types of data containing a high inherent density of information and requiring more sophisticated methods for anonymization. A typical example is medical imaging data, which – even with no additional information available – contains obviously identifiable physical properties of the patient, such as the face or specific pathological alterations visible in the image. It has been demonstrated that the combination of three-dimensional rendering techniques applied to CT and/or MRI scans of the head with facial recognition software is able to

reidentify patients contained in medical imaging datasets from for example, social media images [25, 26]. One approach to prevent such attacks is the so-called *de-facing* of imaging datasets, that is, processing of the image dataset such that no identifiable structure of the face remains [27]. However, such a process may be prone to technical failure and thus requires quality control. Furthermore, certain imaging characteristics are required for diagnosis, such as the depiction of reproductive organs, which are nevertheless sufficient to identify a patient's biological gender, which might still represent data leakage. Lastly, it is unclear whether other image-derived characteristics, such as body shape or specific pathologies, might also be able to lead to concrete reidentification.

The Requirement for Next-Generation Privacy-Preserving Techniques

It becomes clear that the abovementioned current-generation de-identification techniques all suffer from notable drawbacks: They provide privacy guarantees only within a very restricted scope, are prone to degradation in the presence of side information and – for the most part – do not provide a quantifiable notion of privacy. The common denominator of next-generation privacy-preserving machine learning (PPML) techniques, which will be presented next, is their motivation by information-theoretic notions of privacy, and their provision of quantifiable guarantees of privacy or resilience to given attacks under given threat models.

Federated Learning

A conceptually simple method to eschew centralized data sharing, and thus restore both sovereignty of the data owners and the ability to enforce arbitrary governance schemes over datasets is to no longer share data, but instead send algorithms to the sites at which data is kept for training models locally. The transmission of model copies to the sites of data residence for

local training via distributed computation techniques is termed *Federated Learning* (FL) [28].

Technical Framework

FL in medicine is usually performed in the setting of *cross-silo federated learning* [29]. Here, each site (*data silo*) contains significantly more than one data sample (usually an entire dataset), on which the distributed algorithms are trained. For training, a network is established in which each site (or *node*) represents one client containing data within a *hub-and-spoke topology*, and a central instance (*hub* or *server*) plays the role of training coordinator [29]. So-called *peer-to-peer* approaches, in which the model is sent in a chain between training institutions, also exist; however, they have been shown to yield lower performance [30]. In the hub-and-spoke topology, the AI algorithm is distributed to the nodes, where a number of training iterations is performed. Then, the model parameters are *aggregated*, usually by taking their *federated average* and the updated models redistributed to the nodes. At the end of training, all nodes and the hub contain the trained algorithm without any data ever having left the nodes. Several studies [30, 31] have shown that the performance of centralized and federated learning performed in this fashion can be on par. However, federated model training introduces a series of challenges over its centralized counterpart.

Challenges in Federated Learning

The centralized aggregation of datasets provides several benefits with respect to dataset curation. Thus, quality control of datasets is facilitated, data harmonization steps can be conducted on the entire dataset and corrections to the dataset can be easily undertaken. Furthermore, access to aggregated data can help data curators ascertain fairness and representativeness of the training data and remove unwanted samples which would lead to deterioration of the algorithm's performance. These factors are substantially complicated in the

federated setting, in which the coordination of multiple data curators is required.

Furthermore, the specific statistical data distribution on the nodes can impact model training. For example, imbalanced data with respect to certain attributes (e.g., overrepresentation of certain classes), extreme statistical characteristics of the data (*outliers*), incorrect data labels (*label noise*), or low quality/unrepresentative data can all lead to poor performance of the federated model. It is a common modeling assumption that data on a node represents a representative sample drawn at random from a population (in the case of FL, the union of all datasets). Under certain circumstances, the data on the nodes might violate this assumption to such a degree that training a model locally (*personalization*) instead of contributing to or utilizing the collaboratively trained model might be preferable.

Moreover, methods to evaluate data quality in the federated setting without direct access to the data are still under investigation. In addition, FL raises questions of reimbursement and model ownership. Reimbursement of data providers can, for example, be calculated on the grounds of how much the final model profits from this data, which is dependent on a number of factors such as dataset size, quality, and diversity. Recently, game-theoretic approaches have been introduced to assist with such quantification [32]. Ownership of the final model in the setting of multiple stakeholders including the algorithm developers, data contributors, imaging equipment vendors, health insurance companies, and patients is also a complicated question requiring further interdisciplinary discussion.

From a technical point of view, federated model training introduces considerable network overhead as model parameters have to be continuously sent over the network, which, considering the size of modern deep neural network architectures with several million parameters, is a considerable amount of traffic and can represent a significant bottleneck for training time. Efficiency-centered methods, such as model compression, quantization, or the design of specific architectures adapted to distributed computation workflows, will therefore be required to address

these challenges. For a comprehensive literature review on FL challenges, see [29].

Attacks Against Federated Learning Systems

Last but not least, federated learning systems are in themselves not fully privacy-preserving. They are vulnerable to attacks that extract information about data from the model weights or gradient updates [33, 34]. Such attacks include, for example, *model inversion* or *dataset/feature reconstruction attacks*, which aim at reconstructing patient attributes or entire datasets from the model weights and derived attacks, such as *membership inference*, aimed at concluding whether an individual was present in a certain dataset and thus likely had a specific attribute. Such *privacy-focused* attacks mean that federated learning must be combined with further techniques, discussed below, to be fully privacy-preserving. Furthermore, attacks also exist against the federated learning system itself, termed *utility-focused* attacks. For example, under certain threat models, malicious participants can perform *model poisoning attacks* [35] by which low-quality data or data specifically designed to manipulate the algorithm (adversarial data) is deliberately introduced. Techniques such as *federated adversarial learning* aim to harden federated learning systems against such adversarial changes to the input space [36]. Finally, unencrypted access to models sent over the network can also give rise to model theft, thus infringing on the intellectual property of the model owners.

Applications of Federated Learning

Federated learning has already yielded several promising applications. The European Union has funded large-scale academic and mixed consortia including academia and industry, to advance federated machine learning, such as the MELLODDY consortium [37], which announced the establishment of a large-scale FL platform for drug discovery in September 2020. The

FeatureCloud consortium, also supported by the European Union, is developing FL tools which have been utilized in genome-wide association studies [38]. In the medical imaging field, mixed consortia such as the London Medical Imaging & AI Centre for Value Based Healthcare, including companies such as NVIDIA have recently showcased federated learning for brain tumor segmentation [39, 40]. Finally, during the COVID-19 pandemic, federated learning was proposed for collaborative training of predictive models on electronic health records to improve outcome risk prediction [41].

Differential Privacy

As mentioned previously, a key drawback of de-identification methods such as anonymization is—generally their lack of quantifiability regarding the specific *amount* of privacy protection they provide. Differential privacy (DP) is an attribute of an algorithm and provides a method to quantify the change in the output of the algorithm caused by the addition or deletion of a row in a dataset using information-theoretic measures [42]. Furthermore, it permits the targeted alteration of either the data or the algorithm training procedure to assure that the individual’s privacy loss in the worst case remains bounded by some quantifiable limit. Dwork et al. formulate the guarantees offered by DP as a promise: “You will not be affected, adversely or otherwise, by allowing your data to be used in any study or analysis, no matter what other studies, data sets, or information sources, are available” [43]; equivalently, the individual retains *plausible deniability* of the fact that their data was used for a certain analysis.

Properties

DP has several useful properties, such as the fact that DP algorithms, when used in conjunction, also yield a DP algorithm (*closure under composition*). Furthermore, DP offers resilience to *post-processing*, that is, privacy is retained no matter what further algorithmic processing is applied to

the output of a DP algorithm. Moreover, its guarantees generalize to datasets differing by more than one individual (*group privacy*) [43, 44]. The predictable behavior of DP in these scenarios is sometimes termed *graceful degradation* to delimit it from the catastrophic degradation of other techniques discussed above. As originally defined, DP is now usually termed *epsilon*-DP. However, due to the overly pessimistic outlook on privacy loss under this definition, newer definitions exist, such as *epsilon/delta*-DP or *R&Qc niy*-DP, which are, however, beyond the scope of this chapter [43, 44].

Implementation

DP is typically realized by targeted perturbation of some part of the data/algorith pipeline, typically by random noise injection. For instance, noise can be added to the data before processing (*input-DP*) or to the result of the analysis (*output-DP*) [45]. However, this technique is only effective in a limited set of scenarios. For instance, when considering imaging data, additional noise to the input does not change the inherent physical properties of the image and thus does not contribute to DP; hence other techniques, such as stochastic output perturbations [46], the generation of DP synthetic data [47], or differentially private algorithm ensembles [48], are utilized. Noise perturbation can also be applied to the training of algorithms using techniques such as *differentially private stochastic gradient descent*, customized for training neural networks in a differentially private manner [49].

Sensitivity and Privacy Budget

A central concept in DP is the notion of *sensitivity*, capturing the impact of an interaction with the dataset (*query*) on privacy guarantees [42], from which the amount of perturbation required for a certain level of privacy can be assessed. As an extension of this consideration, the concept of a *privacy budget* is derived. Such a budget can be assigned by the data owner or curator to third

parties wishing to interact with or process the dataset in order to monitor and limit their interaction to a certain scope. After the *budget* is exhausted, no further interaction is allowed and thus, repeated queries (e.g., *averaging attacks* [50]) are prevented from leading to a neutralization of the DP mechanism.

Challenges

It should be noted that DP is conceptually similar to other techniques leading to reduced reliance of algorithm training on individual data samples with the aim of improved generalization and robustness and reduced overfitting, such as regularization [51]. This highlights that privacy and robustness are not incompatible (but rather mutually reinforcing) concepts. Nevertheless, strong DP guarantees can dramatically shift the privacy-utility tradeoff away from high algorithm performance. Furthermore, new considerations are introduced, such as the definition of how *acceptable* privacy should be quantitatively defined. This difficulty of definition leads to challenges, for example, when attempting to assign privacy budgets. Moreover, although in the general case, DP protects the individual from privacy loss due to their inclusion in a certain analysis, the results of the analysis can still lead to negative consequences for the individual. For example, although it might remain hidden that an individual who is a smoker partook in a study to answer the question whether smoking causes cancer, the result of the study (i.e., that smoking indeed causes cancer) might nevertheless lead to an increased insurance premium for the individual.

Applications

DP is a flexible and powerful concept and can be applied at all stages of interaction between algorithms and data. For instance, local DP can be utilized to protect the privacy of sensitive data collected from wearable devices measuring health-related parameters [52]. DP at analysis or publication time has for instance been showcased

in genomics studies [53, 54], electronic health record studies [55], or for enabling the privacy-preserving dissemination of analysis results [56]. More recently, DP has been combined with federated learning for large-scale biomedical dataset analysis [57]. Further surveys and reviews on the utilization of DP in health care can be found in [58–60].

Homomorphic Encryption and Secure Multi-Party Computation

An idealized method to provide end-to-end security and privacy to machine learning systems is to encrypt both the data and the algorithms. Such a system would offer the perfect secrecy guarantees of cryptography in the setting of, for example, *diagnosis as a service*. For instance, a patient can encrypt their data and send it in encrypted form to a service provider where an encrypted algorithm resides. The algorithm can then perform inference on the data and send back an encrypted diagnosis, which can only be decrypted by the patient. The paradigm described is termed *end-to-end encryption* and can enable data to be processed by an untrusted third party, such as a model owner, without revealing sensitive information to them and likewise allow the algorithm owner to encrypt their model and prevent its theft or misuse. More generally, such schemes can be utilized to enforce *single-use accountability*, that is, the guarantee that a system or good (such as data) will only be utilized for a designated purpose.

Two main cryptographic approaches will be covered, which allow the training of AI models or their use for inference, homomorphic encryption and secure multi-party computation.

Homomorphic Encryption

Homomorphic encryption (HE) can be considered an extension to existent cryptographic protocols such as public key cryptography with the added guarantee of enabling structure-preserving mathematical computations to be performed on encrypted data. This means that encrypted data

can be processed as if it were unencrypted and the results of applying the algorithm to encrypted data and then decrypting it are the same as if unencrypted data had been processed.

Not all HE protocols however allow arbitrary operations to be performed. Older HE protocols for instance support only addition and/or multiplication operations, with newer, *fully homomorphic encryption* schemes only having been introduced more recently. Such schemes permit the training of encrypted neural networks over encrypted data [61] enabling the *end-to-end* privacy preserving attributes outlined above. Other work has focused on encrypting neural networks for performing inference in a *machine learning as a service* setting [62]. However, some fully HE schemes rely on approximate calculations. For example, the CKKS Scheme [63] introduces noise to the computational process. The application of HE to neural networks typically relies on approximations of, for example, activation functions to a certain degree of precision. Both can diminish the accuracy of the models. Furthermore, HE introduces substantial computational overhead, in some cases introducing latency which lies in orders of magnitude above unencrypted computations.

Applications

HE applications relying on efficient machine instructions [64] or theoretical advances [65] have recently been proposed to limit this impact. It is to be expected that dedicated cryptographic processing hardware will further reduce latency and computational overhead and render HE applications for fully encrypted machine learning feasible in the near future. Recent biomedical applications of HE include the utilization of *leveled HE* for genome-wide association studies [66]. Moreover, HE can be employed for carrying out individual encrypted operations such as the secure encrypted aggregation of models in federated learning [67]. For further information on HE refer to [68].

Secure Multi-Party Computation

Secure multi-party computation (SMPC) is a set of protocols for the obfuscation of information

by distributing it to multiple parties while enabling the joint application of computations without sharing information about input or output [69, 70]. From an information-theoretic point of view, the information gain of any single member in an SMPC scheme is equal to a situation in which a perfectly trustworthy third party has access to all data and performs the computations, thus guaranteeing privacy. Furthermore, SMPC protocols can be designed in a fashion that requires a quorum of participants to reconstruct the output, while the collusion between fewer than the minimum required number of participants does not offer any information whatsoever. These attributes can be used to guarantee correctness and shield against adversaries within the system. Thus, SMPC can be used under the premise (threat model) that not all participants in a network are trustworthy. Although protocols for *two-party* computation exist, the authors only describe protocols for more than two participants here. An example for such a protocol is *Shamir's secret sharing* [71]. Each data sample (*secret*) is split into several *shares* and distributed among all parties. Collectively, the output of some function (e.g., addition) can be calculated and made public upon agreement. Compared to HE, whose overhead is primarily computational, SMPC entails high communication overhead as most or all parties are typically required to be online at all times and the protocol's design relies on the exchange of large integers and additionally scales with the number of participants. Newer, communication-efficient protocols aim to minimize this penalty [72].

Applications

SMPC, like HE, can be used to encrypt both data and AI models and can thus be used in the setting of end-to-end encrypted services. Its utilization has been proposed for collaborative analytics across healthcare data silos [73] and wireless sensor networks [74]. Recent pilots also implement SMPC for optimizing workflows in hospitals via privacy-preserving location tracking of personnel and in cross-sectional population studies [75]. In the setting of the SARS2-Coronavirus pandemic,

SMPC was furthermore utilized for privacy-preserving contact tracing [76].

Trusted Execution Environments

Trusted execution environments (TEEs) are an isolated memory area created by specific machine instructions. The memory area created is called *enclave* and represents a processing environment where computations can be carried out securely [77] without any other process on the system being able to access the encrypted memory area. It provides guarantees for authenticity and confidentiality of the code upon startup, with some implementations also ensuring the integrity of runtime states. These approaches can be used in different scopes to either just protect small secrets, such as private keys, or provide system-wide encryption for secure and private computing.

In secure and private AI, TEEs can be used either in conjunction, or as a drop-in replacement to pure software cryptography methods like SMPC and HE. They have indeed been shown to deliver performance suitable for real-time deployment of ML models behind secure inference APIs [78]. At the time of writing, they represent a more developer-friendly solution to implement PPML solution than SMPC and HE thanks to abstraction frameworks such as *Graphene* [79] which allows transforming container images into *enclaves* ready for execution on appropriate hardware (in this case, Intel *software guard extensions* (SGX). TEEs are however notoriously susceptible to *side-channel attacks* [80]. Furthermore, it is obviously harder to patch vulnerabilities in hardware modules once they are in commercial use than to provide software updates, as would be possible when attacks or vulnerabilities against pure-software cryptography are detected.

The risk of vendor lock-in for TEEs can be regarded as low, seeing as standards such as the *Open Enclave* software development toolkit (<https://github.com/openenclave/openenclave>) have recently emerged to allow hardware-agnostic implementations. However, it is worth noting that Intel SGX is the most commonly solution as of today, which recalls the quasi-monopoly situation

in the realm of graphics processing unit (GPU) computing in AI.

The main downside of TEEs in the context of PPML is that most of the available implementations are designed for use on central processing units (CPU) only. This can of course be a problem for deep learning models that have thrived because of the joint availability of large datasets and powerful GPU hardware. Some recent works attempt to address this shortcoming with proposals for GPU TEEs [81] as well as protocols leveraging a CPU TEE alongside a regular GPU while maintaining data privacy [82].

Outlook

Privacy-preserving machine learning has the potential to revolutionize AI in the medical field and beyond. It can allow researchers to avail themselves of larger datasets without infringing on the fundamental patient right to data privacy, impart a larger measure of control over personal data, and enable the provision of AI-based services under appropriate assurances of confidentiality and single-use accountability.

For the utilization of PPML to enter the mainstream, research is still required to address several crucial challenges. Federated learning systems able to train algorithms on heterogeneous data with the same predictive accuracy and performance as centralized data sharing will be required. Differential privacy research needs to address the challenging questions of granular privacy budgeting and tracking, and develop innovative solutions to apply DP to any data in the medical field such as imaging. Homomorphic encryption schemes with high accuracy and low computational overhead need to be developed, while SMPC protocols will be required to become more efficient and suffer from lower network overhead to be practical for widespread utilization.

PPML techniques evidently co-evolve with machine learning and data science. Hence, questions of human interaction with data and algorithms will have to be addressed to optimize outcomes. For example, it remains unclear how

encrypted data can be quality-controlled and curated, or how privacy guarantees interact with crucial requirements for algorithmic fairness and interpretability [83, 84]. Addressing specific legal requirements will also require targeted research. A prime example is the European General Data Protection Regulation *right to be forgotten* (Article 17), which has prompted exploration of the topic of *machine unlearning* [85]. Beyond mere privacy concerns, AI in critical applications such as health care needs to be responsible, auditable, and trustworthy. Research into verifiability of AI systems and objectively provable system attributes [86] will yield advances in this regard.

Healthcare is inherently a multi-stakeholder field. Although not specific to PPML, the questions of who owns an AI model and how they should be reimbursed are more complex in the setting of collaborative algorithm training over several sites, such as federated learning.

Nevertheless, many indicators, not least the success of the abovementioned pilot projects, suggest that PPML represents the future of AI in healthcare. The democratization of PPML tools has an important role to play in this regard. Free and open-source software libraries such as PySyft or TensorFlow Federated lower the barrier to entry into privacy-preserving AI research. Current work on software and infrastructure frameworks for healthcare-related tasks, such as the PriMIA library [87] or the German Cancer Consortium Joint Imaging Platform [88] has very recently yielded successes in end-to-end privacy-preserving deep learning on medical imaging and multi-institutional clinical data analytics, respectively. Last but not least, PPML represents a highly multifaceted field, which will require contributions by diverse teams of interdisciplinary researchers, not limited to AI and its adjacent subject but including – among others – ethics, philosophy, and jurisprudence and, perhaps most crucially, involving patients and society as a whole. OpenMined (<https://www.openmined.org>), a fully decentralized nonprofit community uniting over ten thousand individuals, aims to provide a forum for such discussion and foster interdisciplinary research in the field.

In summary, the current chapter introduced basic concepts and techniques of secure and private AI in medicine. As the field matures, it is the authors' belief that it has the potential to cause a quantum leap in nearly every area of health care, serving to unite researchers and healthcare providers from all over the world in privacy-preserving and equitable collaboration.

Abstract

While artificial intelligence has been promised to revolutionize healthcare for decades, the field has yet to reap the benefits of automation compared to other domains. This chapter presents an overview of the vast field of decision-making in healthcare and proposes a functional classification of decision tasks. We aim to equip the reader with a working knowledge of

methods for clinical decision-making, including logic-based, learning-based, and Bayesian methods. We then introduce the reader to modern causal approaches to decision-making and reiterate the need for externally validated, explainable, and fair methods. Beyond the individual strengths and weaknesses of these methods, we argue that future AI products should embrace hybrid approaches and focus not only on improving clinical outcomes but also on offering a streamlined design that accelerates processes and facilitates clinical practice.

Introduction

Automation of Decision-Making in Healthcare

Since Antiquity, Medical practice has been organized around codified rules of conduct such as the Code of Hammurabi (1740 BC) or the Hippocratic oath (circa BC 460–360), derived from an understanding of physiopathology as well as political and religious constraints [1]. However, it was not until the development of modern decision theory in the 1950s [2, 3] that medical decision-making found a mathematical basis in symbolic logic and probability [4]. From then and until the early 1970s, the first wave of research focused on statistical approaches to perform diagnosis [5]. However, these methods lost their appeal when the field of AI emerged, built around knowledge representation and logic [6]. The 1980s gave rise to many logic-based “*Expert-Systems*” which, to this day, are among the most successful and finalized clinical decision support systems (CDSS) [7, 8].

In the 1990s and 2000s, during and after the *second AI winter*, research and institutional interest in AI and automated medical decision-making became more sporadic, and except for a few

projects [9, 10], the development of expert-systems dwindled. However, during that time, the internet facilitated the dissemination of medical knowledge, and computer systems became prevalent across most healthcare domains, especially for administration, data management, data analysis, and medical imaging. The use of computer systems in clinical decision support was relegated mainly to hospital EHR subsystems, such as drug dosage and interaction tools, or for simple automated detection, such as rule-based alarms for continuous monitoring in critical care units [11] or ECG machines able to perform diagnosis [12].

Besides the natural reticence and prudence of the medical culture [13], the slow development of automated decision tools not only highlights the complexity of decision-making in healthcare settings and the difficulty to improve clinical outcomes, but also the challenge of implementing AI research into well-designed products. The feeling that the science has not yet been made into acceptable technology is not new [6, 14], and it can be surprising that after 70 years of research and development, hospitals and clinician are still not equipped with computerized assistants. However, with recent innovations in Machine Learning, the last decade has seen a renewed interest in AI in the private and public sector [15]. In tandem with these theoretical advances, numerous innovations in basic science in the past decade have allowed us to gather new and complex types of data (e.g., fast genome sequencing and gene editing [16]). Software and hardware development has also gone through a tremendous revolution, including the creation of many new languages, interactive development environments, and programming frameworks to formalize and speed up development. The CUDA framework, for example, developed by NVIDIA, facilitated access to the parallel processing of Graphical Processing Units (GPUs) for non-graphics tasks, which later helped improve Machine Learning performance [17]. The proliferation of cloud storage and cloud computing has enabled large-scale deployment and maintenance of complex projects. Many of the digital technologies of the ‘90s and 2000s have matured, accompanied by a solid product design know-how reflected in the importance given to new roles

such as UX designers. As a result, since 2010, the market for patient-centric medical apps and smart-wear has bloomed [18]. Overall, most of these apps were developed outside of the healthcare sector, had poor retention rate [19] and – due to gaps in the regulatory frameworks – were improperly evaluated [20]. Recently, the mobile health sector has started a transition towards better frameworks of evaluation, publishing academic papers, and evaluating clinical outcomes using Randomized Control Trials [21, 22]. We are also observing an increasing interest in telemedicine solutions allowing direct patient access to their medical files, remote monitoring and consultations [23].

These recent innovations highlight the maturing interface between the medical and the technology sectors. They are strong indicators that the generation of medical products of the 2020s could finally offer the performance, automated functionality, ease of integration, and design quality necessary to deliver on the promises of AI in clinical decision-making – kick-starting the long-awaited revolution in healthcare access and practices.

Taxonomy of Medical Decisions

Healthcare systems are notoriously complex and comprise thousands of agents making decisions individually or collectively over multiple scales, from patients and clinicians to policymakers. Before introducing the AI methods used to solve complex decision-making tasks in healthcare, we must sketch the boundaries of these tasks and offer a general taxonomy inspired in part from previous works [24, 25]. The majority of the decision-making tasks in healthcare can, in principle, be automated or supported by computational methods. We can distinguish five decision domains (see Fig. 1). Across those domains, automated methods hold the promise of reducing human error, enabling better-individualized decisions, reducing costs, improving access to healthcare, and accelerating research and innovation.

Firstly, automated methods can be applied to basic and medical research to understand better human physiology and physio-pathology of diseases using large scale datasets or to discover new treatments. The RX project, developed by Blum in

CLINICAL TASKS		BASIC SCIENCE AND MEDICAL RESEARCH		LOGISTICS		HEALTHCARE POLICY	
Diagnosis	To discover the cause of a patient's abnormal condition	Statistical Modelling And Simulation	Model generative processes to test hypotheses or forecast a system's evolution (e.g. agent based modelling)	Resource Allocation	Workforce management tasks (e.g. nurse to patient assignment problem, operating room scheduling), patient planning (e.g. inpatients planning or geographical patient allocation), crisis management, but also other sub-tasks in more significant planning efforts such as hospital department design	Evidence Synthesis	Tools for automated or semi-automated analysis and summarization of research data and expert knowledge in order to facilitate decision making
- Passive Diagnosis	Single step diagnosis process which only rely on currently available information	Experimental Data Interpretation	Treat, visualise and analyse complex data (e.g. 3D reconstruction and labelling of microscopy data)	Quality Assessment	Tasks aimed at facilitating or performing automated assessments of processes in place in a healthcare setting. Such as evaluating the correct use and efficiency of decision algorithms and clinical pathways inside a hospital	Clinical Guideline Definition	Produce decision algorithms to homogenise and improve clinical practices
- Active Diagnosis	To plan an efficient data gathering sequence, and update it as new information is available, in order to make an accurate final diagnosis	Disease Understanding	Discover new conditions or partition existing conditions in a clinically or physiologically relevant manner (e.g. gene network cluster analysis)	Other support tasks	Coordinate or enhance productivity and communication across an organisation, or perform administrative tasks such as generating and processing financial statements	National And Supranational Policy	Define large scale health policies, financed by taxes for disease prevention, such as cancer screening, food and drug regulation, and publicly financed community care programs.
Prognosis	To forecast the likely course of a medical situation	Drug Discovery	Generate and evaluate new drug candidates (e.g. quantitative structure-activity relationship models)				
Therapeutic decision	To devise one or several plans to remedy, or prevent, a patient's condition.						
- Single-stage	To make a single therapeutic decision						
- Multi-stage	To make several therapeutic decision in time, adapting to the patient's response						
Surveillance	To implement a plan to monitor the evolution of a patient's condition during treatment, as well as to detect adverse effects and complications						
Physical Procedures	Embodyed tasks which require physical interactions with the patient, such as performing a clinical examination, an invasive test, or surgery						
Medical Imaging	Support tasks related to the treatment and analysis of medical imaging data						
- Enhancement / Reconstruction	Tasks aimed at improving the quality of medical imaging such as denoising, upscaling of low resolution imaging, or volume reconstruction						
- Detection / Segmentation	Detect, label, and/or contour anomalies or anatomical structures						
- Registration	Map one or several imaging methods to a single reference frame (e.g. registration of MRI and stereotactic radiography for deep brain stimulation implantations)						
Other support tasks	Many other tasks asked of physician during their practice can be automated. For example, speech processing, note taking and summarizing, translation, drug interaction detection, administrative tasks (insurance, certificates), or therapeutic education						

Fig. 1 Decision-making tasks in healthcare span across four broad categories: basic science, clinical, logistics, and policy-making. We present a non-exhaustive taxonomy of the main tasks in each category

1982, was one of the first such systems used to automate hypothesis generation and testing from a knowledge base of facts and statistical knowledge [26]. A more recent example is in drug discovery, where Deep Learning methods have been used to develop better Quantitative Structure-Activity relationship models and improve the selection process for promising molecular candidates [27]. Other examples include systems able to match patients to available clinical trials [28], predict protein folding [29], build disease progression models [30], or reconstruct 3D volumes from large microscopy datasets [31].

The second class of decisions relates to clinical care. This category covers most of the daily decision-making of medical doctors: triage, diagnosis, prognosis, treatment selection, but also all the support tasks surrounding these. These functional categories conceal a rich diversity, such as the nature and precision of the expected output, or the time scales at which decisions should be made. For example, evaluating the risk of lifestyle decisions over the lifespan or predicting the immediate evolution of a hemorrhagic choc are both prognostic tasks. Similarly, in the case of a cancer patient, treatment decisions can be deliberate, multi-disciplinary, and thorough, while life-threatening situations may require fast, purposeful, and sometimes approximate decisions [32].

The third domain relates to logistics and planning, where automated methods could help to better distribute resources, or to test and improve internal processes. For example, computational approaches could help forecast MRI scanners utilization in a hospital, better distribute patients across hospitals in a city [33], or help in the distribution of life-saving resources in a crisis [34].

Finally, computational methods are already used to support decisions regarding healthcare policies. This type of decision-making process is complex and multi-disciplinary and relies on data-driven insights, experts' opinions, as well as economic and political constraints. Statistical approaches are already vital to developing and refining clinical guidelines, as well as for deciding on global health policies at the national and international level [35]. The recent innovations in data-

driven methods, the increased access to larger datasets and the structuring of medical and research knowledge in large knowledge bases provide new opportunities for making sense of the vast amount of information now available to experts [36].

While the logic-based, learning-based, combinatorial optimization and Bayesian methods used to solve these tasks are theoretically distinct, the majority of clinical decision support systems (CDSS) are hybrid systems [24, 37]. To equip the reader with a working knowledge of AI methods, we present the general ideas of each of these approaches in the following sections.

Logic-Based Methods

Clinical knowledge is highly structured, both in terms of medical concept hierarchies and through the guidelines and clinical pathways which steer clinical decisions and draw the boundaries of malpractice. Logic-based methods can naturally encode these structures, making them usually safe and interpretable [24]. As a result, they are some of the most trusted and successfully deployed AI solutions for automated decision-making in medicine with projects such as MYCIN [7], INTERNIST-I [38], CADUCEUS [8], which employed logic-based reasoning solely or in part. This approach is often referred to as Knowledge-based AI because inferences are generated by applying logical rules to stored knowledge, usually gathered from experts.

The Language of Logic

Logic-based systems generate decisions by representing truth statements such as 'the patient has a fever' symbolically and combining these into logical propositions whose truth value generates the desired output. Depending on the logical formalism used, these propositions may include different types of objects. Propositional logic, or 0th-order logic, only deals with manipulations of atomic statements such as:

$$\begin{array}{l} \text{patient_has_fever} \Rightarrow \\ \text{administer_paracetamol. } p \Rightarrow q \end{array} \quad (1)$$

which represents a treatment rule whereby paracetamol is administered if and only if the patient has a fever.

On the other hand, higher-order logic, such as first-order logic, can handle universal quantifiers and variables, as well as predicates and functions over these. In turn, it allows for compositionality and reusable structures for constructing propositions. For example, instead of building two statements for p : “Core temperature of the patient is above 37.5 °C” and q : “Core temperature of the patient is above 39 °C,” with p and q stored and assigned through specific code, first-order logic enables one to express those two statements as $Gt(t(x), 37.5)$ and $Gt(t(x), 39)$ – a composite of the functions $t(x)$, which returns the core temperature of x , and the greater-than function $Gt(x, y)$ which is True if $x > y$. Variables can also be quantified as in:

$$\forall x(\text{Patient}(x) \wedge Gt(t(x), 38)) \Rightarrow \text{Fever}(x), \quad (2)$$

which corresponds to the sentence *For all patients x , if x has a core temperature above 38 then x has a fever*. While such composite statements would also need to be stored, their implementation is now modularized and offers many advantages. For example, it allows experts to work with composable objects during knowledge elicitation, which can be integrated into a readable user interface. It also better reflects how the code is implemented, with reusable and composable functions (i.e., accessing core temperature sensor) working on known objects (i.e., the patient).

Knowledge Representation and Reasoning

In real-world applications, the set of propositions known to the system is usually stored in a knowledge base (KB) and represented differently depending on the use-case. In “Rules-based” systems the KB emulates human

expertise and reasoning processes. It is comprised of sequences of If-Then conditions in a branching fashion, effectively forming decision trees of the form “*If P is True then do A , else do B* ,” with A and B being either a decision or another condition. Rule-based systems, such as MYCIN [7], are usually purely deductive (*forward-chaining*), and generate decisions as the tree is explored (see Fig. 2).

Other systems use an *ontological KB*, which defines concepts by their relationships to each other and answers logical queries via a combination of deduction, abduction and heuristics. Ontological KBs represent knowledge in the form “*A Relation B*,” where A and B are concepts, and *Relation* denotes a primitive relationship between concepts. For example, “Meningitis IS AN Infectious Disease” uses the relation “IS AN” to encode Infectious Disease as a parent concept of Meningitis. Queries of the form “What is Meningitis?” can be answered deductively by a lookup for all concepts X which satisfies the proposition “*Meningitis IS A X*,” for example returning {“Infectious Disease,” “Disease,” “Medical Finding”}. Examples of abductive queries include “What is the most likely cause of this patient’s fever?” which requires a ranking of compatible causes (“ X CAUSES Fever”) via a heuristic scoring function. For example, in INTERNIST-1 [38], characteristic disease profiles, known as *frames*, are used to match a patient clinical presentation to the “closest” known profile.

Beyond First-Order Logic

Despite their large adoption, logic-based approaches are unable to deal with high combinatorial complexity. For example, with a hundred symptoms, the number of valid symptoms combinations and potential rules easily exceeds the number of atoms in the observable universe. Another drawback is their inherent weakness in handling uncertainty and ambiguity, which are found throughout medical decision-making. To better handle the stochastic nature of real-world tasks, a new family of methods based on Fuzzy-logic was developed. Fuzzy-Logic arose from the

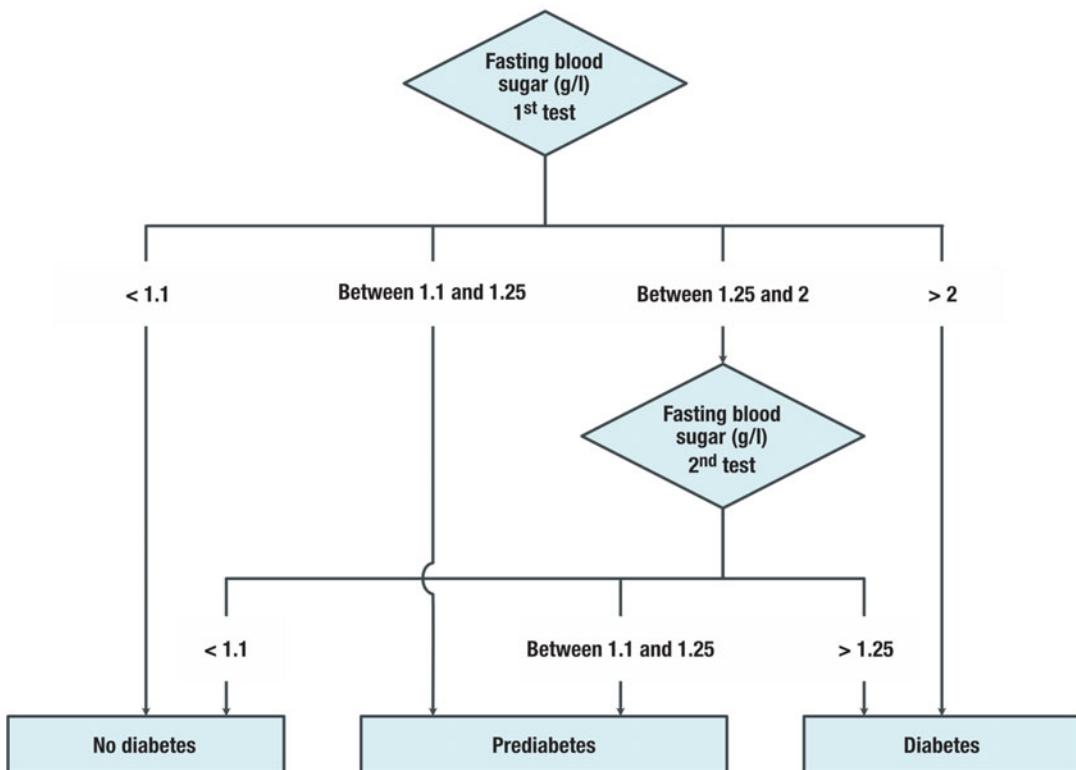

Fig. 2 Example of a decision tree used for diagnosing diabetes

concept of Fuzzy sets [39], and deals with approximate truth values by relaxing the notion of set membership to account for partial membership. While it is not meant to produce valid probability distributions, Fuzzy logic allows for incorporating scoring functions to weight propositions and rank or combine the resulting decisions. This extension to logic-based methods can deal with ambiguous situations and facilitates knowledge elicitation from experts in areas where medical knowledge is imperfect [24]. Fuzzy logic CDSS are still being actively researched [40], for example, in radiotherapy treatment planning [41], or management of urinary tract infections [42].

The methods presented in the next sections resolve some of the issues of logic-based systems and their combination with logic-based approaches (e.g., Markov Logic Networks) can offer best-of-both-world solutions as a “judicious combination of categorical and probabilistic reasoning” [37].

Learning from Data

Statistical Modelling and Machine Learning

Since the 1960s, statistical modelling has transformed the way we conduct clinical research [43], has shaped the common language of Evidence-Based Medicine [44], and defined the quality standards for experiments and data analysis. It could be surprising to realize that those applied statistics methods, well known in the medical field, are in fact Machine Learning (ML) methods, in that they construct models by *fitting* them to data, optimizing for the best parameters in order to minimize prediction error. This defining characteristic means that, unlike knowledge-based methods, ML methods do not rely on experts to craft decision rules or select model parameters. While the models used in statistical analysis are

typically simple and transparent, ML models can be highly complex, in some cases comprising of billions of parameters [45]. While simple statistical models are used to solve *inference* tasks, e.g., answering queries such as “How much does event A increase the risk of disease B?” ML methods have excelled at *prediction*, which aim to approximate unseen data points [46]. In the following section, we outline the main principles and medical applications of statistical machine learning, and further explore the trade-off between the predictive power of ML methods versus their ability to answer direct associative queries (see [7]).

Three Machine-Learning Approaches

Learning can be defined as the process of discovering and storing functional knowledge about invariant properties of the world, patterns conserved in time, in order to make predictions. Machine learning methods are commonly divided into three main classes, corresponding to three different types of invariant property and task

objectives: *Supervised Learning*, *Unsupervised Learning*, and *Reinforcement Learning* (see section “[Reinforcement Learning for Sequential Decision-Making](#)”).

In *Supervised Learning* the task is to find the best parameters of a model able to map a set of predictors X into a target variable Y (see Fig. 3). This class of problems is ubiquitous in applied statistics. In biomedical research, for example, one would try to estimate the impact of a specific treatment (X) on survival (Y) using a linear model (see Fig. 4).

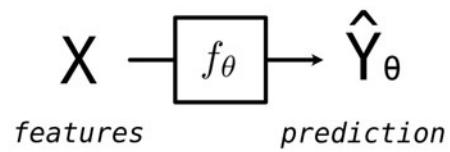

The arsenal of methods applicable to supervised learning tasks is vast, among them simpler approaches like Classification and Regression Trees (CART) [47] and Generalized Linear Models (e.g., Logistic Regression) [48] are frequently used in the medical literature. Efforts were made in recent years to facilitate the adoption of more complex approaches by non-expert and clinicians [49]. Nevertheless, models such as Structural Equation Models [50], Support Vector Machines [51], or Neural Networks [52], still necessitate in-depth knowledge in specific tools

C.

D.

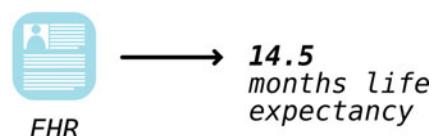

Fig. 3 In Supervised Learning, the dataset is composed of two types of variables: the features (X) from which the model is to predict one or several target variables (Y). **B.** The task is to find the optimal parameters θ^* of a model f_{θ} so that the estimate Y^{θ^*} is as close as possible to the known target Y , which corresponds to minimizing the loss function (Y, Y^{θ}) . The nature of defines the task objective and what the parameters will be optimised to solve. For example, additional constraints may be

added to the estimation error of Y to promote specific properties of the model, e.g. adding an L1 regularisation term to promote sparsity (LASSO). **C. and D.** Depending on the nature of the target variable Y , we classically separate supervised learning tasks into two subtypes: when Y is a discrete variable (e.g. tumour label, C.), the task is called *classification*, and when Y is a continuous (e.g. life expectancy, D.), the task is called *regression*.

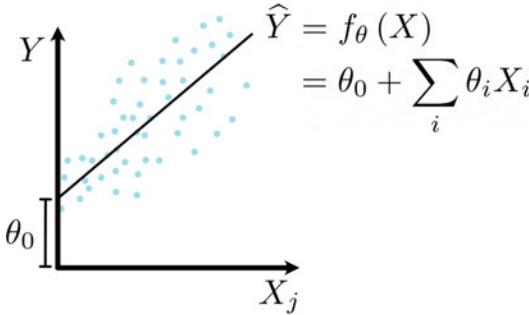

Fig. 4 f_θ is a model with parameters θ , linear in the input variables $X = \{X_0, \dots, X_k\}$. A linear model's simplicity allows estimating the magnitude of a direct and linear association between any predictor X_j and the target variable Y , expressed by a single parameter θ_j .

ad programming languages, which limits their diffusion into epidemiology and clinical research.

The second family of ML approaches is *Unsupervised Learning*, so-called because learning occurs in the absence of “supervision signal” contained in the target labels Y . Instead, the objective is to find a compressed and informative representation Z of the data X , which can explain the data or from which we could reconstruct the data using a *decoder* function (see Fig. 5). The relative importance given to the representation and the decoder depends on the specific method, with certain methods only interested in obtaining a useful representation Z (e.g. clustering), others in learning an efficient decoder to generate X (e.g., GAN, Autoregressive models). The encoder function, which transforms X into Z , and the decoder function, which recovers \hat{X} from Z , can be learned or be known a priori. One simple class of unsupervised learning algorithms is the binning algorithms used to build histograms. Indeed, a histogram is a compressed representation of continuous data, requiring only one number per bin. Using a sampling scheme as decoder, a dataset can then be reconstructed by sampling from the distribution described by the histogram. Another classic example is the task of data compression, where the goal is to find the encoding scheme which yields the smallest description (Z) while being able to generate a faithful reconstruction of the original data (\hat{X}) (see [53]).

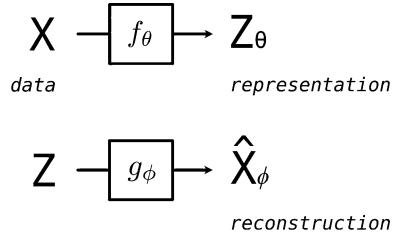

Fig. 5 In unsupervised learning, the objective is to find a representation Z of the data X . The *latent* representation Z is not directly measured but can be used to visualize, explain or reconstruct the data. Here, the invariant properties are captured both in the *encoder* f_θ , a function with parameters θ which maps X to Z_θ , as well as the *decoder* g_ϕ which is able to reconstruct \hat{X}_ϕ from Z

Unsupervised learning methods routinely used in applied statistics include clustering approaches (e.g., k-means clustering), and dimensionality reduction methods such as Factor Analysis, Principal Component Analysis, or Singular Value Decomposition. Although, in recent years the Deep Learning revolution has allowed to learn more complex encoder and decoder functions, the Deep Auto-Encoder architecture being one of the first examples [54], followed by Variational Auto-Encoders [55], Adversarial Approaches (e.g., GAN [56]), Autoregressive models [57], Normalizing Flows [58], and more recently self-supervised approaches relying on Contrastive Loss [59].

Along with advances in optimization methods, the machine learning toolbox has grown steadily since the 1960s. For example, the 1986s algorithm *ID3* allowed to learn decision trees [60], and Support Vector Machines (SVMs) [61] were able to learn decision boundaries in large input spaces. The idea that ML would become an essential tool for automated decision-making in healthcare is certainly not new [26]. However, before the turn of the century, these learning methods found limited applications in the medical field and were not deployed at scale. It started to change in the last two decades due, in part, to the digitization and storage of large medical data sets [62], as well as the increased computational power and scalability of modern algorithms (e.g., the kernel trick in SVMs). Recently, the field of AI, its reach, application, and most of all, its funding was profoundly

transformed by the development of modern Deep Learning methods.

The Impact of the Deep Learning Revolution

The 2010s have seen the rise of a transformative class of AI methods called Deep Learning (DL), which rely on large Neural Networks (NNs) models [63]. The architecture of NNs is inspired by the nervous system and was first introduced in Rosenblatt's seminal 1958 paper on *Perceptrons* [64] in an effort to describe a quantitative

approach compatible with the Hebbian Theory of synaptic plasticity. Those networks are organized hierarchically in layers composed of computational units called “*neurons*,” from the input layer to the output layer, with in between a series of “*hidden*” layers. Each unit is optimized to represent a simple function of its input, unique to each neuron, which is the composition of a linear function and a nonlinear *activation function* (e.g., sigmoid or ReLU [65]). For each neuron, the parameters of its linear function are optimized (i.e., “learned”) so that its overall participation to the error is minimized (see Fig. 6). Under certain assumptions, NNs can provably approximate any

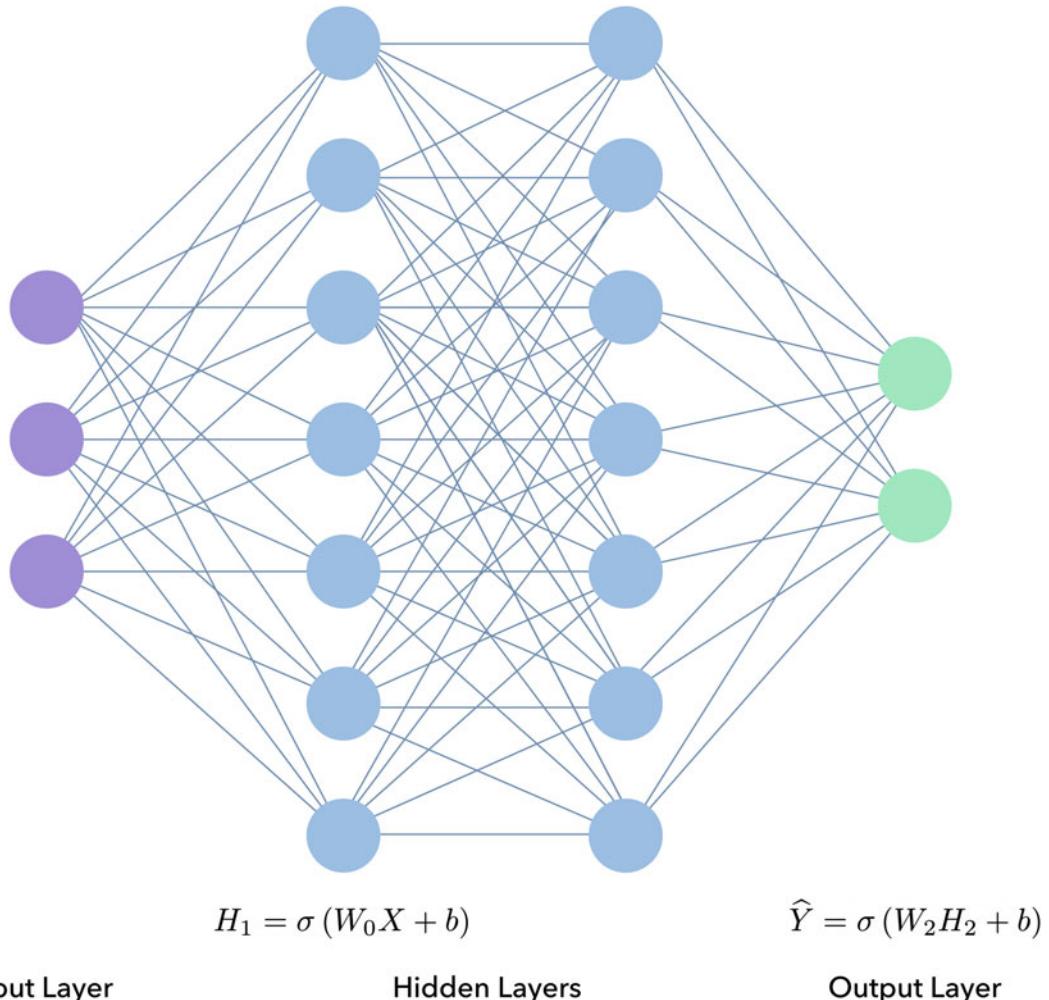

Fig. 6 Example of a feed-forward neural network taking $X \in \mathbb{R}^3$ as input, with W_k the weight matrix for a layer k , and σ the activation function (e.g. sigmoid or ReLU). The output \hat{Y} is a vector in \mathbb{R}^2

function with arbitrarily small error [66]. They are also distributed algorithms, with each neuron treating the information independently of other neurons on the same layer. Hence, same layer operations can be computed in parallel and boil down to large matrix multiplications well suited for increasingly powerful Graphical Processing Units (GPUs), which considerably speeds up learning and prediction.

These characteristics, along with several key innovations in the training methods and architectures, have enabled neural networks to efficiently find patterns inside complex, messy, and unstructured datasets beyond the limits of human perception and processing abilities. It explains the success of DL in the field of medical diagnosis from medical imagery, which will be largely covered in the next chapters, in particular in its application both as a tool to help process images and isolate critical regions, as well as a stand-alone automated diagnosis tool. DL's ability to exploit highly complex patterns could revolutionize our ability to classify, diagnose, and treat diseases earlier and with more precision [67]. However, despite its successes, DL methods typically lack the explainability and safety requirements that are central to medical practice – an issue that we explore in section “[Explainability, Interpretability, and Fairness](#).”

Combinatorial Optimization Methods

Combinatorial optimization methods were devised to speed up the search for valid solutions in well-defined systems that require solving for several interdependent variables. Rather than exploring all potential solutions blindly (see brute-force

search Fig. 7), they rely on the structure of the problems to improve efficiency. They play a crucial role in automation and are a central part of the AI toolbox. The dependencies between decisions can be causal, in time, due to the sequential nature of the problem. For example, when playing chess or when looking for the shortest path between two points. The dependency could also be through shared constraints, for example, a limited resource, such as when looking for an optimal nurse-to-patient assignment.

While some may not consider those methods as AI, it remains that it is such variations on the classic search algorithms that defeated Kasparov at chess in 1996 (alpha-beta pruning [68]), and more recently won against Lee Sedol, the world champion in the game of Go (Monte-Carlo tree search [69]). Combinatorial optimization has been researched extensively in healthcare settings [70], mainly to solve logistic tasks, resource allocation or help in global policy decisions, with a few examples in diagnosis and therapeutic decision tasks [71]. Among those methods, we will discuss exclusively the very active field of reinforcement learning, an approach worth mentioning both because of its recent super-human results on many non-medical tasks, as well as its unresolved limitations in highly regulated domains such as medicine.

Reinforcement Learning for Sequential Decision-Making

Reinforcement learning (RL) describes a family of methods inspired by operant conditioning, a form of associative learning through which rewards and punishments reinforce behaviors.

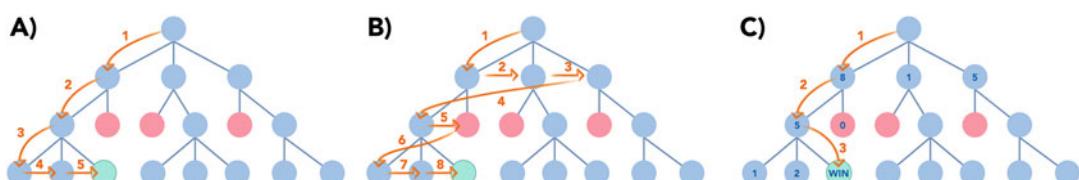

Fig. 7 Three search algorithms are looking for the target state (green). Depth-First (a) and Breadth-First Search (b) are brute force search algorithms, as compared to Best-

First Search (c), which is an informed search algorithm using *state values* to speed up search and avoid costly states (red)

They aim to solve sequential decision problems in settings where the underlying system and its dynamics are usually only partially known or too complex to simulate in reasonable time [72]. In order to facilitate the search for an optimal decision sequence, RL algorithms learn the value of states and/or actions through exploration, which allows at test-time to efficiently perform a best-first search approach (*model-based*) or to use a deterministic policy (*model-free*).

Recently, these approaches have greatly benefited from advances in Deep Learning, which unlocked the ability to represent and solve problems of much greater complexity. These *Deep* RL methods were particularly impressive in solving complex games, such as Go, Chess, Starcraft, Dota, several 1980s' Atari games, as well as many hard robotic tasks [73]. RL relies on a model called a Markov Decision Process, which formally describes a system's evolution in terms of state and actions, as well as a preference over certain states quantified. The Markov property specifies that the future only depends on the current state and the actions of the agent(s). This setting is pervasive in healthcare, for example, when planning a series of questions and tests to diagnose a patient or when defining clinical pathways for managing a particular disease.

Contrary to supervised learning approaches, in RL the goal is to learn a function able to map a state to an action (the *policy*) so that the average reward is maximized. Moreover, the data used in RL is usually gathered progressively through interactions rather than given a priori, and the history of actions leading to a particular state is used to learn how to behave optimally. Crucially, outside of particular settings, it would be dangerous, unethical and relatively slow to train agents in real environments. This is why researchers have relied either on simulated environments or on observational datasets (given this time a priori) where the actions are performed “off-policy” by real agents (e.g., doctors) rather than the algorithm itself.

In medicine, those methods have been used to train agents to perform active diagnosis [74] and triage [75] from structured evidence (see [76] for a formal treatment). It has also been used for

diagnosis using unstructured data, either directly or with a human-in-the-loop approach [77]. For example, it has been used to aid radiologists to parse medical images [78] and to perform diagnosis using new sources of data (e.g., using connected devices to diagnose lung cancer [79]). Regarding treatment, RL has been used in specific diseases and with a narrow set of actions to optimize. In particular, it has been used to learn the best treatment policy, or to adapt treatment, for diabetes [80], intensive care [81], sepsis [82] and respiratory failure [83].

Several drawbacks of the method impede the deployment of RL agents in real-life settings [84]. Mainly, the difficulty in measuring all potential confounders to avoid biased decisions, the high sensitivity to task parameters, and the opacity and the difficulty enforcing the safety of the learned policy. Methods have been proposed to help reduce the bias, produce human-understandable policies [85], evaluate the safety [86], and quantify the uncertainty of the resulting policies [87]. While safety could be improved using human-in-the-loop approaches, or logic-based constraints baked inside the environments (e.g., treatment dose limit), safe reinforcement learning remains a marginal but growing area of research. Like any ML-based system, deploying RL agents in real-life settings should be performed with extreme care only after a thorough clinical evaluation.

Bayesian Models for Decision Support

While fuzzy logic methods introduced in section “[Beyond First-Order Logic](#)” offer a path to working with partial and ambiguous knowledge, Bayesian methods take this a step further, offering a principled way of making decisions that take into account uncertainty and degrees of belief. Bayesian models can be learned from data, elicited from experts, or a combination of the two [88]. For example, the optimal model parameters can be identified by maximum a posteriori estimation,

$$\theta_{\text{MAP}} = \underset{\theta}{\operatorname{argmax}} P(D|\theta)P(\theta) \quad (3)$$

Carefully selecting the prior $P(\theta)$ allows domain knowledge to be injected into the learning process. While regression-based models described in section “[Learning from Data](#)” predict values of Y from features X , the outputs of Bayesian models are probability distributions $P(Y|X; \theta)$, supporting inferences on the statistical relationships between variables and principled uncertainty estimates for predictions. Despite these benefits, principled and effective priors can be hard to construct [89], and the computational cost of performing inference at train and test time is typically much higher than the equivalent overheads for function approximation methods.

Bayesian models are either generative models, representing the full joint distribution $P(X, Y; \theta)$, or are discriminative models, representing the conditional distribution $P(Y|X; \theta)$. Examples of generative Bayesian models include probabilistic graphical models, Gaussian mixture models, and linear discriminant analysis. Examples of discriminative Bayesian models include Gaussian processes, logistic regression, and Bayesian neural networks [88]. A generative model can generate any discriminative model over its variables by applying Bayes rule and marginalization. Thus, generative models can “drop” and “swap” inputs and outputs without requiring learning a new model or imputing missing values. This is particularly useful in clinical decision tasks such as diagnosis, where missing features are common and where variables such as those modelling the presence of a disease can be both input evidence and a target variable. This power comes at a cost – learning the joint distribution is often far more challenging than learning the conditional distribution for a small subset of target variables. Hence, discriminative models often achieve better performance by focusing modelling and computational resources on a simpler learning objective.

Bayesian Networks for CDSS

Bayesian networks (BNs) are intuitive graphical representations of joint probability distributions that offer several key advantages over logic and regression-based methods while presenting their

own unique challenges [90]. BNs are generative models comprising of nodes situated in a directed acyclic graph (DAG), representing variables and their causal relations, respectively (Fig. 8). It is this injection of causal knowledge that endows BNs with some unique properties, making them particularly well-suited as clinical decision models. For one, the joint probability distribution factorizes with respect to the DAG, greatly reducing the computational cost of inference and learning compared to unfactorized representations [88]. It can also be exploited to learn BNs from expert opinion, or directly from data using constraints-based and score-based learning algorithms, or a combination of the two [91]. This ability to learn from expert opinion is particularly important in tasks where carefully annotated data is scarce or non-existent, as is often the case in clinical decision tasks where labels are often generated by expert elicitation.

This addition of causal knowledge not only expedites model learning and inference – it also enables BNs to perform inferences that are impossible with other methods. The encoding of causal and conditional independencies as graphical structure allows complicated independence relations such as d-separation to be recast as simple graphical criteria, and enables causal and counterfactual “what-if” inferences under rigorous and testable assumptions [92]. These causal inferences are vital for many clinical decision tasks including individual risk prediction [93] and diagnosis [94], and can be used to construct explanations for automated decisions [95]. Finally, this graphical structure provides a route for extending BNs to influence diagrams by including decision and utility nodes [96]. These models are widely used in CDSS for determining optimal decisions via cost-utility analysis, including identifying optimal tests and evidence gathering through value of information (VOI) analysis [97].

For these reasons, BNs have been widely adopted as clinical decision support models, appearing across a range of medical specialisms including oncology [98], cardiology [99], neurology [100], psychiatry [101], and pediatrics [102], intensive care [103], and primary care [94], including systems developed by an emerging market of

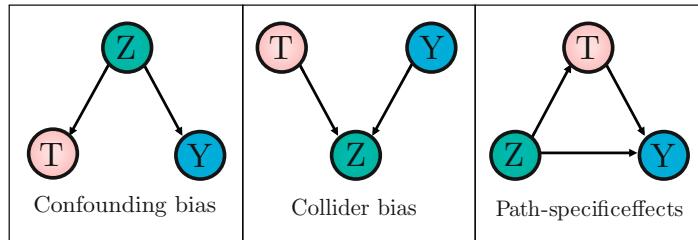

Fig. 8 Figure depicts common causal biases. Confounding bias arises when there is an unobserved common cause (Z) of both the treatment (T) and outcome (Y) variables. For example in [116] confounding bias is discussed as an explanation for the obesity Paradox, as smokers tend to have reduced rates of obesity and increased risk of morbidity. This bias can be corrected for using methods including the back-door adjustment formula and propensity score matching. Collider bias arises when the treatment (T) and outcome (Y) both independently cause a third variable (collider Z), which is then inappropriately controlled for either through statistical analysis or study design (selection bias). For example in [117], collider bias was identified as the cause of a strong association between locomotor disease and respiratory disease, spuriously suggesting that treating locomotor diseases could reduce the incidence of respiratory diseases. As the study was performed on hospitalized patients, and both locomotor and respiratory diseases independently cause hospitalization, then

selecting for hospitalized patients resulted in a spurious association between these disease groups, despite no such association being present in the general population. Collider bias can be controlled for using the tools of causal modelling and study design [118]. Path-specific effects arise in the presence of multiple causal pathways between treatment and outcome. For example in [115] several machine learning methods were employed to predict mortality of patients hospitalized for pneumonia. The models incorrectly learned to treat asthma (Z) as a protective risk-factor for pneumonia inpatients, reducing the mortality risk (Y). This result is due to path-specific effects – patients with asthma were more likely to receive aggressive treatments (T), which results in a lower mortality rate due to the path $Z \rightarrow T \rightarrow Y$, despite the negative direct causal effect of asthma on mortality from the path $Z \rightarrow Y$. Methods for resolving and correcting for these direct and indirect causal effects have been developed using counterfactual inference and mediation analysis [119]

digital healthcare companies [104, 105]. They have been applied to a variety of decision tasks, such as prognosis and risk prediction [106], treatment selection [107], and diagnosis [38, 94]. Despite these benefits, the use of BNs as decision support models has tapered off in recent years in favor of data-driven machine-learning algorithms. This transition has been driven by the move towards large, unstructured data sets and away from the expensive and time-consuming elicitation of structured expert knowledge. Another disadvantage of BNs in the big data regime is that the search space of DAGs grows super-exponentially with the number of variables. This makes learning BNs from large multivariate data sets very challenging, although there has been significant progress to reduce learning complexity in recent years [108]. On top of this, regression-based algorithms typically achieve higher accuracies than BNs at prediction tasks [109], and have emerged as the clear favorite models for constructing CDSS when sufficient labelled data is available. There is

however one area that Bayesian networks continue to play a key role – identifying cause and effect.

The Need for Causality in Clinical Decision-Making

The ultimate export of clinical decision support systems is to help clinicians select the best actions – to answer questions such as ‘what would happen to the patient if I administered this treatment?’. In statistical theory, interventions are treated distinctly from observational data as they carry additional information about cause and effect [92]. Consequently, the effects of interventions cannot be determined from observational data alone, requiring interventional data from randomized control trials or the application of causal inference techniques, which in turn require domain knowledge and causal assumptions that are not included in most clinical data sets [110]. Despite this, observational data sets such

as electronic health records are routinely used to make predictions and train decision algorithms without correcting for causal biases, potentially resulting in sub-optimal and even harmful decisions [93].

A classic example of this is the so-called obesity paradox – a routinely observed association between obesity and reduced mortality risk in patients with chronic diseases including cardiovascular disease, renal disease, diabetes, and stroke [111]. Causal explanations for this paradox have been proposed, including confounding bias [112] and collider bias [113], which in turn can be understood and mitigated using the tools of causal inference (Fig. 8). Decision support systems naively trained on observational data will learn to treat obesity as a protective risk factor for these conditions – a dangerous conclusion that could result in a less aggressive treatment regime being selected for obese patients despite their increased mortality risk. Similar examples arise in a variety of clinical settings [114, 115].

Causal biases are present to some extent in all real-world observational data sets [120]. The challenge is therefore to learn decision-making algorithms from abundant observational data while employing the tools of causal inference to correct for these biases. For example, the most common causal inference task in clinical decision-making is the estimation of treatment effects [121], which measure the response of individuals and populations to clinical interventions (treatments), and determine optimal personalized treatment decisions for individual patients [122]. Treatment effects quantify the causal relationship between a treatment variable T and an outcome Y (e.g., recovery rate) by comparing the expected value of the factual outcome (e.g., the recovery rate of treated individuals) to the corresponding counterfactual outcome (the recovery rate that would have been observed for treated individuals, if they had not been treated). This comparison of factual and counterfactual outcomes deals with the confounding bias that arises in the absence of randomization – patients with different propensities to receive treatment may have different recovery rates, e.g., sicker patients are more

likely to be treated and less likely to recover regardless of treatment (Fig. 9).

However, estimating treatment effects is notoriously difficult and typically relies on strong assumptions on how the data is generated and collected [124].

A common approach to estimating treatment effects is to apply the potential outcomes framework [125], under the assumption that all confounders between the treatment and outcome variable are observed. Recent advances extend this framework using methods from statistical machine learning including tree-based methods [126], deep learning [127], generative adversarial networks [128], and Gaussian processes [129]. Other advances have focused on applying the potential outcomes framework to more complicated prediction tasks involving time-series data, such as dynamic treatment regimens [130], dose-response curves [131], survival analysis [132], disease progression models [133], and state-of-the-art clinical decision support pipelines [49].

Structural causal models (SCMs) and Pearls' calculus of intervention are often used to estimate treatment effects in more complicated causal scenarios where fewer assumptions can be made [92, 134], such as in the presence of unobserved confounding or collider bias [135]. While these two approaches to causal inference – potential outcomes and SCMs – are complementary and logically equivalent [92] (pp. 2314), SCMs have the benefit of making causal assumptions explicit and testable by encoding them in directed acyclic graphs (DAGs), rather than relying on counterfactual assumptions such as strong ignorability [92, 134]. SCMs have been adopted in many cutting-edge methods, including estimating treatment effects using deep generative models [136] and dynamic treatment regimens [137]. Beyond estimating treatment effects, SCMs have been used to transport treatment effects between populations [138], to enhance explainability [139], fairness [140] in clinical decision-making, and in diagnostic decision-making [94], due to their ability to estimate the complicated counterfactuals required for diagnosis. These relatively recent advances hint that we are only beginning

Counterfactual	<p>Activities : Imagining, retrospection, explaining.</p> <p>Questions : How would my belief in Y change, given that I observe X to be some value, if instead I had forced X to take some different value?</p> <p>Examples : Is it likely that the patients symptoms were caused by this disease?</p>
Intervention	<p>Activities : Acting, intervening.</p> <p>Questions : How would my belief in Y change if I forced X to take some value?</p> <p>Examples : If we gave a patient a disease, how likely is it they will develop these symptoms?</p>
Association	<p>Activities : Observing, seeing.</p> <p>Questions : How would my belief in Y change given that I observe X to be some value?</p> <p>Examples : How often do patients with this disease develop these symptoms?</p>

Fig. 9 Pearl's causal hierarchy [123]

to understand the central role that causality will play in the next generation of clinical decision-making algorithms and, more broadly, artificial intelligence [141].

Explainability, Interpretability, and Fairness

One of the essential qualities of clinicians is their ability to communicate their findings and explain the reasoning behind their decisions. This ability allows for clinical decisions to be discussed and sense-checked against recommendations and clinical guidelines, and is critical for ensuring the trust and mutual understanding necessary for any automated system to work in a clinical setting. For

example, several deep learning systems for diagnosis from medical images have been found to learn image features relating to the specifics of the imaging device, which were predictive in a particular dataset but do not generalize and are clinically irrelevant [142]. Because these models are black-boxes, their decisions cannot be explained by humans, and these failures are often overlooked until they emerge in the field, when these systems fail to generalize to new clinical environments.

Explainable AI [143] seeks to deobfuscate these black-box models, typically by learning a second post-hoc model for generating explanations [139]. This approach is widely applied, especially for deep learning methods in clinical decision-making [144]. However, it is still debated whether or not these post-hoc

explanations are robust and reliable descriptions of what the black-box model is actually doing [142]. Another approach is to use models that are inherently interpretable and generate their own explanations [145]. However, many of these methods (including rules-based AI) ensure their interpretability through tight constraints that hamper model expressiveness, often resulting in decreased accuracy and leading some to propose a trade-off between interpretability and performance [146]. Human-in-the-loop training has also been proposed as a way to continuously sense-check and improve clinical decision-making systems by incorporating expert judgments in a continual training loop [147].

However, fully interpretable models can still produce undesirable decisions due to biases present in the training data. For example, in [148] it was found that a widely used commercial algorithm for guiding population health decisions exhibited racial bias. By using healthcare costs as a proxy to measure illness, the algorithm systematically underestimated the risk for African Americans. Historical biases in access to care inhibited the healthcare costs for African American patients, resulting in artificially lower risk predictions and lower priority access to care. Moreover, simply ignoring sensitive attributes is insufficient, as other attributes act as proxies (for example, postal code acting as a proxy for race) and can lead to even worse discrimination [149]. The emerging field of algorithmic fairness seeks to mitigate these biases [150], and while still in its infancy, it will be an essential part of AI research in the coming decade.

Conclusion

In this chapter, we have introduced the main approaches in artificial intelligence as applied to decision-making in healthcare. We have reviewed the recent innovations in AI, basic science, software and hardware products, as well as the maturing interface between technology and healthcare, and have argued that these developments indicate that the long-awaited paradigm shift in medical decision-making may be near. We have given a

functional classification of decision tasks that could be automated and successfully deployed at scale in the next decade. By introducing the main families of AI methods available, we aimed at highlighting their complementary properties and the potential of combined hybrid approaches. However, we have highlighted that these fast innovations, particularly in the machine learning field, do not come without risks and several biases that we have discussed. We presented causal methods to reduce causal biases in systems working from observational data and reiterated the need for modern clinical AI-product to prove their efficacy on clinical outcome metrics in Randomized Control Trials. Finally, we have argued that explainability, safety, and fairness are central to the applicability of AI to clinical decision-making beyond efficacy considerations and will undoubtedly continue to grow as a central research area in the next decade.

Abstract

Medical diagnosis has been one of the primary targets of Artificial Intelligence research since the inception of the field. In recent years, rapid

advances in Artificial Intelligence have seen the emergence of diagnostic algorithms that perform as well as clinicians and can be applied at scale in clinical practice. This chapter presents a broad picture of the foundations, history, and the current state of AI in medical diagnosis. We provide an overview of the complex and interdependent tasks required to perform diagnosis and explore how ideas from the study of diagnostic reasoning and diagnostic errors can guide the effective development and deployment of Artificial Intelligence solutions.

We then review the three main approaches to diagnostic AI; rules-based, model-based, and machine learning, detailing their strengths and weaknesses, and how each of these approaches tackles diagnosis from a different angle.

Keywords

Clinical decision-making · Artificial intelligence · Medical diagnosis · Causality · Computer-assisted diagnosis

Introduction

Diagnosis is one of the most important tasks that clinicians perform. Diagnostic errors account for one of the largest sources of burden to healthcare systems globally [1], with wrong or delayed diagnoses occurring in an estimated 10–15% of cases [2]. These errors cause more serious patient harm than any other type of medical error [3], resulting in between 40,000 and 80,000 death per year in US hospitals alone [1]. Improving the accuracy and timeliness of diagnoses reduces costs incurred by inappropriate testing, wrong treatments, and malpractice lawsuits, with the potential to save up to \$100 billion per year in the USA alone [4]. Improving access to clinicians for undeserved communities is also an important component of any solution to these issues, and is increasingly prioritized by governments, NGO's, and digital health companies [5]. Over the past 40 years, AI has always seemed only a few years away from resolving these issues; promising to improve access through automation and digitization, while simultaneously reducing the incidence of diagnostic errors.

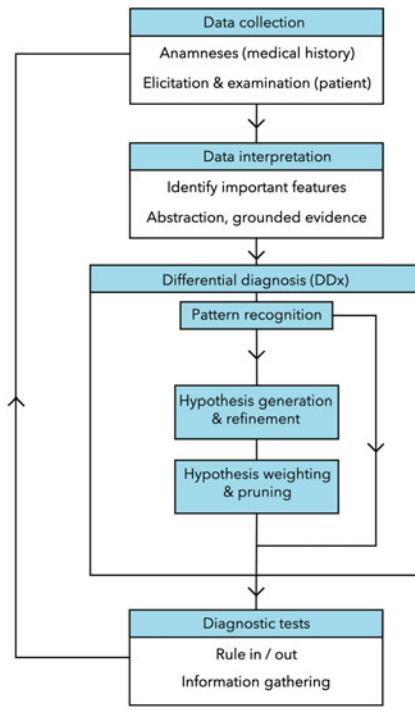

In this chapter we present a broad picture of the foundations, history and current state of AI for diagnosis. Diagnosis is a specialized instance of clinical decision making, and in this chapter we extend upon the methods presented in ► Chap. 11, “[Artificial Intelligence for Medical Decisions](#),” with a focus on the specific complexities that arise in diagnostic tasks. We provide a brief review of diagnostic reasoning, including the non-systemic biases and limitations that cause

diagnostic errors, how these can be addressed with AI, and how they can inform the development and deployment of AI solutions. We will cover the three main approaches to diagnostic AI: rule-based, model-based, and machine learning. These three approaches developed at different times and were borne out of fundamentally different AI paradigms, and each tackles diagnosis from a different angle. Due to the complexity of the diagnostic process, which comprises of multiple sub-tasks with their own requirements and strategies, none of these approaches alone is sufficient to characterize and “solve” diagnosis, which ultimately requires a hybrid of these methodologies.

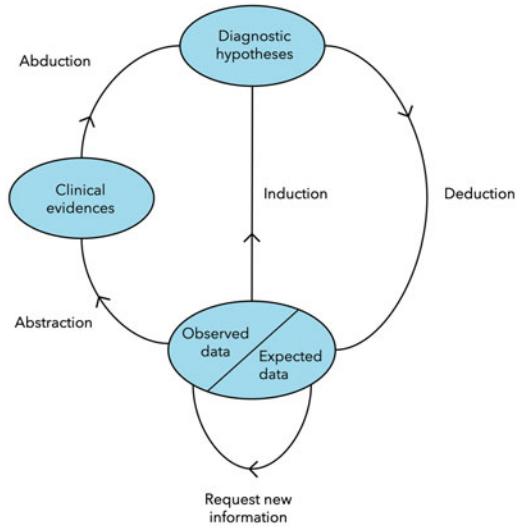

Diagnostic Reasoning

The goal of diagnosis is to identify the possible diseases or conditions that best explain the signs and symptoms presented by the patient. In clinical practice, diagnosis is an ongoing dynamic process between the patient and doctor, consisting of a sequence of interdependent tasks that revolve around gathering and interpreting patient data, and generating and testing hypotheses (Fig. 1). In their initial interaction, the doctor collects relevant medical history (anamnesis) and symptoms through direct elicitation from the patient, gathers the patient’s signs through physical examination, and optionally plans para-clinical tests (e.g., lab tests or imagery) [6]. This evidence is then interpreted and used to generate and weight diagnostic hypotheses, which are then used to inform the gathering of additional information to rule in or out conditions. Once these hypotheses are whittled down to a final diagnosis, remedial actions are selected, for example selecting treatments or “wait and see.”

We refer to this dynamic and investigative process, through which the underlying cause of the patient’s presentation is discovered, as “active diagnosis” [6, 7]. The iterative process of hypothesis generation and hypothesis testing has been formally described by Pierce’s “Select and Test model” [8], later adapted to medical diagnosis by Ramoni (Fig. 1) [9, 10]. This describes diagnostic reasoning in terms of sub-tasks involving

[a]

[b]

Fig. 1 (a) Depiction of active diagnosis process. Data is gathered, interpreted and abstracted. If the diagnostic case is identified in memory (pattern recognition), diagnostic tests can be immediately selected (type 1 reasoning), otherwise a process of hypothesis generation and refinement is initiated (type 2 reasoning). Diagnostic tests feed back into data collection, and the process continues until a final diagnosis is reached. (b) The Select and Test model [8, 9] describes the diagnosis process as first an abstraction step,

abstraction, abduction, deduction and induction which, when performed by clinicians, require a combination of complex cognition, metacognition, experience and formal knowledge [11]. These cognitive processes and their relation to each other are often described using the dual-process theory of clinical reasoning [12], which frames diagnosis as a combination of automatic, intuitive reasoning based on past experiences (type 1 reasoning), and conscious, reflective and analytic reasoning (type 2 reasoning) based on logic and formal knowledge [13]. Type 1 reasoning is responsible for generating diagnostic hypotheses, and is based on similarity matching the current diagnostic case with past experiences and exemplars. Type 2 reasoning is employed if a

converting raw observations into useful evidence, followed by three types of logical inference steps: abduction as the process of hypothesis generation from evidence, the deduction of which new evidence to expect given the hypotheses, which is used to inform information gathering, and potentially an induction step which allows to immediately revise hypotheses following unexpected observations, or to generate new knowledge

diagnosis cannot be identified from memory, or to correct for errors in type 1 reasoning. Type 2 reasoning also controls the search for information or the selection of follow-up tests which are not immediately triggered by a specific situation, as well as the weighting of diagnostic hypotheses [14]. It has even been suggested to employ symbolic logic [15].

Active diagnosis can be described as a function f that takes as input a set of medical evidence \mathcal{X} and returns a ranked set of disease hypotheses \mathcal{H} and a ranked set of diagnostic tests \mathcal{T} , which includes any follow-up and information gathering actions. On top of this, it should include a stopping criterion \mathcal{A} that determines whether to continue gathering information, or if there is

sufficient certainty to return a diagnosis. Additionally, clinicians are able to identify which cases can be solved with type 1 or type 2 reasoning, and the stopping criterion could be extended to include switching between different diagnostic algorithms. Formally,

$$f : \mathcal{X} \rightarrow \mathcal{O}^{|\mathcal{H}|}, \mathcal{O}^{|\mathcal{T}|}, \mathcal{A} \quad (1)$$

where \mathcal{O} any ordered set, such as \mathbb{R} or $[0,1]$. However, many diagnostic algorithms typically avoid replicating the difficult data-gathering process in its entirety. They instead focus on the task of “passive diagnosis” which simplifies diagnosis to a classification task and allows for simple learning objectives and performance measures to be defined. Consequently, passive diagnosis can be defined as a single-step process producing a ranked set of diagnostic hypotheses given a set of medical evidence:

$$f : \mathcal{X} \rightarrow \mathcal{O}^{|\mathcal{H}|} \quad (2)$$

For example, pattern recognition algorithms that are used to predict diagnostic labels from electronic health records [16] or medical images [17] are passive diagnosis algorithms, whereas the QMR/INTERNIST-1 system is an active diagnosis system as it includes information gathering heuristics and a stopping criterion [18].

The majority of diagnostic algorithms that employ modern machine learning techniques can be categorized as passive diagnosis algorithms [19]. While these approaches typically achieve the highest accuracies at diagnostic classification tasks, they often lack interpretability [20], and can struggle with error correction [21]. Learning algorithms are vulnerable to taking “shortcuts,” achieving high accuracies by exploiting confounding variables that subsequently prevent them from generalizing to real-world settings [22], as evidenced by deep-learning algorithms for diagnosing hip fractures [23] and Covid-19 [24] that have been found to make diagnoses based on confounding variables such as the timing or specific imaging machine used. Evidently, these algorithms are not intended to perform the full suite of diagnostic reasoning, but rather to

achieve high accuracy in rapid pattern recognition without introspection – i.e., type 1 reasoning. Model-based algorithms are better suited to solving diagnostic tasks involving explanation, information gathering, hypothesis testing, and causal reasoning – tasks which are associated with type 2 reasoning in clinicians. Finally, rules-based systems are ideally suited to carrying out the many clinical tasks that require fixed, interpretable, and deductive rules to be followed, such as those encoded in clinical guidelines. A key challenge is to bring these different approaches together to build diagnostic systems that can support all parts of active diagnosis, rather than focusing on a single sub-task, while ensuring that errors are identified and corrected and that clinical guidelines are followed.

Diagnostic algorithms are typically implemented as decision support systems, which aim to augment human decision making and prevent human errors [25]. While many comprehensive diagnostic support systems have been developed over the last 40 years, only the simplest systems catering to general alerts, reminders, summary dashboards and information retrieval systems have ever been deployed at scale [26]. This is due in large part to the more advanced systems often impeding on rather than improving clinical practice [27]. In order to develop diagnostic systems which have an impact in the real world, it is important to first understand the different types of diagnostic error and how they arise in clinical practice [28]. Firstly, knowing the most common causes of serious diagnostic errors helps to focus research efforts on the most impactful interventions. One example of this is satisfaction of search (SoS) bias, where a clinician prematurely terminates information gathering after identifying the first abnormality, and in doing so misses evidence that would otherwise change the diagnosis. Radiographic images are complex and difficult to visually search, and as a result SoS is one of the primary causes of error in diagnostic radiology, contributing to approximately 22% of misdiagnosed cases [29]. This motivates the deployment of computer vision algorithms for image segmentation, which can identify abnormalities with high precision in “blind spot” areas

of images [30]. Another major type of error in radiology is the failure to identify the underlying cause of an abnormality detected in the image, typically due to cognitive biases including anchoring bias, premature closure, and attribution bias [31] (contributing to 10% of errors). Image classifiers can accurately identify and differentiate abnormalities in radiographs, even surpassing experts [32]. The second motivation for understanding cognitive errors is that errors with different causes require different interventions, with every diagnostic error having on average 6 different root causes [33], each potentially requiring a different kind of intervention. For example, if a diagnostic classification task has a high error rate, but these errors are due to irreducible uncertainty (e.g., clinicians are approximately Bayes-optimal classifiers), algorithmic classifiers cannot be expected to have a significant impact, and efforts

should focus instead on improving data gathering and interpretation. Given the complexity of the active diagnosis task, and the number of interacting sources of diagnostic error that must be addressed, it is perhaps unsurprising that clinical decision support systems have struggled to achieve their intended impact. Figure 2 provides a non-exhaustive taxonomy of the main cognitive causes of diagnostic errors, examples of their prevalence in different diagnostic areas, and examples of current AI solutions.

Knowledge-Based Diagnosis

Because medical knowledge is vast, symbolic, and deeply structured, the most natural approach for automating medical diagnosis is through knowledge-based methods. Clinical practice is

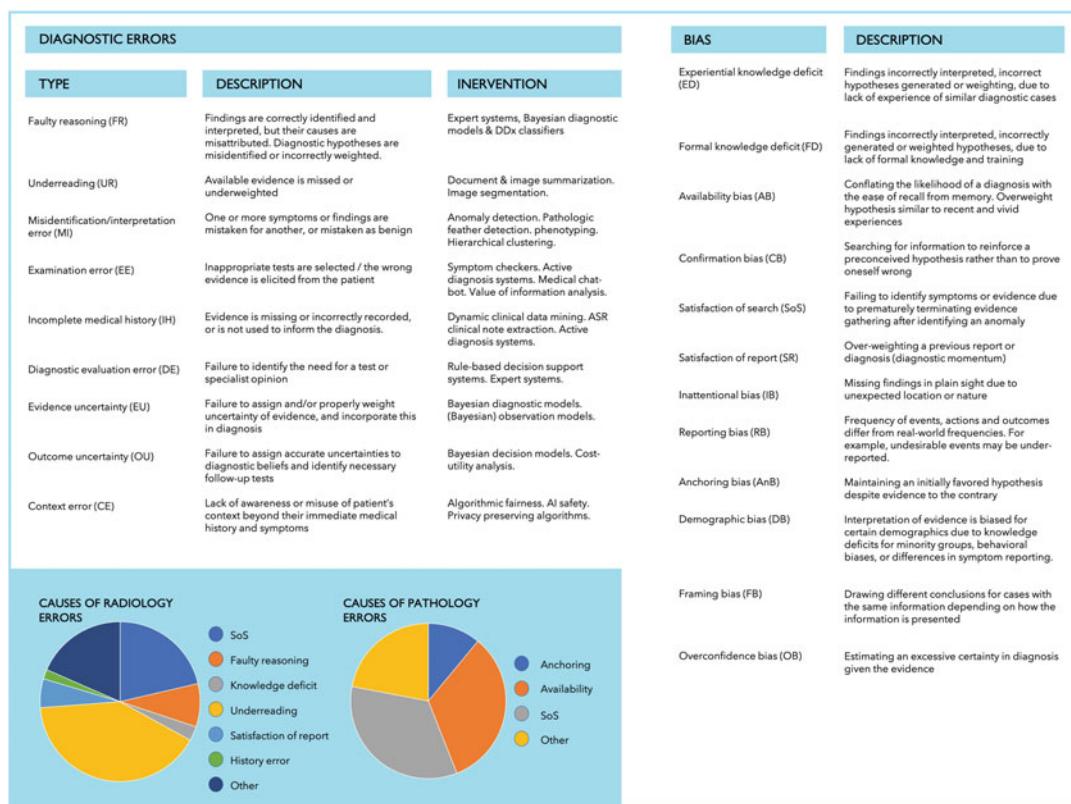

Fig. 2 Table shows nonexhaustive list of common errors in diagnosis, and current AI interventions. Table also describes common cognitive causes of these errors. Pie

charts depict the prevalence of different error types for diagnosis in radiology [29] and pathology [34]

highly codified through diagnosis criteria, staging scores, checklists, treatment decision algorithms, up to the detailed list of information a patient should legally receive. Whether it be about anatomy, physiology, pathological processes, or clinical practice, this type of knowledge is hard to learn from data, but readily represented in a logic-based format gathered from experts.

Knowledge-based methods exploit such logical statements stored in a database referred to as a “Knowledge-Base” (KB). While recent research has shown some of those KB can be learned from data [35], the process is not fully automated, and experts are often required to translate their knowledge into logical statements that the system can use. As described in the previous chapter, logic-based systems can be *crisp* or *fuzzy*, and depending on the type of knowledge stored in the KB, are referred to as rule-based or model-based systems.

Rule-Based Diagnosis

We call “rule-based” a system which relies on a collection of nested rules of the form “IF A THEN B” organized in complex decision trees. These systems are fully explicit and understandable by humans, and their behavior can be easily defined and debugged. They are particularly well suited for describing diagnosis rule such as:

IF

1. Rapid onset
2. AND Middle ear effusion
3. AND Otalgia interfering with sleep
4. AND Core temperature above 39 °C

THEN (Diagnose) Acute Severe Otitis Media.

The rule-based format is also the best suited to explicitly encode the natural flow of question a doctor may ask during Active Diagnosis, during which they aim to gather key information to improve his diagnosis. For example, the previous “passive” diagnostic rule could be associated with data gathering rule, in order to gather missing evidence:

IF Otalgia interfering with sleep *THEN*

1. ASK when the symptoms started
2. LOOK FOR Middle ear effusion
3. MEASURE Core temperature above 39 °C

ASK, LOOK FOR, and MEASURE, are three equivalent terms which mean the system should test for the presence of those signs, whether through human input or in an automated fashion. However, such approaches fail for large problems due to the sheer number of rules necessary to cover the space of valid states, which in part explains why the most prominent rule-based expert-systems developed in the 70–80’s each took on the order of a decade to complete. For example, the MYCIN system [36], the archetypal rule-based system, took six years to complete. It was deployed during that first wave of medical expert systems, along with many other rule-based systems such as PUFF [37], AI/RHEUM [38], or CADIAG-1 [39]. As discussed in the previous chapter, those systems mainly served as research prototypes and never were deployed at scale, in large part due to their incompatibility with a clinician’s daily practice.

Fuzzy-Logic Systems

Another dimension to rule-based systems is whether they are *crisp* or *fuzzy*. Crisp systems correspond to the classic logic formalism where statements are either True or False. *Fuzzy-logic* on the other hand relaxes this constraint allowing for statements to receive a *truth value* between 0 and 1. As described in the previous chapter, this approach is rooted in the notion of partial membership and fuzzy sets [40], and can deal with ambiguous situations and facilitates knowledge elicitation from experts in areas where medical knowledge is imperfect.

For diagnosis, these truth values can represent *uncertainty* and encode such statement as “Flu Rarely Causes Vomiting,” where “Vomiting” is a partial member to the set of symptoms caused by flu. They are also useful to encode *vague terms* which may be more natural for experts or represent the level of description matching with clinical

knowledge. For example, the term “early adulthood” is vague but clinically useful to talk about age groups in such statements as “Schizophrenia’s usually starts during early adulthood.” Each integer age value could then be associated with a partial membership to the “young adulthood” set, with a peak value around 25 years old. Both the rule-based and the ontological knowledge format can be fuzzified to allow for vagueness during knowledge elicitation and inference.

These methods have successfully been used since the 1980’s to perform diagnosis, in such systems as SPHYNX [41], CADIAGS-2 [39] or MILORD [42], and fuzzy-logic systems are still being actively researched [43]. Future systems may always require a layer of logic-based reasoning to ensure safety, and allow for the direct use of symbolic medical knowledge. Hybrid methods, such as Neuro-fuzzy systems combining fuzzy-logic with Neural Networks [44], offer the possibility to combine both approaches’ strength and build more efficient products.

Ontology-Based Systems

The second knowledge format is called ontological and encodes a model of the world. It describes symbolic entities, or concepts, and their associations with each other through relationships such as

*“Meningitis IS AN Infectious Disease” or
“Meningitis IS LOCATED IN THE Meninges”
or
“Meningitis CAUSES Fever”*

This second approach can store much of the medical knowledge, which is highly symbolic. It is also more manageable for large problems such as diagnosis, as the representation does not encode a specific step-by-step policy but relies on “model-based” inference algorithms to make decisions. For example, the KB could store that both Meningitis and Otitis Media causes Fever. However, the diagnostic algorithm would then have to rely on a specific strategy to either rank the two hypotheses (i.e., passive diagnosis) or ask for information to disambiguate them (i.e., active diagnosis). As detailed in the next section, these

diagnostic algorithms are called model-based algorithms because they perform abduction by exploiting a causal model of the world [45, 46].

Contrary to rule-based systems which are monolithic products, ontologies usually represent a general model of the world which can be shared and used in different applications. They can be exploited by logic-based [47], as well as learning-based algorithms to solve various tasks (e.g., link prediction [48], question answering [49], or ontology alignment [50]). And as detailed next, although they are not called an ontology, probabilistic methods also use causal models linking diseases to medical evidence for diagnosis.

Prominent ontologies such as ICD10 [51], SNOMED-CT [52], or UMLS [53] are extensively used in EHR systems to code for medical concepts. They allow for semantic interoperability, normalization of data gathering practice, and they facilitate research efforts [54]. However, those widely available ontologies focus on building a “class-system” in order to place concept in semantic hierarchies, such as

*“Meningitis IS AN Infectious Disease”
“Infectious Disease IS A Disease”*

This type of semantic knowledge has little use for an automated diagnosis system and, generally, those openly available ontologies do not hold any knowledge, or incomplete knowledge, about the relationships between diseases and symptoms.

On the other end of the spectrum, phenotype databases were developed to describe and link patient presentations, or phenotypes, to either a genotype or a particular disease. There have been several efforts in the 1970s–1980s to build such causal networks. For example, CASNET [55], MUNIN [56], and INTERNIST-1/CADUCEUS and its derivatives (e.g., QMR-DT) [45, 57] had such disease to symptom connections, but those systems are proprietary and now four decades old. More recent efforts such as Orphanet [58], or the Human Phenotype Ontology [59] are research-oriented, have focused on rare diseases, and the data is only available under certain conditions. The most comprehensive KB might be Google’s Health Knowledge Graph [60], although little is

known about its coverage and it most certainly will remain proprietary.

Overall, the field has yet to see an entirely open ontology which can support standard diagnosis tasks. Efforts such as WikiData for medicine [61] or Human Dx [62] made promises of an open and rich ontology supporting clinical tasks, but they are still incomplete or unavailable to the public. The lack of such a system is a testament to the complexity of the task. However, in the future, open ontologies of common clinical situations and national and international guidelines will be essential to build public benchmarks and safe systems that can inter-operate with clinicians. In the next section, we describe model-based algorithms which operate on causal knowledge about diseases to perform diagnosis and present their advantages over rule-based systems.

Model-Based Diagnosis

Supplanting early probabilistic approaches to diagnosis [63], the first large scale diagnostic systems developed were logic-based expert systems [36, 45]. As described in the previous section, these systems classified patients following a pre-defined diagnostic path from their symptoms and signs to a diagnostic decision, based on the application of deductive rules [64]. Despite initial optimism that all medical decision tasks could be solved in this way, cracks started to emerge in this approach in the 1980s [65]. For one, logical proofs have a limited applicability to solving problems with dynamic, incomplete, ambiguous or unstructured data, making these systems inherently brittle to many real-world diagnostic tasks. On top of this, the labor required to elicit expert knowledge and maintain and update large rule-based knowledge bases became a major bottleneck in the construction and deployment of expert systems [66].

Model-based methods started to be investigated as an alternative approach to expert systems in the late 1970s [67]. The idea behind these initial efforts was to exploit objective information about a system's behavior, rather than relying on expert knowledge based on subjective experience to

model the diagnostic process itself. The major insight of this approach was to separate domain knowledge from diagnostic rules, and instead to allow diagnostic rules to emerge from a combination of a diagnostic model and a set of simple inference rules and hypothesis ranking heuristics [68]. Even relatively small models including a handful of variables can in principle encode a vast number of rules which are defined for every possible input, making them more practical than hand-coding rules. In diagnosis, these models are pathophysiological models, encoding the relationships between conditions and symptoms; what diseases can occur, how they interact with the wider physiological system, and how they cause observable manifestations as signs and symptoms [69]. They describe the expected behavior of the physiological system, and discrepancies between expected and observed behavior are used to infer the presence of conditions or diseases.

This approach to diagnosis was first formalized in the late 1980s [70], and referred to as “diagnosis from first principles” due to its use of objective information about the system being diagnosed. It is also known as consistency-based diagnosis, as early implementations treated faulty systems as a logical inconsistency that is resolved by a diagnostic hypothesis that assumes some components are functioning normally and others are faulty [71]. The main drawback of these model-based approaches is that the cost of inference can be much higher than in rules-based systems [72]. For example, the query complexity of a decision tree is fixed by the tree depth, whereas a Boolean model could require solving a B-SAT problem that is NP-complete. As a result, memory-based and rules-based approaches can be used to amortize this complexity for common inputs, much in the same way that dual-process theory describes type-1 reasoning being used to amortize the more computationally expensive type-2 reasoning for common diagnostic cases.

Abductive Diagnosis

At approximately the same time that consistency-based diagnosis was developed, a

separate definition of diagnosis based on a combination of first-order logic and causal models was developed by several researchers [73, 74]. The first attempt to use causal pathophysiological models to perform diagnosis was the CASNET project of the late 1970s [75], which used a model of medical knowledge encoded as cause-effect relationships and logical conditions. Rather than basing the diagnosis on logical consistency, this approach – known as abductive diagnosis – treats diagnosis as the task of inferring the set of causes that are most likely to be responsible for the patient’s symptoms, i.e., the “best causal explanation.” Abductive inference involves reasoning from a fact (evidence, e.g., a symptom) and a causal rule (how diseases cause this symptom) to a case (diagnosis) [71]. This can be seen as a mapping from a data space of findings (e.g., symptoms and signs) to a space of diagnostic hypotheses (e.g., the presence or absence of diseases), facilitated by a causal model (Fig. 3). Unlike in rules-based diagnosis, hypotheses can interact in complex ways. For example, lower immune function can decrease a fever, while flu can increase a fever, and the two conditions can interfere and cancel out. Typically there are multiple hypotheses that can explain each piece of

evidence, and abductive inference involves enumerating the set of consistent causal hypotheses and weighting them, commonly using a heuristic measure [76]. For example, the parsimonious set covering heuristic [77] weights hypotheses based on parsimony (the number of diseases) and explanatory coverage (the number of symptoms explained), in an attempt to balance the principles of Occam’s razor and Hickam’s dictum [78].

Bayesian Diagnosis

An additional complexity of diagnostic decision-making stems from the fundamental ambiguity and uncertainty of diagnostic information. As seen in the previous section, while some model-based diagnostic systems tackle this uncertainty with fuzzy logic another approach is to extend pathophysiological models to causal Bayesian networks (BNs) [79] (see ► Chap. 11, “Artificial Intelligence for Medical Decisions” for a detailed discussion), and replace abductive heuristics with Bayesian inference. The use of Bayes’ rule in diagnosis predates even rules-based systems [80]. Compared to rules-based systems, which use forward and backward-chaining inference [81], and abductive diagnostic models, which use heuristic weighting, Bayesian models employ Bayesian inference to weight diagnostic hypotheses. This offers a more principled diagnostic weighting that incorporates uncertainty estimates, which themselves are important determinants of diagnostic decisions. Hypotheses are weighted using the posterior probability of the hypothesis given the evidence, computed via Bayes rule, and known conditional probabilities. For example, for findings f and hypothesis H the posterior is calculated as,

$$P(H|f) = \frac{P(f|H)P(H)}{P(f)} \quad (3)$$

Where the conditional probability $P(f|H)$ is the likelihood of observing a finding f given that a hypothesis H is known to be true, and $P(H)$ is the prior probability of the hypothesis being true (e.g., the prevalence of a given disease in the population)

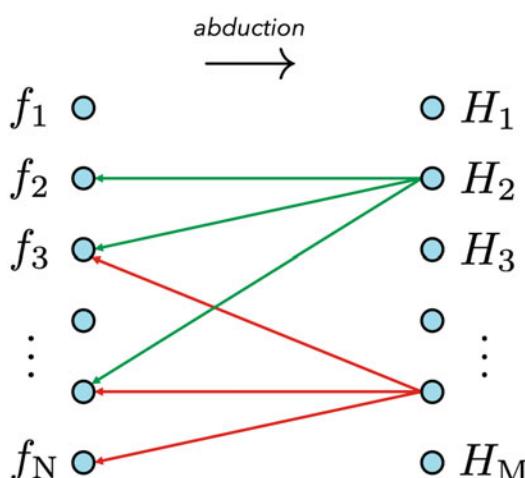

Fig. 3 Underlying diseases or conditions cause abnormal signs and symptoms (findings f). Abduction is the process of selecting diagnostic hypotheses H over these conditions, given knowledge of the findings and the causal rules that generate them

and likewise for $P(f)$. These conditional and prior probabilities are directly encoded in the causal pathophysiological model, and can be learned from multiple data sources including epidemiological data and expert knowledge (see ▶ Chap. 11, “Artificial Intelligence for Medical Decisions”).

The simplest example of a Bayesian network, still widely used for diagnosis, are naive Bayes models. These use the assumption that findings are conditionally independent given the hypothesis, providing a simplified form of the conditional probability that can be easily calculated for multiple findings,

$$P(f_1, \dots, f_N | H) = \prod_{i=1}^N P(f_i | H) \quad (4)$$

This independence assumption can be summarized as a graphical model (Fig. 4). The factorized conditional probability table is simple to learn from expert knowledge and can be easily extended to incorporate new findings, making the task of extending decision rules to larger test sets vastly simplified compared to rules-based systems. The drawback of naive Bayes classifiers is that the strong conditional independence assumption removes hypothesis interactions, resulting in an overly simplistic hypothesis weighting.

In general, BNs are generative models comprising of nodes situated in a directed acyclic graph (DAG), representing variables and their causal relations respectively. As with the naive Bayes model, BNs encode conditional independences that expedite model learning and inference (see ▶ Chap. 11, “Artificial Intelligence for Medical Decisions” for discussion). These models emerged in 1980s, most notably through the work of Judea Pearl [79]. The earliest landmark examples of model-based diagnostic systems using Bayesian networks include QMR-DT/Internist-1 [18] and later iterations of the CASNET project [55]. The first iteration of QMR-DT employed a bipartite BN, consisting of a layer of diseases (hypotheses) and symptoms (evidence). Even these simple bipartite models exhibit non-trivial hypothesis interaction such as explaining-away [83]. More

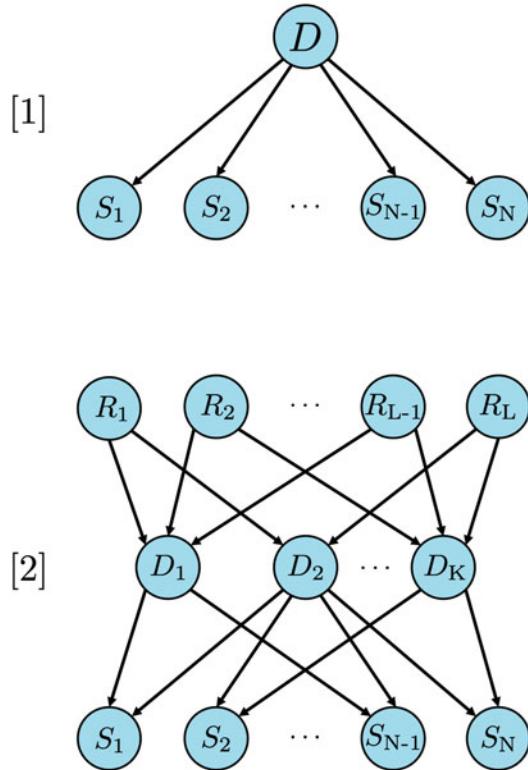

Fig. 4 [1] depicts the naive Bayes model. In this example, findings are symptoms S_1, S_2, \dots, S_N and the model incorporates a single disease hypothesis D . The joint distribution factorizes with respect to the DAG by the Markov property, $P(D, S_1, \dots, S_N) = P(D) \prod_{i=1}^N P(S_i | D)$. [2] depicts the three-layer BN extension of the CASNET network [82], including multiple disease hypotheses, a layer of symptoms (effects of diseases) and risk factors (causes of diseases)

complicated BNs (Fig. 4) with less restrictive conditional independence assumptions are more expressive and capture increasingly complex hypothesis interactions (for example, mutual exclusivity of hypotheses), allowing for more complex diagnostic decision rules at the expense of increased model learning and inference complexity [84]. The bipartite QMR-DT network was eventually replaced in [82] by three-layer BNs that incorporated an additional layer of disease risk-factors (Fig. 4), allowing for the inclusion of evidence on the causes of diseases rather than just the effects (findings). QMR-DT employs a sequential Bayesian approach to diagnosis that attempts to use Bayes rule in combination with information

gathering and hypothesis refining heuristics to mirror the active diagnostic process performed by doctors. Symptom gathering heuristics are used to rule-in/out hypotheses, gradually refining the diagnostic hypothesis set and explaining away symptoms until a final diagnostic hypothesis is returned. These early information gathering heuristics for BN models have since been superseded by more principled approaches including value of information (VOI) analysis [85, 86] and cost-utility analysis [87].

Causal Reasoning for Diagnosis

Another benefit of causal models is that they support causal inferences, establishing the effect of intervening on clinical variables (e.g., treating diseases), and counterfactuals “what-if” inferences, which can be used to quantify how well a disease hypothesis causally explains a patient’s symptoms [79, 88]. Counterfactual hypotheses are logical analogues to counterfactual thinking in human cognition, which are often used to ascribe cause-effect explanations and responsibility – for example, “the accident would not have happened if the driver had not been inebriated” is a “but-for” counterfactual hypothesis stating that driver inebriation was a necessary cause of an accident [89]. Recently, a new approach to Bayesian model-based diagnosis has been proposed that uses counterfactual inference instead of Bayes rule to weight disease hypotheses, motivated by the observation that the standard posterior weighting fails to satisfy certain common-sense postulates for diagnostic hypothesis weighting (such as assigning a weight of zero to non-causal diseases) [88]. This approach replaces the hypothesis “disease D is present,” $D = T$, with counterfactual hypotheses, for example,

$$P(S_{D=F} = F | S = T) \quad (5)$$

which is “the probability that symptom S would be absent if disease D had not been present, given that S is present,” which captures the likelihood that the presence of disease D is a necessary cause of symptom S [90]. $S_{D=F}=F$ describes the

counterfactual event that symptom S would be off, had disease D been off (counter to the fact $S = T$). By comparison, the posterior $P(D = T | S = T)$ captures only the probability that D is present, independent of whether or not it is causing the symptom S . This counterfactual approach combines the benefits of Bayesian diagnosis with the causal reasoning of abductive diagnosis and the logical reasoning of consistency-based diagnosis, and has been shown to improve the accuracy of model-based diagnostic algorithms, even outperforming human experts at differential diagnosis [88]. More details on the role of causal and counterfactual reasoning in medical decision-making are provided in ► Chap. 11, “Artificial Intelligence for Medical Decisions.”

Machine Learning for Diagnosis

Learning from Data

Machine learning methods enable the discovery of useful patterns and effective decision rules directly from data. Contrary to the rule-based methods for diagnosis, which follow a predefined series of nested queries, or model-based methods, which use causal knowledge about the world to investigate hypotheses, pattern recognition methods are akin to searching in memory for the closest match to a particular situation, in direct analogy to type 1 cognition in medical diagnosis. For example, a simple pattern recognition system could be built around a database of “patient presentations” called *exemplars*, composed of a set of clinical signs as well as their associated diagnosis. The crudest inference algorithm would then score all diseases with the average number of signs they have in common with the patient presentation and return as diagnosis the “nearest neighbor” in this medical evidence space (Fig. 5a).

While a valid approach, this simple algorithm suffers from several drawbacks that machine learning algorithms have addressed. First of all, searching an extensive database of known exemplars (specific situations), composed of millions of patient presentations, would arguably take time. A simple approach could be to produce

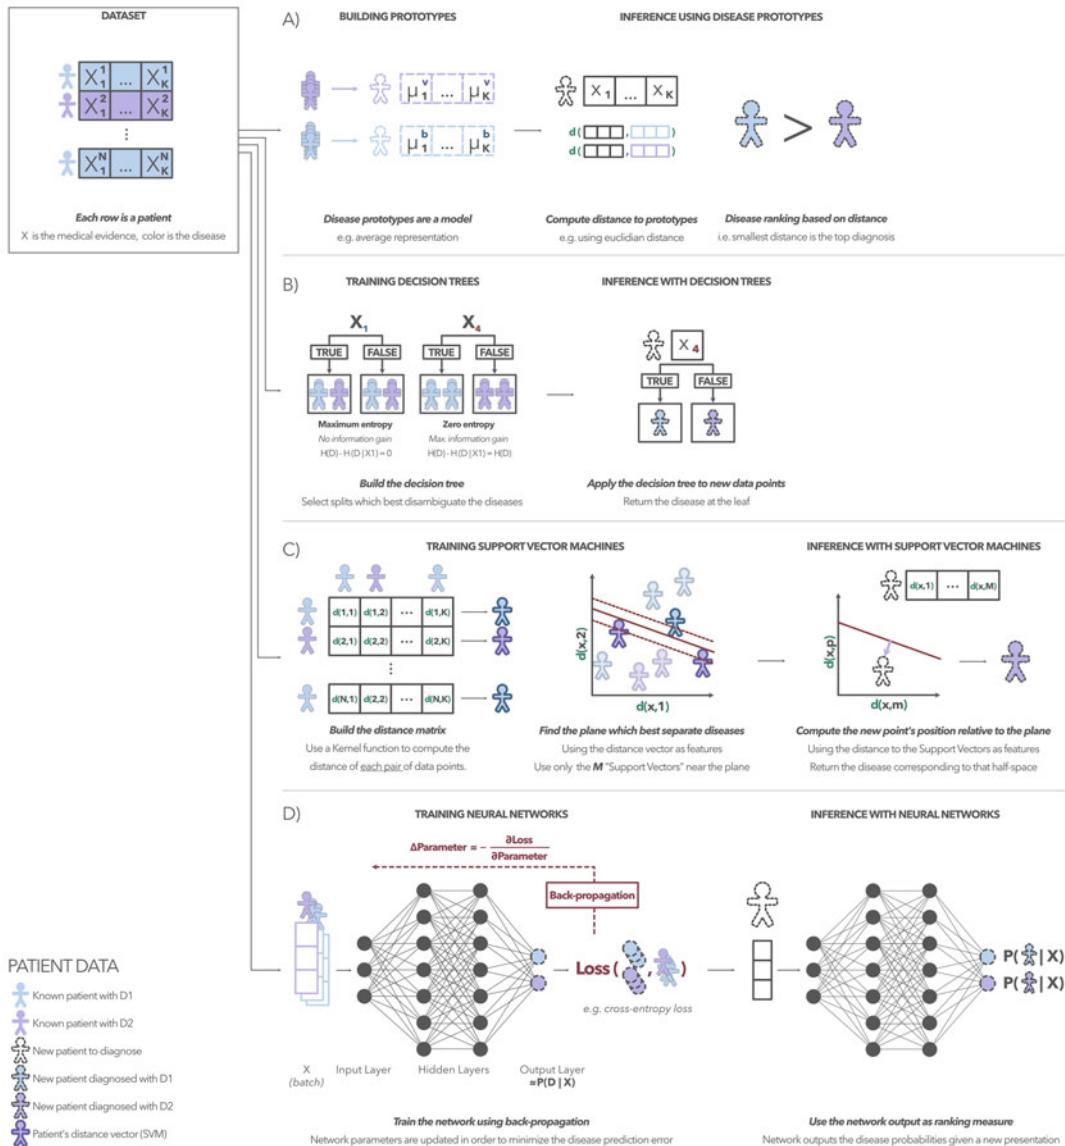

Fig. 5 Schematic description of four Machine learning approaches to diagnosis, using either (a) disease prototypes (“frames”), (b) Decision Trees, (c) Support Vector Machines, or (d) Neural Networks. The inference task

“prototypes,” an average presentation, for each specific disease. Rather than search over the space of millions of examples, the search would then be over the space of a few hundred disease prototypes and yet produce identical results. This step of “concept learning” from data, prototype building through averaging, would be an

presented here is to return the most likely hypotheses among two diseases (blue or violet). The multi-class problem of classifying more than three diseases, or returning a full hypothesis ranking is not presented here for simplicity

elementary form of machine learning. The learned “model” now being this collection of prototypes, which the counting algorithm can then use to produce diagnostic decision faster. While not learned from data, relying on such disease prototypes, called “frames,” was for example used in the CADUCEUS expert system [45].

However, by merely counting clinical signs, we would adopt many wrong assumptions. Firstly, we would assume that all signs are equally informative of a disease's presence, which is obviously wrong. The absence of a particular sign can eliminate a hypothesis, and specific "pathognomonic" signs indicate with almost complete certainty the presence of a disease. Hence, some signs should weight more in the final decision, and a better system would be able to associate a unique weight to each sign-disease pairs. Simple counting also assumes that any association of signs can be treated equally. However, clinical reasoning is full of known associations of signs (syndromes), often specific to a particular disease or class of diseases. A better system here would learn the dependencies between signs and the dependencies of groups of signs with specific diseases. This could take the form of learned weights, not only for specific sign-disease associations, but for associations between disease or classes of disease and groups of signs. Finally, counting requires the binning of continuous variables (e.g., core temperature). A better model would be able to adapt its decision smoothly over the range of the continuous variables, and ideally would even be able to rely on a derived quantity such as a polynomial function of the variable (e.g., the temperature squared). Overall, simple counting obfuscates the complex underlying processes generating the patient presentation, the dependencies between clinical signs and how strongly they are associated with their generating pathology. From a statistical standpoint, machine learning algorithms resolve those issues by learning, often implicitly, the dependencies between input features (e.g., clinical signs) and the strength of their association to the predicted target(s) (e.g., diseases).

Machine Learning as Function Approximation

As previously described, producing a measureable to rank hypotheses given a set of evidence is the answer to the *passive diagnosis* task (see Eq. 2). For each potential evidence combination, a

diagnostic function should then return a value for all hypotheses. For elementary problems, assuming the function is known, you could store all these values inside a database. However, this approach rapidly becomes intractable as the size of the evidence and hypothesis space grows. With ten binary pieces of clinical evidence (present or absent), the number of values is $2^{10} |\mathcal{H}|$, it would be $3^{10} |\mathcal{H}|$ if you account for missing evidence, and such a system could not handle continuous variables without binning. As described previously, the number of potential symptoms is in the hundreds, not counting physical signs, and para-clinical evidence. Machine learning offers the possibility to learn a function, a model, with a manageable number of parameters, which approximates the expected output. This approach relies on the assumption that there is an exploitable structure in the task which allows such approximation for example, assuming that for a small variation of the input, the output varies only slightly (smoothness) — or that the noise in the data is relatively homogeneous (homoskedasticity). As models increase in complexity, they can represent more of the data's sharp irregularities, and those assumptions loosen. Nevertheless, even for the largest known deep learning model of a trillion of parameters, the model's complexity is still several orders of magnitudes below the size of the hypothesis and input space. Those models are manageable, and fast to query — they *amortize* the complex lookup task. They are also able to generalize. They are trained to average the data and avoid *over-fitting* the noise while proposing sensible values for out-of-distribution data points (absent from the dataset), that is, performing extrapolation and interpolation.

Contrary to the natural evolutionary refinement of clear and memorable semiological descriptions seen in medicine, the decision rules learned by ML methods are often challenging to understand for humans and produce "black-box" models. The natural limit of human cognitive abilities has generally pushed semiology toward high yield combinations of signs (syndromes) and the production of simple diagnostic rules, facilitating learning and clinical practice. On the other hand, Machine learning approaches, while still limited in certain

respects (e.g., privacy, safety, explainability) [91], are best able to handle most of the task-relevant complexity present in the data. For example, all medical students can remember the characteristic description of melanoma on visual inspection as A (asymmetrical shape), B (irregular borders), C (unevenly colored), D (diameter over 6 mm), and E (evolving) [92]. However, while the simplicity and detection sensitivity of this combination of signs led to its diffusion into medical textbooks, it remains a very coarse-grained description of a highly variable skin lesion.

Recently, Deep Learning models were able to beat experienced dermatologists in diagnosing melanoma from skin lesion photographs [93]. Contrary to the simple ABCDE rule, those *computer-vision* models can learn directly from data how to best extract the information in an image to solve a particular task. Most computer-vision models used in medical research still primarily rely on the convolutional neural network architecture, which was among the first model to take full images directly as input (i.e., as X) [94, 95]. These architectures were designed to be better able to handle translational invariance, in this case, to learn useful features equally well irrespective of their absolute position in the image. We call an *inductive bias* this type of embedded property in a DL architecture. More recently, innovations in network architectures inspired from the concept of *attention* have allowed to increase the model's ability to capture complex dependencies in the data while remaining efficient [96, 97]. In the future, those approaches will probably take a more important place in the toolbox used in clinical research.

Three Supervised Methods

The field of machine learning as applied to medical diagnosis has been active for several decades. This vast family of algorithms was applied across many medical specialties covered over the next chapters. In early 2021, a PubMed query for the MeSH term “computer-assisted diagnosis” returned 82’777 results dating back as early as 1966. Eighty-six percent of those papers were

published in the first two decades of the twenty-first century, at an average rate of 3’814 publication a year. Among those, 4’084 relate to machine learning approaches (terms: Neural Network, Support Vector Machine, and Decision Trees), from 40 publications in 2000, with a peak at 987 publications in 2019. These figures constitute a loose lower bound on the actual number of research papers published on the subject, which may be published in AI conferences or journals, as well as on open platforms (e.g., ArXiv), or may not be picked up by the PubMed MeSH terms.

Among the many ML methods developed over the years, a few key algorithms are worth mentioning: decision tree algorithms, Support Vector Machines (SVM), and Deep Learning Approaches. After the enthusiasm for expert systems died down, the 1990s saw a renewed interest in data-driven, learning-based methods, beyond applied statistics. The field of ML as applied to diagnosis was then dominated by “Symbolic Learning” which aimed at discovering decision rules from data and producing models which remained understandable for clinicians. Those “decision tree” algorithms, stemming from work by Quinlan who developed the Iterative Dichotomizer 3 (ID3), work in a fundamentally similar way to “prototype building.” In our case, given a set of “exemplars” (the dataset of evidence associated with a disease) we want to produce the most discriminative prototype for a disease. To do so, the algorithm creates a sequence of branching conditions where one piece of evidence is “split” at a specific value. This value is picked to maximally reduce the entropy, or uncertainty, associated with the diseases of the remaining exemplars on both sides of the fork. In other words, the split is chosen so that it gives the most information about the exemplars’ disease. The optimal branching decision would then group all the cases with disease A on one side, and all the cases of disease B on the other (Fig. 5b). This algorithm and its derivatives (e.g., random forest, extreme gradient boosting) are still extremely prevalent and are often a key part of the pipelines which win data science competitions [98]. For example, they have been used efficiently for diagnosis in cardiology [99], gastroenterology [100],

endocrinology [101], and can even beat SVMs and DL methods on those tasks [102].

While decision trees algorithms are powerful and produce transparent models, they are limited to features (here, the evidence variables) in their raw form. They cannot learn to compose features into more complex variables, for example, from the evidence variable t for “core temperature,” they would not be able to use the variable t^2 to make a decision. In regression trees, for example, we say that it produces models that are “piecewise-linear” in the features. Similarly to polynomial models [103], given certain assumptions, both SVM [104] and DL [105] methods are “universal approximators,” that is they are able to produce models approximating any function up to arbitrary small error. While considerably different, both methods produce complex models, which have decision boundaries that are non-linear in the features, offering gains in model expressivity, i.e., the computation it can perform [106], at the cost of transparency and explainability.

In broad terms, modern SVMs [107] rely on a general notion of distance between data points, performing a high-dimensional triangulation of sorts. In the case of diagnosis, it would compute the distance between each pair of patients’ presentations in the dataset using a distance function called the *kernel function*. Once all distances have been computed, they would become the algorithm’s new features (see Fig. 5c). The SVM algorithm would then segment this space of distances in two regions by finding a hyperplane which maximally separates the labels (e.g., diseases) associated with the data points (e.g., patients). During inference, given a new point (e.g., patient presentation), the algorithm would first compute the pairwise distances with the rest of the dataset, and then *classify* (e.g., diagnose) the new point with the label of the half-space it belongs to. However, keeping in memory the whole dataset to compute all those distances would not be efficient, or even feasible for large datasets. A key insight of the SVM algorithm is that only a few points, called “the support vectors,” located near the hyperplane are necessary to define it – a property exploited to produce smaller models and

fast inference. In 2017, SVMs accounted for around 40% of the ML papers in healthcare [108] and have been used extensively for diagnosis from structured data. For example, they have been used for diagnosing diabetes [109, 110], or breast cancer [111, 112]. SVMs have also been used to classify medical images, such as mammograms [113], OCT [114], or slit lamp lens images [115]. However, contrary to the more flexible and scalable DL approaches, SVMs cannot handle images directly and requires a pre-processing step to extract relevant image features [116].

As described in the previous chapter, DL approaches can handle any input and produce any output while relying on the same learning algorithm (see backpropagation, Fig. 5d) [117]. Although feature engineering can be helpful, those architectures can be trained “end to end,” without requiring a pre-processing step. In 2017, DL approaches accounted for a third of ML papers for healthcare available on PubMed [108]. From medical imagery [118], Deep Learning architectures have proven extremely efficient, producing super-human results on complex tasks, and versatile, with the same models able to solve tasks on different imagery modalities [119]. They have allowed to directly solve diagnostic tasks, notably reaching human or super-humans levels in ophthalmology, dermatology, gastroenterology, as well as cancer detection across many modalities (see [120] for a recent review). But DL has also facilitated diagnosis by solving for supporting tasks, such as image segmentation [121], feature extraction [122], staging [123], image enhancement [124], and registration [125].

Other Machine Learning Formalisms for Diagnosis

As described in the previous chapter, the passive diagnostic task is fundamentally a classification task, hence a “Supervised Learning” task. Indeed, it has an identified target to predict (i.e., the hypothesis ranking measure) from a distinct set of input variables (i.e., clinical evidence). However, it is worth mentioning that unsupervised learning approaches have a long

history in computer-assisted diagnosis for solving supporting tasks [126]. Methods such as dimensionality reduction (e.g., PCA, ICA, SVD), clustering (e.g., K-means neighbors), or more recently Auto-Encoders [127], Generative Adversarial Networks [128], or contrastive methods [129] have been used in the prepossessing steps of ML pipelines to perform feature extraction [130], perform data-augmentation [131], but also for improving data visualization and understanding [132], query medical databases for similar known cases [133], or enhance medical images [134].

Reinforcement Learning has been used for diagnosis and support tasks as well. RL is particularly suited to solve the combinatorial optimization task of learning to gather information during active diagnosis [135–137]. Rather than live interaction with real patients, the RL agent relies on an offline dataset of presentations associated with target label (e.g., disease) to learn whether to ask for more information or stop the process and propose a diagnosis. To our knowledge, RL is the only learning-based approach used to tackle active diagnosis so far, but sequence-to-sequence models, such as the novel transformers [96], should also be able to solve that task in the future.

The Importance of Data

A key blocker in the application of ML in healthcare is the relative scarcity of publicly available datasets. ML algorithms require data to learn models, and these models can only be as good as the quality of the training data allows. Biases and low signal to noise ratio in the data will directly impact the models, above and beyond the choice of learning algorithm used to train those models. Data is the critical resource of ML, and the field thrives on quality datasets to build robust benchmarks that allow for fair comparisons and to measure the field’s progress. However, despite the exabytes of health data produced each day, for obvious reasons of privacy there is still only a few datasets made publicly available (e.g., MIMIC [138], Deep Lesion [139], OASIS [140], openfMRI [141], CT Medical Image [142], EyePACS-1 [143], STARE [144]). In recent

years, this problem has been tackled head-on by several countries and universities which have increased their effort to making anonymized healthcare data publicly available to facilitate research [145, 146].

Outlook

In this chapter, we have presented an overview of diagnosis both as an active task, explicitly involving interaction with the patient and data gathering, and as a passive classification task, and have explored how different AI methods are complementary to these different definitions. As diagnostic AI is primarily employed for decision support and often ultimately ends up in doctors’ hands, we have aimed to present diagnosis within the context of research into human diagnostic reasoning and the cognitive causes of diagnostic errors. These research areas can shine a light on the issues facing doctors in clinical practice, and we have argued that these factors can guide the development and deployment of effective diagnostic decision support systems. We then reviewed each of the three main approaches to AI-assisted diagnosis, detailing how they capture the diagnostic process and which diagnostic tasks they are best suited for. While these methods were borne out of different times, and often fundamentally different approaches to AI, each of them is an important tool that can be used for building diagnostic AI. Diagnosis is a special instance of clinical decision-making, and in the previous ▶ Chap. 11, “Artificial Intelligence for Medical Decisions” we outlined the importance of explainability, safety, and fairness in clinical decision algorithms. These issues are equally important in diagnostic algorithms, and we refer the reader to these sections. One factor that we have left out of this chapter is the importance of design and implementation in diagnostic decision support, which has arguably been one of the major constraints preventing the widespread adoption of AI solutions. This is a large topic and is heavily dependent on the specifics of hospitals, healthcare systems and clinical practice, which go beyond the scope of this chapter. For this we refer the reader to follow review articles for diagnostic decision support systems [147, 148] and medical AI in general [149, 108, 150].

While Artificial Intelligence is thought to be a twenty-first-century development, it can be traced back to earlier times. Throughout history, philosophers have been influenced by some versions of the idea of other consciousnesses. Plato suggested that all material objects have absolute forms in his *The Dialogues*, in

the form of a series of conversations with his teacher, Socrates. This was clearly an attempt to discuss the first efforts in the representation of information. Furthermore, these early musings by Plato also display structured efforts to solve problems.

A project designed for one purpose can yield outcomes other than what it originally intended. This section will track the historical traces of Artificial Intelligence and mention some uses of artificial intelligence in medicine. Research on intelligence could lead to the creation of machines that can outdo the thinking capabilities of humans in fields like “calculating, decision making, memory, learning, creating and planning,” which are all areas that require expertise. There could also be concerning consequences.

Artificial intelligence (AI) · History of Medicine · Symbolic languages · Numbers · figures · Hurufism · Myth · Automaton · Computerized medicine · Thinking machine

Introduction to the History of Cognitive Science and Intelligence

In her book named, *Building the Second Mind: 1956 and the Origins of Artificial Intelligence Computing*, Rebecca E. Skinner [1] explores the basic concepts of artificial intelligence (AI) in ancient tales and philosophical works.

The first conceptual examples of AI came up in Athens in the sixth century B.C. Ancient Greek thinkers were less interested in the meaning of numbers alone than in expressing intelligence and rational ideas using numbers. They produced the first expressions of the reality of abstract ideas, the first geometrical proof for the logical forms for argumentation, and put forth a primitive version of the theory of mind. Plato (429–347 BC) [2] suggested that that all material objects have an absolute form through a series of discussions with his mentor Socrates in *The Dialogues*. This was the first effort for the representation of

knowledge or a clear way to discuss ideas of various sorts. Furthermore, these early proofs found in *The Dialogues* seem to have been Plato’s endeavors to solve formulated problems. Plato’s student Aristoteles (384–322 BC) [3] also carried out systematic research into questions in the field of natural sciences. This is reminiscent of a prehistoric explanation for the initial condition and the targeted condition or approaches a search as it is called in AI. In fact, it approximates the search in all kinds of problematic fields. The concept of protocol was mentioned in the mid-twentieth century by philosopher George Polya as “an Ancient Greek intuitive approach” defined as “an adjective meaning to serve discovery.” [3] The philosopher Euclid’s dream of “representing geometric figures in space” was set up as a part of the field of geometry [3].

Mechanical and Biological Automatons

Automatons are relatively self-operating machines designed to automatically follow encoded instructions. Building automatons in the sense of recreating a human has been a recurring theme explored in many essays, novels, and fictional writings throughout history. The word automaton has Latin roots, based on an Ancient Greek machine that had the ability to move on its own. The so-called recreation of the human body and intelligence was defined in the Babylonian Epic of Gilgamesh and the Hebrew human conceptualization that God created from earth. Mechanical automatons and prosthetics with automaton-like features abound in all ancient mythologies, particularly in Greek mythology, which took on many features from preceding civilizations. Legend has it that Hephaestus, the Olympian God of fire and metalworking incorporated automata into Achilles’s shield. The Greek inventor and thinker Heron of Alexandria wrote a piece on automata. Such machinery in Heron’s fictional accounts was usually activated with falling water, heat, or atmospheric pressure. According to another Greek myth, the inventor Daedalus, after building the Minotaur’s labyrinth,

made wings out of wax for himself and his son Icarus to escape Crete, but Icarus's wings melted when he flew too close to the sun. It is also said that Daedalus built a copper machine called Talos to protect Crete [2].

The Golem

In the late middle ages, alchemists experimented with an anthropomorphic figure, the Golem, who was made of clay and would be summoned when God was called upon. According to the mystical tradition, Golem was created by Rabbi Loew to protect Jews in seventeenth-century Prague from mistreatment. Like "Adam" in Hebrew (of earth), human Golem is made of clay. However, the legend highlights the uniqueness of the Holy one, who is the only one with true power to create life, because Golem was misshapen [4]. This idea comes through each time an anthropomorphized robot comes up, such as in Mary Shelley's nineteenth-century story, Frankenstein. The concept seems to fascinate the founders of Artificial Intelligence as well: John Von Neumann, Norbert Wiener, and Marvin Minsky claimed they are direct descendants of Rabbi Loew [4].

The Ars Magna

The Golem might have been a legend, but it had long-lasting psychic influence. During the Enlightenment, many had ideas of machines that could be used for mathematical operations as well as for the systematic production of ideas. It is interesting that the first effort for the systematic generation of logical statements was a long time before then.

The *Ars Magna* (Great Art) was invented in the thirteenth century by the pre-Reconquista Catalan theologian Raymond Lull (1232–1315) [5]. This tool could generate all combinations of a limited number of axiomatic principles, or concepts which were "true." These "true" axioms were desirable attributes in the Catholic tradition like eternity and goodness. The tool with two concentric circles contained the fourteen divine

attributes. The rotation of the circles could produce 196 twofold combinations of factors. By combining each element with every other, an extensive inventory of all true statements could be produced. The generation of combinations was not heuristic but syntactic. The tool gave all combinations, not just selected or constrained results. Other tools Lull made were for studying the seven deadly sins and other theological artifacts [5].

The Concept of Symbolic Languages

Hurufism

In the fourteenth century, a movement called Hurufism was established by Fazlullah Hurufi (d. 1394) [6]. As a unique religious movement, Hurufism (Makers of the Muslim World) influenced a wide area from India in the East to Anatolia and Balkans in the West. Fazlullah systematized the process of ascribing esoteric meanings to letters, which had already been done by his predecessors. After its founder's death, however, the Hurufism movement disintegrated, incorporating over time into other movements. Fazlullah's talent for interpreting dreams or the connections he drew between prayer sequences and someone's face or even between the number of joints a human has and their "degree" in the astrological world are some examples of his applications. Through these, Fazlullah made interpretations on topics no one had ever mentioned or considered and convinced his followers that he was a Messiah illuminating mysteries.

The Calculator

Inspired, in my opinion, by the Hurufism movement in the Islamic world, the first person to come up with essential symbolic calculation was the inventor of calculus and the inventor of the Stepped Reckoner calculator, Wilhelm Gottfried Leibniz (1646–1716) [7]. A most interesting theory Leibniz developed concerned monads, or atomic bits expressing the small aspects of given philosophical principles, introducing the

systematical use of symbols. Like Hobbes, who said “Reasoning is computation” one hundred years ago, Leibniz lacked the practical digital calculation and computation language to show that he had a good understanding of the concept. In the absence of any objective economic need for a computer, Leibniz and Hobbes’ suggestions for symbol processing remained more philosophy than computation. It was obvious that Artificial Intelligence required general purpose digital information processing and would have to wait until the twentieth century.

The Technological Myth Persists

AI and its early beginnings were accompanied by the technological myth of the creation of thinking machines through digital computing. Martin [8] mentions the image of the computer as an “awesome thinking machine.” When the digital revolution began around the 1950s and 1960s, many people saw the new computers as “intelligent brains, smarter than people, unlimited, fast, mysterious, and frightening.”

While the trend of “expert systems” in the 1980s resulted in profitable applications, new expectations about artificial intelligence also appeared. Around then, Japan launched a project called “Fifth Generation” to build intelligent machines over 10 years. The USA and UK had similar efforts, but none succeeded [9]. Developments in neural networks also led to a more connectionist approach to AI rather than symbol manipulation. The myth of Artificial Intelligence and its global influence could help us understand how such technological myths can impact the current digital media and its social presence [10].

In 1967, about 5 years after his work on “Fuzzy Sets” was published [11], Lofty A. Zadeh (born 1921), the founder of this mathematical theory saw the name of his department then at UC Berkeley change to incorporate “Computer Science” into its name: “Electrical Engineering and Computer Science”. He wrote: “What we still lack, and lack rather acutely, are methods for dealing with systems which are too complex or too ill-defined to admit of precise

analysis. Such systems pervade life sciences, social sciences, philosophy, economics, psychology and many other “soft” fields [11]. In the first years after his discovery, Zadeh’s theory was intended to be applied to other fields like humanities and the social sciences. In a 1994 interview in the *Azerbaijan International*, Zadeh was asked, “How did you think Fuzzy Logic would be used at first?” his retrospective answer was, “In many, many fields. I expected people in the social sciences economics, psychology, philosophy, linguistics, politics, sociology, religion and numerous other areas to pick up on it. It’s been somewhat of a mystery to me, why even to this day, so few social scientists have discovered how useful it could be.” [11]. Zadeh underlined that the fundamental principles of “thinking machines” had been developed by mathematicians.

AI, a research program launched in 1959, has now become widespread, and more or less successful at times, in the fields of science and technology, but after half a century, it would not be wrong to say that AI has not met the world’s expectations. Take chess as an example. Chess has always been considered a game of intellect, and many computing pioneers have said that machine that could play it well would display true artificial intelligence. Machine intelligence is usually challenged with the Turing Test but chess can also be a good test. In fact, the ability to play chess was even used as a valid question to ask during a Turing Test in Turing’s original paper. AI researchers have created programs that even beat the world’s best chess players. However, this does not mean that the best machines understand the concepts of chess, only that they use plays well.

AI is on its Way

Ironically, the history of information processing is quite mysterious. While presently the Internet enables us to reach more information than we could ever need, computers were actually developed within a policy framework that limited information flow and only a limited number of people knew about them at the time.

Solutions are sought for the early diagnosis and treatment of the diseases, especially in regions

Table 1 The development of AI as we know it today

Period	Stage	Highlights
1940–1950	Gestation	McCulloch & Pitts: Boolean circuit to model of brain Turing's computing machinery and intelligence
1950–1970	Early enthusiasm, great expectations	Early AI programs, Samuel's checkers program Birth of AI @ Dartmouth meeting 1956
1970–1990	Knowledge-based AI	Expert systems, AI becomes an industry
1991	Today and future	AI becomes an essential partner in all areas of our lives

where access to physicians is difficult. Verifying the reliability of the system can become a greater challenge, as it requires verifying what the system is trying to do rather than verifying the safe behavior of the system in all areas in which it operates. Table 1 shows the stages past, present, and predicted regarding AI, based on its features, starting from its inception [12].

High capacity electronic calculators were actually born as military inventions to decrypt enemy messages or to calculate missile routes and were thus highly protected to ensure no details got leaked. It took several decades for the British government to completely de-classify secret documents involving the digital computing machine used during the war, developed at Bletchley Park military base [13] (as will be explained in greater detail below). Electronic information is able to wander the earth over the Internet as it pleases but it is also surrounded by a web of secrecy.

In the mid-twentieth century, as science became more and more militarized, two conflicting ideologies appeared. Scientists believed in the free exchange of information (at least in principle), which could hasten progress. On the other hand, governmental intelligence agencies broke down activities into small cells, each with limited information. These differences in opinion, each unconditionally adhered to by its proponents, turned into severe conflicts when military commanders began heading war projects involving scientific research such as the atom bomb and electronic computers. Instead of sharing their results at international conferences, scientists chose to comply with the limitations introduced for the sake of national security and kept their work a secret.

This culture of secrecy in computer science continued with the Cold War, during which secret research was done on defense systems. In an effort

to establish electronic dominance over the Russians, the American government spent a great deal of money not only on its armed forces but also on private companies and universities producing computers. Military, academic, and commercial interests were enmeshed. The computer called Harvard Mark III was designed for the US Navy and produced in a university laboratory under the sponsorship of IBM.

Military efforts clearly had an important role in the advent and development of computer and related technologies. War is truly horrific, but it must be acknowledged that continued efforts to build a nation and a powerful military force can result in important technological innovations, especially general-purpose technologies for new ways of processing material or information [14]. These technologies can result in changing entire sectors. Some examples concern energy creation, information processing such as steel replacing iron, autoes replacing horse drawn carriages, and the computer replacing other older tools. These technologies will be accompanied by new forms of communication, activities, and many ancillary industries. Therefore, the roots of AI, the digital computer, portable music players, smart phones, and many software applications can be traced back to World War II. The Cold War was also paradoxically instrumental in shaping the Computer Revolution [15].

Conceptual Revolutions

Until 1930–1950, intelligence was viewed as having a more tangible quality rather than having qualitative aspects to it, thus necessitating a drastic change. The new focus meant that the new goals needed to be clarified and planned. Like Paul Thagard [16] mentions in “Conceptual

Revolutions,” a total paradigm change was to happen with the adoption of Artificial Intelligence as a fundamental science and engineering problem, causing an overall shift in focus.

At that time, it seemed like a win-win situation: The private companies were getting funding from the government and making it through the hard times, taking advantage of a guaranteed market. Meanwhile, military experts had immediate access to the newest products. On the other hand, scientists without access to government funding had great difficulties accessing the benefits of information processing. And those who did accept funding support could not be ethical and transparent, having to comply with their employers’ condition of nondisclosure [17].

During WW2, the military inventors for Britain, Germany, and the USA worked in the computer science field secretly and separately. In 1942, physicist John Mauchly was working on the all-electronic calculating machine as the US Army needed a device that would calculate complex wartime ballistics tables. Within a year, Mauchly began building the Electronic Numerical Integrator And Computer (ENIAC) and took 2 years [17]. Civilians only got wind of these developments a year later, in 1946 when the US military announced it. This machine was built in a university laboratory, but its production took place under military oversight. Until a lightning strike in 1955, the ENIAC might have carried out more calculations than all of humanity had until then [17].

The media presented the ENIAC as the world’s first electronic computer. It took up a whole room, but it would not compare to a present-day laptop in terms of speed and power. The newspapers still announced: “The devices in this machine” worked “faster than the neurons in the human brain.” [18]. It often broke down and had to be fixed by humans. It emitted heat, and moths and flies would get in and ruin the connections. The term “debug” can be traced back to these first pests. A more serious issue was its limited capabilities. The ENIAC was actually designed to calculate ballistic tables, but anything else like the weather or the movement of shock waves required elaborate rewiring, which would take days and was

usually done by women. The ENIAC was more of a giant calculator than a precursor to a computer and it made no sense to ask it to calculate something else without physically rebuilding it [18].

World, Meet the Personal Computer

Known as the world’s first digital electronic computer, the Atanasoff-Berry Computer (ABC) was built between 1939 and 1941 by electrical engineer, mathematician, and physicist John Vincent Atanasoff and his assistant, physicist Clifford Edward Berry. Atanasoff established the four main ideas on which the digital electronic computer is based [19]:

- 1) The use of electricity and electronic technologies to ensure speed in computer environments,
- 2) using the binary system to simplify the computing process,
- 3) using renewable memory to decrease production cost, and
- 4) computing using direct logical processes rather than counting to increase accuracy.

Around that time, known only by a small group of British scientists at Bletchley Park, another military project was underway to build functional machines called the Colossus that would aid in decrypting German intelligence. Secrecy was crucial, since the entire project depended on the German’s remaining unaware that the British were decoding diplomatic messages and acting according to these even if the Germans changed the encryption daily. Speed was also crucial. If a German submarine or air strike was to be preempted, the order had to be decrypted before the encryption changed. For security purposes, the staff at Bletchley worked in small groups and was only informed of their immediate task. Thousands of men and women kept true to their vows of secrecy, never revealing that the first digital computer had been built not by the Americans but by the British [20].

What set the Colossus apart from the ENIAC was that it could make choices. By the end of the war, 10 electronic Colossus machines worked on messages intercepted, compared them to countless message samples, found patterns and similarities and suggested a way of encrypting that day’s

secret code. It had been this ability – that could choose – that ensured the success of this mission. Instead of scanning all probabilities without thinking, it followed the previous commands put into it or paused for a moment to ask questions of the human operator and quickly eliminated numerous dead ends. The entire base functioned as a giant information processing machine, receiving unintelligible messages, and produced comprehensible details about the Germans' plans. The human, mechanical, and electronic components in the machine followed certain instructions and interacted. Unbeknownst to the many people there, one of the world's most prominent mathematicians in the field of decision making, Alan Turing, had also worked at Bletchley Park. Today, Turing is famous for founding the modern information society on which the global communication of power and money control depend [21].

The Big Question: Can Computers Think?

With Turing and his colleagues keeping their wartime activities a secret, the *first programmable computers* were invented without anyone knowing. Regardless, Turing's influence was immense, since he had not only thought up the technology that made computers work, but also the implications of this technology. After the war, military and commercial institutions focused on producing bigger, faster, stronger, and most importantly, easily programmable computers that could shift between tasks. Turing posed some fundamental questions about *machine intelligence* and brought the *human mind and electrical circuits* closer than ever. Since his closest friend had died at a young age, he had a skeptical view of the traditional Christian concept of the soul, a view that was reflected in machine philosophy. Like biological determinists who sought the secrets to life in complex molecules, *Turing thought computers might be able to think despite their make-up of electrical circuits*. Though he acknowledged thinking was a hard act to define, he was convinced that humans and computers could think.

Agreeing with Turing's view meant having a new conception of both *humans and machines*. Were computers modeled and designed after the human brain or was it the opposite? The scientists who, at the beginning, were excited to proclaim that these circuits resembled super-fast neurons, quickly claimed the nervous systems of living things functioned just like electronic systems. According to their conception of the human soul, humans made decisions as a result of signals moving like electronic buttons that chose one of two ways, zigzagging through branches. Typists were a popular example. It was said that when the boss was dictating, the secretary's ears would catch the sound waves and the body/brain would decrypt these and turn them into simple electronic signals, which in turn activated the fingers (computer enthusiasts would take it further to add that the secretary could enter the memory storage part to correct grammar mistakes) [21].

In Turing's projects for the future, real and mental experiences were intertwined. In the 1930s, at a time when it was not possible to physically build electronic computers, Turing had invented a machine that took instructions from a long strip of paper filled with signs and spaces and claimed that his *machine behaved just as a human would*.

Earliest Steps towards Computerized Medicine

In the eighteenth century, when **Giovanni Battista Morgagni** (1682–1771) published the magnificent “*De sedibus et causis morborum per anatomen indagatis*,” or “Anatomy Rules,” he could not have known that he had just laid the groundwork for *computerized medical diagnosis*. His volumes and their indices resulted in the first true encyclopedia accurately correlating pathological and clinical information. This would provide immensely useful in assisting pathologists and other physicians as they tried to diagnose diseases [22].

The indices of Morgagni's “*De Sedibus*” were perhaps the first step toward the automation of medical information. Then, a perforated-card

mechanism was used in the weaving machine of Morgagni's contemporary, Jacquard, building upon the work by Bochon (1725), Falcon (1728), and Vaucanson (1745). Punched cards would be used as a method to store and sort data for later analysis. About a century later, in the early 1850s, Dr. Joseph Henry, the first Smithsonian Institution Secretary, foresaw the need for new methods of classification and correlation of information as he observed that existing methods could not handle the vast scientific data compiled at that time [23]. Jumping forward to the 1930s and 1940s, the more rapid accumulation of data accumulated in medical research pushed an increasing number of researchers to use punched cards as mechanical aids to classify and correlate data in their own fields. In 1952 punched cards were used to automatically correlate data in the differential diagnosis of hematologic diseases, and in 1961 a computer was introduced into medicine for that purpose [22]. The many great advances that followed in the application of computer technology, in so many areas of medical research and practice, have led to revolutionary improvements in bibliographic, laboratory, radiologic, and other branches of medicine and have fulfilled expectations of those active in the field, who could barely have been imagined several decades ago [22].

In short, the Morgagnian correlation exemplified in the indices of "De sedibus," and the later development of automated methods of correlation of medical information that arose in the 1950s and 1960s set the foundations for using computers in medical diagnosis [22]. The first large-scale application of automated techniques in medical practice was carried out by Collen [24] in his multiphasic screening program. This was broadened by the application of electronic data processing systems to many medical specialties.

Collaboration Between Medical Scientists and AI Researchers

The first efforts towards collaboration in the field of life sciences took place in the USA between computer scientists and medical scientists and led

to computing resources such as the *Advanced Research Projects Agency Network (ARPANET)* and the *National Science Foundation Network (NSFNET)*, allowing researchers to address medical problems using AI methods. In 1985, as awareness that computers could be useful in the clinic increased, the first *Artificial Intelligence in Medicine (AIME) Conference* took place, bringing together computer scientists, doctors, and biologists among others. In 1989, a journal named *Artificial Intelligence in Medicine* was founded to advance research within the field [25]. Many existing scientific gatherings often incorporated presentations on different aspects of machine learning. More conferences were also held on machine learning in health care such as "Artificial Intelligence in Medicine (AIMed)," which holds separate conferences in Europe, North America, and Asia, the "Human Intelligence and Artificial Intelligence in Medicine" symposium, and "Machine Learning in Healthcare" meeting at Stanford University, the "Deep Learning in Healthcare Summit" in Boston, "Machine Learning, Big Data and AI in Healthcare" conference in Washington, and the "Predictive Analytics World for Healthcare" in Las Vegas.

Examples of the Use of AI in Medicine

Mirroring the developments in other industries, the use of artificial intelligence in the field of medicine is on a steady increase. Major companies in various medical sectors, notably the pharmaceutical and imaging sectors, have made large investments in this field. Artificial intelligence software research has also attracted a great deal of academic interest. While there are many publications on artificial intelligence applications in different medical fields demonstrating the breadth of the uses of these techniques, those approved are not as many.

One important example of artificial intelligence applications used in medicine is DeepVariant, the artificial intelligence framework announced in 2016 by Google. It is able to identify single nucleotide polymorphisms, the most common genetic variation, with 99.9587%

accuracy, for which it was awarded by the FDA [26]. Then, there are applications for assessing suspected malignant melanoma based on skin lesion photographs and detecting lymph node metastasis of breast cancer by analyzing pathology slides [27]. Another example is a radiology algorithm developed at Stanford University that was able to diagnose pneumonia more accurately than radiologists [28]. Finally, in the field of ophthalmology, many artificial intelligence studies have been successful in numerous digital techniques like color fundus photography, optical coherence tomography (OCT), and computerized visual field (VF) testing and the huge databases they provide. As populations live to an older age, there have been an increase in eye diseases that cause preventable vision loss. The artificial intelligence applications underway particularly for diabetic retinopathy (DR), age-related macular degeneration (AMD), glaucoma, and retinopathy of prematurity (ROP), as the leading causes of vision loss will be of immense use [12, 29]. More and more examples come up every day in various medical fields.

The progress made in artificial intelligence studies makes it clear that potential future applications are promising. AI holds great potential for identifying patients with preventable diseases and referring them to a physician, especially in developing countries where health-care access is challenging [12].

Artificial and Biological Life

In terms of aspects of humanity, artificial and biological life can be compared as much for rational thinking as for feelings and emotions. In fact, there have also been attempts to anthropomorphize computers and robots in terms of how computers learn the way children do, theorizing that computer might also learn through experiences and trial-and-error [30].

One end of the AI myth spectrum is occupied by the Apocalypse, but there are more moderate, utopian theories as well. As personal computers spread and the Internet became a daily presence in our lives, many new technological myths

emerged, involving new forms of the myth of AI, these days usually around collective intelligence and networks. The new themes explored by authors within the myth in “*networking AI*” feature utopian visions based in previous telecom advances, with the Internet seen as the final stage of human interconnectedness, leading to interactions between humans and machines collaborating to increase collective intelligence to new levels. The new global brain could offer humans a new level of consciousness [31]. Pierre Levy, the media theorist, says traditional AI is limited and suggests a new concept he calls a collective “*Hypercortex*.”

The patterns that characterize the AI myth dating back to the 1940s to the 1970s are visible in contemporary versions of the AI myth, too. Technology is both humanized and associated with superhuman or even supernatural powers [32]. We have yet to see which ones will come true within our lifetimes.

Conclusion

C. W. Mills [33] says that each era has its own mindset. This mindset, while not the only one, is the most important sign of that era, as it contains our strongest beliefs and perspectives of the time. It is also a summary of our most accurate senses and vulnerabilities. It is the organization of the senses around this sign as the manifestation of a social utopia. Simply put, it is a visualization and realization of society and social relations. Sociological thought, or the ability to create a social dream, can organize within itself, the farthest (such as machines) with the nearest (such as the human mind) through other and new senses to construct a self-sufficient, harmonious, and inclusive vision.

The increasingly extensive and complex computer programs that control human life in a myriad of ways are becoming harder to understand. Applications that have the ability to transform themselves are slowly appearing and will become more widespread and even harder to understand. The unpredictability of the outcomes of such programs is an important problem.

Developing machines that we cannot have complete control over and handing over the most sensitive aspects of our lives to these machines are some of the greatest risks humanity has ever taken [34].

We are witnessing research into intelligence extend into fields that require expertise like “*computing, decision making, memory, learning, creating, planning*” towards the production of machines that can outdo the human capacity to think. Given that machines can transmit all that they have learned to the next generation, machines could have an evolutionary advantage against humans [34]. As humans do this transmission using external mediators, only part of the information and experience transmitted can be internalized by the next generations.

Zadeh [35] did not believe that “*thinking machines*” thought the way humans do, so one aspect of his work involved “*making computers think like people*” in the mid-1980s. He suggested that the machine’s ability “to compute with numbers” was supplemented by an ability like human thinking. In 1990, he started developing a scientific concept he called “*soft computing - and, in particular, fuzzy logic - to mimic the ability of the human mind to effectively employ modes of reasoning that are approximate rather than exact.*”

For over 30 years, AI has been expected to have a revolutionizing influence on medicine. There have indeed been important technological developments recently that could have enormous effects, including exponential increases in computing power, big data processing technologies, access to large clinical data sets using electronic health records, and machine learning [36]. These could allow doctors to make more accurate diagnoses due to improving algorithms and also individualize patient treatment [37].

Science and technology are like the proverbial shining sun, as a constant source of light. However, many tests are still needed to ensure the safety of artificial intelligence applications, like any technological advances directly affecting healthcare in particular [38]. The way to ensure the safety of humankind against any risks in developing AI is to establish well-thought-out

restrictions and regulations and to work within an ethical framework. The development of new ethics, laws, and a philosophy compatible with our new life is crucial.

It is important for physicians to become more familiar with the basic concepts and metrics of machine learning and their potential applications and follow the increasing integration of artificial intelligence and machine learning into modern medicine. We can already see that artificially intelligent robots are going to evolve in unique and peculiar ways, which are currently hard to predict. One thing we want to avoid is rendering the robotic difference into a stigma, in terms of how far this difference can be from the human norm. The difference may become an evolutionary trait of existence. The integration of the potential of humans and robots in the future could lead to an *onto-epistemological approach* and ultimately develop into an *existential quest* for the original interspecies [39].

A more recently popularized term sometimes equated with artificial intelligence is “*deep learning*,” which is actually a tool included in the many offered by various statistical and probabilistic algorithms. With “*learning*” now possible, the smallest data put into algorithms could result in unforeseeable consequences, making developers and designers responsible for preventing unexpected and unforeseeable actions by AI systems. Overseeing resources and projects should be diverse boards comprising academics and professionals to ensure safety. The need and rights of humans and patients such as autonomy should always be taken into consideration since the probable outcomes and the risks of certain medical interventions, especially neurological ones, involve uncertainties [38]. Effective safety measures can only be possible through continuous ethical evaluations and monitoring technological development.

Let us hope, as Aristotle says in first book of *Nicomachean Ethics*, [40] that “*Every art and every kind of inquiry, and like-wise every act and purpose, seems to aim at some good: and so it has been well said that the good is that at which everything aims.*”

Abstract

Patient safety has constituted a huge public health concern for a long period of time. The focus of safety in the healthcare context is around reducing preventable harms, such as medical errors and treatment-related injuries. COVID-19 pandemic, if anything, has act as a wake-up call for health experts to address latent safety problems. Advancements in the field of artificial intelligence have highlighted the use of intelligent systems as a proven means of improving patient safety and enhancing quality of care.

This chapter explores trends in quality and safety research, the use of machine learning and natural language processing in the context of improving patient safety and outcomes, the use of patient safety databases as a source of data for machine learning, and the future of artificial intelligence in quality and safety.

Keywords

Patient safety · Quality and safety · Medical errors · Treatment injury · Adverse events · Polypharmacy · Natural language processing · Machine learning

Introduction

Patient safety has represented a serious global public health concern for centuries. As the worldwide health systems come under increasing strain and burdens surge, medical errors and treatment injuries will make up for a growingly large proportion of the world's total morbidity and mortality [1]. The complexity of healthcare systems involves a mismatch between "patient guidelines" and "patient needs" and arguably increases the probability of errors and suboptimal patient care, rendering safety improvement a major challenge facing modern healthcare systems. Patient safety is defined as the absence of preventable harm and medical errors to a patient and the prevention of potential harm risk associated with the healthcare

process. Central to this is the prevention of medical errors and treatment injuries [1].

Medical errors are reported as the third leading cause of death in the United States and are process faults that have the potential to cause adverse patient outcomes and can occur at any stage on the continuum of care [2]. Treatment injury (TI), on the other hand, is the personal injury caused by an accredited health professional as a result of delivering treatment [3]. Most medical errors are a result of system- or process-based failures, and not an individual's mistake [2]. Shojania et al. [4] recommended 11 practices as "clear opportunities for safety improvement"; however, patient-related factors are also surrogate markers of patient safety and include accurate detection of treatment injuries, adequate and effective treatment and recovery, and high function in the mid to long term [5].

Over the past decade, rapid advancements in artificial intelligence (AI) techniques have sparked a revolution in the medical sector as a possible means of delivering optimal patient care, and there has been an abundance of evidence to support the effectiveness of such technology in improving quality and safety measures across a variety of use cases. Leveraging AI with medicine is not only aimed at transforming the roles of healthcare providers but is also thought to provide a patient safety platform to eliminate medical errors and adverse events and enhance quality of care and safety outcomes [6]. The AI Clinician system was demonstrated to provide personalized and clinically interpretable sepsis treatment decisions to assist human clinicians [7]. An AI algorithm was similarly robust in detecting breast cancer using mammogram images [8]. Several studies showed the role of AI in improving workflow and reducing medical errors in different medical fields [9].

However, given the limited availability of data repositories in the safety and quality domain, we sought to present the potential use of AI techniques to enhance patient outcomes. The following sections draw from recent advancements as well as existing gaps in quality and safety research in order to highlight potential AI strategies in this field.

Trends in Quality and Safety Research

The trend toward electronic health records (EHR) and electronic-based compulsory audit software has given rise to large structured and unstructured datasets of patient information. The electronic health record has been regarded both as an advancement in quality and safety and as a resource for quality and safety research [10].

There has also been a move toward the privatization of quality and safety through the creation of large-scale quality and safety improvement entities such as the American College of Surgeons National Surgical Quality Improvement Program (ACSNSQIP) and the use of commercial audit software to meet the audit requirements of professional regulatory bodies [11]. This software gives the clinician specific data points to fill in for each patient audited in order to generate structured data points that are more interpretable and comparable to other centers using the same system. As quality and safety is now a business venture in medicine, it is further incentivized to improve.

In the field of primary care, there has been a move to greater accessibility of EHR which has been proposed as a way of improving patient satisfaction alongside other tenets of quality of care (i.e., efficacy, efficiency, equity, and safety). A recent systematic review and meta-analysis found that EHR sharing improved HbA1c levels in type 2 diabetics [12]. The encouraged sharing of EHR could also contribute to the accuracy of these records by allowing patients to see and correct the recorded information [13]. Improvements in primary care have often been proposed as a solution to the rises in emergency department (ED) attendances, and therefore, avoidable ED attendances have been used as a marker of primary care quality. As a marker, this has been shown to be sensitive to care quality, but the magnitudes of association are small [14].

There has been a cultural change in medicine shifting the focus of quality and safety practices around adverse event reporting from the individual practitioner who errs to the failing of systems and societal impacts [15]. The All New Zealand Acute Coronary Syndrome Quality Improvement (ANZACS-QI) program, is a New Zealand

Ministry of Health (MOH) endorsed nationwide audit, with completion rates built into the annual MOH reporting requirements, and as such, has a high level of capture of Acute Coronary Syndrome (ACS) data [16]. Linking audit requirements into a government funding body ensures the audit has a high level of capture, and also allows the dataset to be linked to the routinely collected New Zealand National Hospitalisation Dataset. Audit software such as this both collects and compares data for future quality and safety improvement, and also provides a platform for additional research [17]. As the ANZACS-QI program is standardized and compulsory for all New Zealand hospitals with patients that meet the criteria, additional areas of interest can be added to the system to look at further areas of research. For instance, the national study on oxygen therapy in ACS, a data field for oxygen was added and made compulsory on randomized days to gain data on usage in the setting of ACS [18].

Similar to the medical specialties, surgery is also subject to compulsory auditing as part of governmental influence and specialty college requirements [19]. The current model for surgical quality assessment and improvement is largely reliant on the characteristics of larger hospital centers, including the presence of other providers for peer review, higher procedure volumes in the center, and resources for data collection systems [20]. For those centers that can afford it, quality improvement programs such as the ACSNQIP and the Otago Clinical Audit provide a method of comparing clearly defined data against the expected standard and targeting quality improvement efforts. These programs also can work synergistically with other quality improvement efforts such as the traditional morbidity and mortality meetings which have been shown to underestimate postoperative complications [21].

Approaches to Patient Safety and Preventing Errors

In 2000, Reason conceptualized error into two broad models; the person-centered approach and the system-based approach gave a rise to

different philosophies of error management. Patient-centered approach accepts that unsafe acts are egregious and that individuals make error drawing on the unwarranted variability in human behaviors. This approach emphasizes the importance of disciplinary measures and training to standardize human acts. The system-based approach focuses on the conditions under which individuals work and aims to build defense mechanisms and layers to minimize errors and mitigate their consequences. This is better explained in Reason's Swiss cheese model of system accidents wherein slices of Swiss cheese have many holes that appear due to both active failures and latent conditions. The theorem argues that these holes are constantly opening, closing, and shifting position according to conditions and it is only when these holes line up to form a trajectory that system safety defenses are breached [22]. This model acknowledges that the pursuit of safety is about changing organizational culture to learn and adapt from occasional setbacks to develop a robust and feasible system that functions in the adversity of human and operational hazards.

Traditional approaches to safety management focus on error reduction using a "find and fix" identification lens and was later translated into the Safety I approach [23]. The aim of Safety I is to minimize error and eradicate harm while accepting the inevitable fallible reality of humans. Unlike Safety I which focuses on minimizing adverse outcomes, Safety II approach recognizes that safe care is provided in 90% of the cases and thus aims to encapsulate and maximize the number of acceptable outcomes. Safety II approach perceives humans as flexible agents of complex change and examines positive outcomes to invest in spreading good practice and knowledge building [24].

The following section highlights the role of AI to provide an alternative perspective of learning that harmonizes with traditional safety approaches and develops resilient healthcare systems.

Intelligent Systems: Machine Learning and Natural Language Processing

AI in medicine is the ability of a computer to make intelligent clinical decisions through analyzing extensive health data; identify trends, risks, and hidden knowledge; as well as enhance the interpretation of clinical outcomes. Among different types of AI, natural language processing (NLP) and machine learning (ML) specifically have promise in the safety and quality domains [25].

Machine learning enables computer systems to utilize algorithms and statistical models without explicit programming in making predictions and identifying latent knowledge from both labelled (supervised learning) and unlabelled data (unsupervised learning). Unlike ML-structured data, natural language processing enables computers to understand and translate human language (unstructured data) to machine-readable structured data which can be then analyzed using ML techniques.

The computerization of EHR to facilitate prevention, diagnosis, patient management, and treatment is still limited because they require access to reliable, coded, and retrievable clinical data. While many patient safety initiatives have been targeting structured data using ML techniques, textual reports of patient encounters include a wealth of unfiltered clinical information. A major challenge of implementing NLP in medicine lies in the diverse writing styles of healthcare professionals as well as the different contextual meanings of words. For instance, if a physician wants to identify patients with sepsis using the notes, they will retrieve too many patient reports containing expressions like query sepsis, sepsis excluded, rule out sepsis, and sepsis cannot be excluded. Although NLP systems have the ability to overcome these challenges to extract and structure relevant text-based clinical information, they require substantial combined medical and engineering knowledge and expertise to develop.

Prevention of Adverse Events

The definition of an adverse event varies widely in the literature. The World Health Organization (WHO) defines adverse events as “An injury related to medical management, in contrast to complications of disease” [26]. Worldwide, adverse events are estimated to affect 10% of hospitalized patients, in which 5–21% of these adverse events result in death and 50% are thought to be preventable with an estimate annual cost in the United States of \$17.1 billion [27]. Previous literature showed that the three most common types of adverse events are related to surgical complications, medications, and healthcare-associated infections [28]. In terms of cost and incidence, pressure ulcers followed by postoperative infections are the most common and costly, followed by central venous catheter infections and infections following infusions [28]. Healthcare has adapted from the aviation industry strategies such as the use of checklists for procedures, care bundles for central venous line insertion, and medication reconciliation.

Although there are national adverse event registries, such as the US Food and Drug Administration (FDA) Adverse Event Report System (FAERS), most hospital systems rely on retrospective chart reviews. Two common methods for detecting adverse events through retrospective chart review include the “Harvard Medical Practice Study” method and the “Global Trigger Tool” method, which have an overall positive predictive rate of 40.3% and 30.4%, respectively [29]. Both of these methods are multistage reviews that require a team of investigators and are time intensive. With the increased availability of EHR and development of NLP techniques, hospital systems and researchers are starting to validate models for accurately detecting high-impact adverse events such as hospital-acquired and ventilator-associated pneumonia and central line-associated bloodstream infections (CLABSIs). Using data mining methods, CLABSIs have been shown to be predictable (and therefore preventable),

significantly improving clinical surveillance programs, reducing hospital length of stay, and advancing patient safety. In improving postoperative infection rates, models using machine learning and AI have been used in identifying spinal fusion infection. With regard to preventing pressure ulcers, deep learning approaches have been developed using wearable computing sensors to alert care providers when a patient is in position for too long a period. Machine learning has also been used to identify which patients would benefit from limited speciality beds to reduce pressure injuries in the intensive care units.

Pharmacovigilance offers a significant opportunity for AI to detect adverse events, with feasibility studies showing effectiveness in processing time, reducing costs, and improving accuracy [30]. Calculation of the volume of fluid resuscitation is important especially for those at risk for complications such as heart failure. AI tools have been developed to accurately predict fluid requirements in the emergency department and intensive care unit. AI offers unique applications for detecting adverse events in the clinical trial phases of drug and medical device development, potentially reducing significant costs and preventing patient harm.

Diagnostics

Accurate and timely diagnosis is a multifactorial process that typically involves an interplay between system-related and cognitive factors of knowledge, experience, and effective patient-provider communication as well as available clinical and technical resources, rendering it high risk for errors. Diagnostic errors often occur over time from initial assessment to follow-up and arise when a diagnosis is incorrect, significantly delayed, or missed. Most people are likely to experience some diagnostic error throughout their life span. It is estimated that 5% of adults in high-income countries suffer from diagnostic errors each year in outpatient settings and the

magnitude is likely to be higher in low- and middle-income countries due to a paucity of healthcare professionals, limited testing resources, and record-keeping systems [31].

The widespread adoption of EHR presents an opportunity to automate tracking of diagnostic errors, understand cognitive biases, and assist healthcare systems with diagnoses. Deep learning algorithms, for example, showed a better diagnostic performance than a panel of 11 pathologists for the detection of lymph node metastases in women with breast cancer [32]. Similarly, EHR-based detection of familial hypercholesterolemia (FH) through random forest classifiers was found to identify thousands of undiagnosed patients with FH leading to better clinical management and screening of family members [33].

However, in contrast to structured datasets, a substantial amount of clinical narratives is semi- or unstructured which requires NLP and automated information extraction tools to extract information through mapping unstructured text into a semi-structured (or structured) form. Therefore, harnessing embedded clinical information through data mining techniques and concept recognition provides a far richer source of safety-related events and cognitive errors as well as reducing expensive labor-intensive chart reviews [34]. Only a handful studies have used unstructured textual data to identify diagnostic errors. Murff et al. (2011) showed that NLP-based approach had higher sensitivity and lower specificity in detecting postoperative complications compared to patient safety indicators of administrative discharge coding [35]. This is in line with previous published studies on the superior role of NLP in identifying genomic mutation-associated cancer treatment change and detecting safety-related events [36].

Medical imaging is another promising area for the application of AI and has the potential not only to improve image quality and diagnostic efficiency but also to optimize staffing and decrease radiation dosing through reducing scanning time. Once an image is captured, it can be incorporated alongside EHR and clinical narratives to aid diagnosis. A recent study illustrated the potential role for an AI system for the rapid identification of COVID-19 patients, combining CT imaging with

clinical information, showing a similar accuracy to a senior chest radiologist [37].

Despite the advances in big data analytics and their potential to improve diagnosis, the challenge remains in measuring the incidence of diagnostic errors. The lack of a standard metric to delineate the scope of the problem makes it difficult to gauge the effectiveness of AI techniques. All these safety issues and technological and political transformations working progressively in tandem will prosper in the creation of a data-driven system that reduces the global burden of diagnostic errors.

Medication Errors and Polypharmacy

Medication errors are a leading cause of injury and preventable harm in healthcare systems, and in the United States, it is estimated there is 1 medication error per hospitalized patient per day and is responsible for about 7000 deaths per year in hospitals [38]. Globally, the annual cost associated with medication errors has been estimated at US\$ 42 billion [1].

In developing and transitional countries, a report from the World Health Organization reviewing 679 studies from 97 countries found that over 50% of all medicines are prescribed, dispensed, or sold inappropriately and half of all patients failed to take medicines correctly and less than 30–40% of patients are treated according to some existing clinical guidelines [39]. With regard to quality of care in low-income countries, one of the very first papers analyzing 15,000 patient records hypothesized that poor quality of care is due to lack of medications, specialists, laboratory services, and other technology [40]. However, their findings showed that the two key factors causing adverse events were treatment errors and diagnostic errors, highlighting the central role of data in optimizing decision-making and therefore patient care [40].

Drug safety has been thought as the most significant contributor to overall medical errors and a target area for AI experts in this field. The Joint Commission on Accreditation of Healthcare Organizations highlighted that improper administration of medications or dosages are two key

sources of medication errors that result in severe patient harm and death [41]. Choudhury and Asan [42] reviewed studies exploring the influence of AI on safety outcomes and found that the majority of AI studies improved patient safety by preventing incorrect administration of drugs and overdoses and identifying adverse drug reactions.

Polypharmacy is a major global health issue posing a significant impact on safety outcomes and increases the probability of adverse medication events. Polypharmacy is often defined as the concurrent use of five or more medications including over-the-counter, prescribed, traditional, and complementary medicines [43]. Inappropriate polypharmacy, including nonadherence and socioeconomic factors, is estimated to contribute to 4% of total preventable costs worldwide, totalling USD 18 billion [44]. Gillespie et al. [45] performed a randomized-controlled trial that showed medication review by clinical pharmacists resulted in significant reduction in hospital visits, morbidity, and financial cost, a strategy that may enhance hospital-level safety measures.

There are a few studies to date which have investigated the role of AI techniques for predicting polypharmacy adverse events including DeepMind's acute kidney injury prediction, [46] a condition that may result from drug-drug interaction. Kocbek et al. [47] built balanced ML models of good performance and interpretability to forecast polypharmacy complications for patients suffering from either cardiovascular disease or type 2 diabetes, using drug prescription and hospital discharge datasets. A handful of studies implemented NLP on a small scale to predict polypharmacy harms or errors, highlighting the need to integrate ML and NLP models to identify high-risk patients and gain insights into the key variables for risk prevention [48]. The development of AI-driven decision support systems has the promise to identify appropriateness of polypharmacy and improve prescribing of medications.

Treatment Outcomes and Quality

Prevalent diseases and conditions in older persons in developed countries include brain diseases, osteoarthritis, hypertension, vision and hearing

loss, and diabetes. However, multimorbidity is common and increases the risk of complications due to treatment. Much of the current research using AI in the diagnosis and treatment of diseases are focused on single diseases or conditions, although risk stratification of patients with multimorbidity is being rapidly developed [49].

AI research in brain diseases is perhaps more advanced than other prevalent diseases. A systematic review [50] on the use of AI in brain diseases noted that the large amounts of data captured as medical imaging, free text, and data from monitoring devices have radically changed the identification and treatment of brain pathologies and tracking of the response to treatment [51]. Machine learning has particularly become widely used for conditions such as Alzheimer's disease, dementia, multiple sclerosis, and degenerative diseases. The use of AI in brain diseases is being applied to predict mortality, surgery response and postoperative hospitalization, and disease recurrence in a range of brain diseases and conditions [51].

Osteoarthritis, another common disease that is heavily reliant on imaging for diagnosis and response to treatment, is another area using AI. Deep learning has been useful in the diagnosis and assessment of knee and hip osteoarthritis and to assess knee pain [52]. However, although AI and deep learning are successfully being applied for diagnostic purposes, the use of AI in clinical trials remains nascent.

Hypertension is another prevalent disease and is the leading risk factor for cardiovascular mortality and morbidity. Despite being widespread and prevalent, treatment of hypertension has not changed significantly in the past two decades [53]. The two broad approaches are lifestyle modifications and pharmacotherapy. The role of AI in the treatment of hypertension has been proposed with the use of cuffless monitors and standardized electronic counselling through digital applications and pharmacogenetics-based algorithms [53].

Related to hypertension management is the management of age-related macular degeneration (AMD) that is the leading cause of blindness in older adults in developed countries. The incidence of AMD is expected to increase 1.5 times over the next 10 years due to an aging population and

increasing rates of hypertension [54]. Using machine learning with AMD-specific image parameter algorithms has shown promising results to predict progression of late AMD within 1–2 years.

Orthopedic surgery is heading in the direction of safety with the implementation of robotics to deliver joint replacement. Robots were first introduced 30 years ago, to abolish surgeon error, but only recently has their assistance been shown to be beneficial. The lack of objective metrics of joint health and disease and of prospective outcome data for many surgical treatments allows surgeons' selection and treatment biases to persist. This coupled with the notoriously poor accuracy of surgeons in predicting patient outcomes [55] and the lack of consensus on optimal management strategies, especially for common conditions, prompts the need for large unbiased data and the use of targeted AI systems. ML-derived prediction techniques are capable of aiding orthopods shift away from solely relying on clinical risk stratification models in making shared informed decisions with their patients [56]. For example, forecasting the probability of postoperative delirium and discharge destination following hip fractures has enhanced efficiency and safety and quality measures while providing opportunities for preventive targeted interventions [57, 58].

Clearly the use of AI in the treatment and outcomes of prevalent medical and surgical diseases is advancing quickly. There is enormous potential for the use of AI in the diagnosis, treatment, and management of multimorbidity, particularly in polypharmacy, which puts patients at greater risk of complications [59].

Patient Safety Databases

By now, we hope it is clear to the readers that the biggest challenge to advancing AI in the area of patient safety is the lack of large, comprehensive, and high-resolution clinical data.

The Centers for Disease Control and Prevention (CDC) and Centers for Medicare and Medicaid Services (CMS) compile reports of hospital-acquired infections, and the FDA collects data on adverse drug events, but none of these

datasets are comprehensive and high-resolution in order to build prediction, classification, or optimization models. There are a number of "opt-in" databases for medical errors, such as the Data Sharing Project (DSP) which was launched in 1985 as an independent collaborative effort to have a solid infrastructure of medical professional liability (MPL) claims and lawsuits. Given that these are mainly a collection of anonymous reports, they cannot be linked with other databases, and are therefore also not particularly valuable for machine learning research.

In New Zealand, the Accident Compensation Corporation (ACC) was established in 1974 and has provided compulsory insurance cover for treatment injuries for everyone in New Zealand since 2005 [60]. The dataset is a comprehensive nationwide reporting of medical errors in a no-fault compensation healthcare system. The dataset is the most comprehensive reliable and unbiased dataset for error and injury claims worldwide.

Future of AI in Safety and Quality

Although the advent of AI offers paths toward transforming the way safety and quality are delivered, an emphasis on their generalizability and interpretability is paramount. To create AI systems that are clinically useful, healthcare professionals should develop an understanding of how, when, and why these systems work, shifting away from the traditional geographical generalizability of clinical research [61]. AI systems are a set of algorithms that were trained to learn and operate under specific assumptions and clinical contexts, lacking the adaptability of expert clinicians. This prompts the need to replace our narrow focus on generalizability with a broader construct of the ultimate goal of AI at the bedside.

At present, AI techniques are usually evaluated by their precision and accuracy, but just because a system is deemed accurate, it does not imply unbiased or fair patient outcomes. Several key ethical considerations have been identified regarding the use of AI in safety and quality research, illuminating racial disparities. The AI community must engage in a holistic perspective in

addressing any disparities and to ensure that such systems will not perpetuate or magnify any marginalized communities' biases. A model pipeline framework is considered as a stepping-stone for AI healthcare ethics in addressing structural inequities, but the responsibility always lies on us as a society to ensure fairness and transparency.

Above all, the challenge in utilizing AI to optimize patient safety and quality remains in accessing a reliable and unbiased database. The ACC dataset provides a solid platform to address many of the global safety challenges considering New Zealand's unique no-fault compensation healthcare system. With the scale of patient impacts at stake and through working with a diverse team of physicians, developers, and engineers while closely understanding and inspecting potential biases and subpopulation disparities, we envision ACC to become a center of excellence in safety and quality science.

Using AI technologies may help create a transparent predictive platform that improves the shared decision-making process among patients, doctors, and policy makers. For example, an AI system would be a valuable tool to detect and track treatment injuries (TI), set benchmarks of medical errors, and may assist policy makers on establishing TI-related guidelines as well as identify TI-related factors. Understanding these predictors is arguably believed to improve the performance of healthcare systems worldwide. Determining which patients will benefit most from which form of medical intervention while understanding associated risks may also help inform policy, minimizing risk and maximizing health gain.

Abstract

The problem of the transparency and explainability of AI decision-making has attracted considerable attention in recent years. In this chapter, we argue that patients have a right to contest AI medical decisions and that the transparency requirements of AI

decision-making in health care should be guided by this right. We define the right to contest AI medical decisions both formally and substantially. Formally, the right to contest AI medical decisions must be a right (i) that is grounded in moral values, (ii) that is effective in protecting patients' rights, (iii) that is proportional to the potential costs to others, and (iv) that is an application of a more general right to contest medical decisions. Substantially, the right to contest AI medical decisions should enable patients to contest (I) the AI system's use of personal and sensitive data, (II) the system's potential biases, (III) the system performance, and (IV) the division of labor between the system and healthcare professionals. We justify and define 14 specific informational requirements – i.e., transparency requirements – that follow from the substantial notion of the right to contest AI medical

decisions. Finally, we briefly discuss the patient-centered approach taken in this chapter against alternative approaches grounding transparency requirements in considerations of democracy and the interests of science.

Introduction

Imagine two closely knit families having spent their holiday together. Celebrating their friendship and the memorable holiday, they go for a large dinner of authentic local foods on the last night of their holiday. Upon their return an adult member of each of the families, say Sarah and Bob, develops very similar, quite unpleasant symptoms of gastroenteritis. Sarah seeks healthcare assistance in the local clinic. The clinic has recently introduced the latest machine learning-based diagnostic and treatment planning support system – “Dr A.I. Grey 5.0.” Based on system recommendations, Sarah is further examined, diagnosed with amoebic dysentery, and prescribed metronidazole. Learning about Sarah’s diagnosis, Bob also turns to the local clinic for diagnosis and treatment. The system concludes that the gastrointestinal symptoms are indicative of a mild case of irritable bowel syndrome and will pass. Bob is recommended rest and fiber supplements to avoid constipation, although unsettled and inquisitive Bob is offered no further explanation or consultation.

The use of artificial intelligence decision-support systems in health care holds great potential for improved and more cost-efficient diagnostics and treatment planning. A recent review found that in terms of diagnostic performance deep learning models may outperform healthcare professionals in a number of cases [1]. The review also showed that in general the diagnostic performance of deep learning

models is equivalent to that of healthcare professionals, although the research providing this evidence is often of low quality. However, the potential gains in improved and more cost-efficient diagnostics come at a cost. Deep learning models are opaque. The reasoning procedure of complex machine learning systems – and deep learning systems in particular – cannot be fully explicated and replicated by a human being [2–7]. There is widespread consensus that the transparency of machine learning systems is desirable. A recent systematic review identified 84 guidelines on responsible use of AI issued by various different stakeholders [8]. The guidelines all emphasize the importance of transparency but differ in their definition of transparency and its requirements. The focus on transparency is also driven by the legal requirements in the EU’s General Data Protection Regulation which states in Article 13 that the data controller must “...provide the data subject with the following further information necessary to ensure fair and transparent processing [...] the existence of automated decision-making, including profiling, referred to in Article 22(1) and (4) and, at least in those cases, **meaningful information about the logic involved**, as well as the significance and the envisaged consequences of such processing for the data subject” (our emphasis) [9]. There is an identical clause in Article 14, and the requirement for “meaningful information about the logic involved” has in the literature been interpreted as a requirement for transparency, although the exact scope of the requirement is contested [10–12].

There is need of identifying a single guiding principle or reason behind a notion of transparency and in particular behind a notion of transparency of machine learning-based decisions in the healthcare context. There are several candidates. Thus, the transparency of machine learning-based diagnostics and treatment planning is important for several reasons. Transparency is important for scientific reasons. Machine learning models establish statistical correlations that may be suggestive or perhaps even constitutive of causal mechanisms [6, 13]. Identifying causal mechanism is key to understanding diseases and

initiating preventive or therapeutic interventions. Transparency is also important for democratic reasons. In a public healthcare setting, the use of machine learning models for diagnostic and treatment planning purposes is a way in which the State exercises power over its citizens, and it is a way of distributing healthcare goods. As anywhere else where the State exercises power over its citizens and makes distributive decisions, transparency should be sought in order for the citizens to be able to hold the State and the decision-makers accountable through the institutions of democracy. In the healthcare system, this is the basis for one of the most widely used underpinning frameworks for priority setting, Accountability for Reasonableness [14].

The simple case of Sarah and Bob illustrates what we believe to be the most fundamental ethical reason for insisting on the transparency of AI decision-making. The AI-generated diagnosis of Bob may or may not be wrong, but what is certainly wrong here is that Bob is in effect robbed of the opportunity to protect himself by contesting the AI diagnosis and treatment suggestion. Essentially, this chapter argues that patients have a right to contest the AI medical decisions and that the transparency of AI decision-making in health care should be guided by this right. We furthermore argue that this right has four dimensions together entailing that 14 types of information about an AI system must be accessible by a patient. Finally, we consider how contestability is linked to some of the other reasons for insisting on the transparency of AI decision-making. All throughout, the term “AI” is taken to denote complex machine learning systems.

The Right to Effective Contestability and Transparency

The right to contest AI decisions advocated in this chapter is a fundamental right to protect oneself by objecting to AI-generated decisions that one believes may have adverse effects on one’s life. It is not only a right to object to these effects but also to have these objections evaluated and potentially rectified.

The right to contest AI decisions presupposes and entails transparency but also at the same time provides an explication of and justification for what kind of transparency we should aim at. If Bob has a right to contest the AI-generated diagnosis and treatment plan, then he must have a right to be provided with some information about the involvement of AI in the diagnostic process. Without access to information, Bob cannot contest the AI decisions in a meaningful way. The real challenge here is therefore to determine the scope and limits of this right to contest and the entailed right to information. We believe that an adequate notion of the right to contest AI decision in health care should satisfy the following four conditions; it must be as follows:

- Value-based
- Effective
- Proportional
- General

That the right to contest AI decisions requires further delineation is readily seen. Bob may have interests giving him reason to contest all sorts of things about AI use in health care. He may want to contest the use of AI systems produced in a particular country or by people of a certain ethnicity or with a certain hair color, but this cannot reasonably be thought to provide him with a right to be listened to nor to information about any of these things. Reaching this conclusion requires, however, a more comprehensive framework for defining positively the content and scope of the right to contest.

We believe that *moral values* should determine the limits of the right to contest and the entailed right to information. That is, the right to contest should be defined and limited by the set of moral values and implied moral rights that it is intended to protect. To illustrate, if Bob’s right to contest is partly grounded in the value of protecting Bob against any physical harm suffered as a consequence of, e.g., inaccurate AI diagnostics and treatment planning – and Bob’s right to protect himself against such harm – then this explains both why Bob has a right to contest the AI-generated diagnosis and treatment plan and

why he does not have the right to contest the use of AI because of the hair color of its developers. Accordingly, Bob should be offered information of relevance for contesting wrongful AI diagnosis and treatment, and not information about the hair color of the developers. Taking this value-based approach implies that any claim to more information must start by showing why this information is relevant for the protection of individuals and their rights. It must make reference to some values and rights and explain why access to a certain type of information is required in order to determine if these values and rights have been or may be violated. Note that, while moral values may determine what information is *relevant* for a right to information, it does not determine the specific character of this information in every detail. Information about the accuracy of AI diagnostics may, for instance, be provided in many different formats.

Secondly, we believe that the right to contest AI decisions must be a right to *effective* contestation. That is, it must be a right to make objections that are as effective as possible in protecting those values underlying the very right to object. If Bob's right to contest is, as suggested above, partly rooted in his right to protect himself against the harms of inaccurate AI diagnostics and treatment planning, then it must be a right to be able to do so as effectively as possible. It must be a right that enables him to contest that a specific AI system with certain algorithms and trained on a particular dataset is being used in a particular organizational setup that seems to have generated an inaccurate diagnosis and treatment. The use of medical technology embedded with machine learning, e.g., for recording and interpreting ECGs, does not in and of itself cause harm to Bob – it is likely to his benefit. However, if Bob is offered no other option, he may choose to contest the very use of such medical technology as part of the diagnostic process. Contesting all forms of AI use in clinical context would be a very counterproductive way of protecting himself against harm since it may end up having harmful consequences for him. Contesting specific aspects of the AI system used for diagnostics and treatment planning in the specific organizational setup would be more

efficient. This delineation of the right to effective contestation has implications for the information Bob should have access to. He cannot most efficiently protect himself on the basis of general and abstract information about the AI use in health care, e.g., "AI technology is being used in this clinic." In order to effectively protect himself, he must have access to information about specific features of the AI system used and the organizational setup that applies to his particular case.

Thirdly, the right to contest AI decision-making in health care must be proportional. That is, it must balance proportionally individuals' right to protect themselves against violations of their rights due to AI system involvement in the diagnostic process against the potential benefits for others and society of such use. The right to contest AI decision-making in health care cannot in and of itself justifiably entail the impossibility of developing and implementing AI in health care that may be beneficial for others and society. The right to contest is a right to self-protection. It is not a right that in and of itself justifies limiting disproportionately the access of others to significant benefits. There may well be other moral reasons for limiting the use of AI in health care. The point here is that a right to contest AI use cannot justifiably constitute such a reason. It follows that the right to contest cannot justifiably entail transparency requirements – i.e., a right to information – that effectively makes impossible the very development and use of AI in health care. However, giving patients access to certain types of information that enables them to contest effectively the involvement of AI in the diagnostic process will inevitably have costs for both for system developers and clinicians that will have to retrieve and make this information accessible. As we aim to show in the following section, this information does, however, not have to be of a character that imposes disproportionate costs on the developers and healthcare professionals.

Fourth and finally, the right to contest AI decision-making in health care should be an application of a *general right* to contest medical decisions and correspondingly a broader right to gain access to information about the medical decisions. It cannot be a right introduced exclusively in

relation to AI for the simple reason that there is no ethically relevant difference that would justify such narrowing of the scope of the right to contest. If Bob had received his diagnosis and treatment plan by a doctor, there would be no less reason to insist that he should have the right to contest the decision and that this right entails that he should have access to essential information about how and why the doctor arrived at the relevant diagnosis and treatment plan. Doctors and AI systems are alike in the sense that they may fail to provide adequate protection of patients and their rights, and they may fail to do so for reasons we may never – for both practical and principled reasons – be able to fully uncover and understand. Research into biases in human decision-making reveals a striking amount of such biases [15]. Therefore there cannot be double standards in relation to the right to information, i.e., transparency. There has to be only one answer to the question of what information patients should have access to: the information required in order to effectively contest medical decisions. However, what information that is certainly depends on who is making the medical decision. Not all questions can meaningfully be posed to both AI systems and doctors. In order to contest the accuracy of an AI diagnosis and treatment plan, it may be considered relevant to know something about the quality of the dataset on which the algorithm was initially trained. It does not make sense to make the same inquiry about doctors whom it would be more obvious to question about their special field of training, competence, and interest and their level of experience. On the other hand, very similar questions about conflict of interest arise and must be answered in relation to the choice of treatment and the commercial influences on that choice. Ultimately, the general right to information may thus in the AI context come to be a right to types of information defined by special features of AI systems.

Satisfying the four conditions laid out above does not by definition entail that all aspects of AI decision-making must be explicable and/or replicable by a human being. They do not by definition require that we have to be able to fully open the “black box.” On the contrary, they only require that patients should have access to *sufficient*,

relevant, and specific information that enables them to *effectively* and *proportionally* contest medical decisions that may harm them or in some other way violate their rights. And that is wholly consistent with current practices in health care which we believe to be morally justified. Consider, for example, the use of medication. Drugs are often also “black boxes” in that the exact mechanism of action – the exact causal mechanism – is partly or wholly unknown. We are still learning new things about exactly how aspirin, on the market since 1888, works. Treating patients with a particular drug is, however, contestable in the sense that the patients can be provided with sufficient, relevant, and specific information about the basis for this decision, including information about the likelihood of effects and side effects, to be able to protect themselves against harm and other rights violations by exercising their right to object. Knowledge about the mechanism of action of a given drug may facilitate a better prediction of the effects and side effects, but information about the effects and side effects could also gradually become available through standard methods of testing. When a drug has been made available, the information required for effective contestation will also be available.

The Four Dimensions of Contestability

Contesting AI involvement in diagnostics and treatment planning should encompass four different aspects of this involvement and the AI system:

1. The use of personal health data by AI
2. The potential bias of AI
3. The performance of AI
4. The decisional role of AI

In what follows we shall establish more firmly the relevance of these dimensions, show how they are grounded in basic moral values and individual moral rights, and finally provide a detailed set of information requirements implied by the patients’ right to contest the AI involvement. In so doing, we will have provided a substantial notion not only of

the right to contest AI involvement in medical decisions but also of the corresponding right to the transparency of such AI involvement. For each of the dimension, we will develop specific contestability variables, leading to contestability questions and required contestability information. These are summarized in Table 1. The content of this section builds on our previous work on this topic [16].

Dimension 1: Personal Health Data

The use of AI models and systems for diagnostic and treatment planning purposes presupposes access to personal health data. Bob's diagnosis and treatment plan is the outcome of algorithms being applied to data of relevance for his present condition, e.g., clinical tests, personal health record data, scans, tissue, data from wearables, and non-health data collected digitally by various actors. Personal health data is sensitive for a number of reasons [17], and studies indicate that a majority of people are concerned about the privacy of their health record or the exchange of health data in the healthcare system [18–20]. The AI system use of personal health data may thus be considered invasions of privacy in the sense of involving the exchange and use of personal and sensitive data. However, personal health data may also be misleading by virtue of being outdated, one-sided, erroneous, and incomplete [21]. The AI system use of personal health data may consequently lead to misdiagnosis and inadequate treatment and thus ultimately come to have harmful consequences.

The potential of privacy invasions and harm makes relevant the right to privacy and the right not to be harmed, and not least the corresponding rights to protect oneself against violations of these rights. We believe that individuals should have a right to protect themselves against violations of privacy and harm by contesting the use of sensitive health data and other personal data in AI diagnostics and treatment planning. In order to be able to exercise this right efficiently, they should be provided sufficient, relevant, and specific information about the use of their personal

and sensitive health data. What information is that? Minimally, patients should be able to contest the use of health and personal data on grounds of its sensitivity and quality. This may be taken to imply that patients minimally should have access to information about (1) the types of personal data used by the AI system, e.g., clinical test data, genetic data, life style data etc., and (2) the sources of this data, e.g., electronic patient record, wearables, etc. The combination of information about both types and sources of data provides individuals with a fair chance of assessing the sensitivity and quality of the data used and to contest accordingly.

Dimension 2: Bias

AI decisions in health care may be biased [22–29]. Biased decisions may tentatively be defined as decisions that systematically differentiates between groups of people beyond what is warranted. What is warranted may refer to at least two different types of baselines. It may refer to what is warranted by the evidence in which case a biased decision is a decision that differentiates between groups people in ways that do not reflect the evidence. An AI system recommending painkillers on the basis of previous prescriptions by doctors could systematically recommend different painkillers for young and old or black and white. In so far as this pattern in the prescriptions would not be found in a representative set of prescriptions, it would not be a recommendation warranted by the evidence. The bias could have various different sources, e.g., the AI system may have been trained on a non-representative dataset, the dataset could contain systematic errors in the human tagging, or the algorithm could contain an explicit bias. It is well recognized that financial conflicts of interest can cause bias in medical research and medical decision-making [30, 31]. There is no reason to believe that the same could not be the case in relation to the development of AI systems. If the development of an AI system in a particular therapeutic area was funded by a pharmaceutical firm with a large commercial interest in the area, there

Table 1 The Four Dimensions of Contestable AI and Associated Informational Requirements

Contestability – object	Contestability – variables	Contestability – questions	Contestability – required explanation
Data	Types of data	What types of personal data are used?	1) The decision D was made on the basis of data of type X, Y, Z about you
	Data sources	Where do your data come from?	2) The decision D was based on data from sources X, Y, Z
Bias	Training data	On which data was the AI trained?	3) The decision D was made by a system trained on existing data of type X, Y, Z
	“Tagging groups”	Who tagged training data?	4) The decision D was made by a system trained on data tagged by X, Y, Z
	Tested for bias	Was training data or AI system tested for bias?	5) The decision D was made by a system tested for bias of type X, Y, Z
	Conflict of interest	Is there a relevant financial conflict of interest?	6) There is no conflict of interest/there is a conflict of interest of type X, Y, Z
Performance	Accuracy	What is the accuracy of the AI system?	7) The decision D was made by a system with an accuracy of X, Y, Z
	Accuracy testing	How was the accuracy determined?	8) The decision D was made by a system with an accuracy determined by tests X, Y, Z
	Essential indicators	What are key variables of AI decision-making?	9) The key input data resulting in decision D was X, Y, Z
	Alternatives	Are alternatives considered?	10) The alternatives to decision D are X, Y, Z with a probability of x, y, z ($< d$)
	Longevity	When is decision	11) The decision D will be reconsidered if conditions X, Y, Z obtain
Decision	AI involvement	To what degree is AI making the decision?	12) The decision D involved an AI system with respect to X, Y, Z
	Human involvement	To what degree are humans making the decision?	13) The decision D was wholly/partly made by health professionals X, Y, Z
	Responsibility	Who is responsible for the decision?	14) The objective/legal responsibility for decision D is held by X, Y, Z

would be a conflict of interest and at the very least a potential for bias in the final system.

The baseline could also make reference to what is morally justified. In that case, a biased decision would be a decision that differentiates between groups of people in ways that constitute unfair or unjust differential treatment, i.e., differential treatment which violates fundamental moral values or rights. The AI system recommending different painkillers to young and old or black and white could be biased in this moral sense. If the painkillers are not relevantly similar – have the same effect, side effects, price, etc. – the difference in recommendation would arguably amount to de facto discrimination, i.e., it would violate basic principles of justice, fairness, and equality. Moral bias of AI decision-making may have all the same sources as statistical bias, but it may also result if all the data on doctors’ previous recommendations of

painkillers are reflective of a discriminatory practice. Statistical and moral bias are not thus co-extensional. If the AI system is trained on complete data reflecting a discriminatory practice in previous prescription of painkillers, then the difference in recommendations will be morally biased but statistically unbiased. Conversely, if there are no relevant differences in effects, side effects, price, etc. of the different painkillers, then a difference in recommendations – due to the AI system being trained on a non-representative dataset – will be statistically biased but morally unbiased.

Biased AI decision-making may not only violate principles of equality, fairness, and justice, it may also lead to misdiagnosis and inadequate treatment of the groups being discriminated against. Bob may not only be the victim of gender-based discrimination, but this discrimination is likely to result in harm following the wrong

diagnosis and the failure to receive adequate treatment as well as the harm resulting from the wrong treatment, i.e., by feeling compelled to eat excessive amounts of fibers. However, the potential bias of AI systems is not unavoidable. Prior to its implementation, an AI system may be tested for bias by applying the AI model to datasets differing on known “triggers” of discrimination, e.g., gender, age, ethnicity, and the like. Indications of bias may also come from testing an AI system against alternative systems or against doctors’ diagnostics and treatment planning.

The potential of AI bias resulting in discrimination and harm makes individuals’ right not to be discriminated against and not to be harmed relevant and the corresponding right to protect these rights. We believe that individuals should have a right to protect themselves against violations of privacy and harm by contesting the potential bias of AI systems. This requires sufficient, relevant, and specific information about the potential bias of the AI system. Minimally this should include information about (1) the character of the dataset on which the model is built, where by character is meant both the type and source of the training data. This is relevant for assessing the potential of bias inherent in data. For machine learning systems based on supervised learning, it also becomes relevant to know (2) who labeled the data and what instructions they were given concerning how to label. This is relevant for assessing the potential of bias occurring as a result of the labeling. For any type of machine learning system, it is important to know (3) the character and level of testing for bias that the AI system has undergone. Finally, it is important to know (4) whether there are any financial conflicts of interest in relation to the development of the AI system. Knowing that an AI system and the training data has been tested for bias and knowing about the quality of this testing is clearly important for assessing the potential of bias.

Dimension 3: Performance

As we have seen, AI diagnostic systems may issue a wrong diagnosis if applied to erroneous health

data. However, they may also – as in the case of biased systems – fail due to flaws in the underlying AI model. The previously referenced review concluded that the performance of deep learning models in health care is generally on a par with healthcare professionals [1]. The accuracy of the AI diagnostic model – including true and false positives and negatives – may be determined through tests in which the model is applied to sets of validated data of varying composition and size and for which the diagnosis is known. The accuracy may and may not change in the course of time. AI models that do not evolve over time, so-called “locked” AI models, have a set accuracy when applied to patient populations that are qualitatively identical to the population on which the model is trained [16]. While the accuracy as well as bias of evolving models may change, and they therefore seem unlikely to be introduced into routine healthcare practice, the accuracy could in principle be determined before the implementation and at set intervals thereafter.

The possibility of inaccurate diagnostics means that AI systems may cause harm by leading to over- or undertreatment. Bob may not only be harmed from inadequate treatment of what may be a case of amoebic dysentery, but he may also – albeit to minor degree – come to suffer from his eating of excessive amounts of fibers. The possibility of such harm invokes the patients’ right not to be harmed and their corresponding right to protect themselves. We believe that patients should be able to protect themselves against such harm by contesting the performance of AI diagnostic systems, and this entails that they should have access to information about (1) the accuracy of the AI diagnostic model and (2) the character and reliability of the tests conducted, including information about the time of the most recent tests in the case of evolving models. This information is, however, not sufficient, relevant, and specific enough to enable effective contestation of AI diagnostics. A doctor providing statistics on his previous diagnostic performance will not have provided information enabling a patient to effectively protect himself against the potential harm following the diagnosis the patient is faced with. Information about previous diagnostics does not

rule out the possibility that the diagnosis at hand is arrived at in some objectionable way likely to make it inaccurate, e.g., by tossing a coin. In order to effectively contest the diagnosis at hand – whether issued by an AI system or doctor – the patient must be provided with information about (3) the key indicators leading to that diagnosis, (4) alternatives to the suggested diagnosis, and (5) the changes in the patient’s condition that will lead to a reconsideration of the diagnosis. Information about key indicators enables the patient to form an opinion on the credibility of the suggested underlying pathology and the application of this pathology to the situation in question – and to contest accordingly. Information about alternative diagnoses and changes leading to a reconsideration of the diagnosis enables the patient to form an opinion on the quality of the diagnostic procedure – and to contest accordingly. Diagnoses are underdetermined by indicators in most cases, unless there is a definitive test or a pathognomonic sign or symptom, and the diagnostic procedure is best understood as a procedure whereby the diagnosis is arrived at by inference to the best possible explanation of the indicators. Consideration of alternative diagnoses is therefore a necessary part of justifying a diagnosis. Consideration of changes in conditions that may lead to changes in the diagnosis is a necessary part of an ongoing justification of a diagnosis. Both types of considerations are thus indicatory of the quality of the diagnostic procedure.

Dimension 4: Decisional Role

AI systems may play a host of roles in diagnostic procedures. They may serve the purpose of screening patients before the actual diagnostic procedures. As in Bob’s case, they may be part of the diagnostic procedures themselves. This involvement comes in degrees. They may be involved by providing limited input into the diagnostic process, but they may also play the role of deciding a diagnosis only to be ratified by a healthcare professional. Following diagnostic procedures, AI diagnostic systems may also be used as a “second opinion” [16].

The involvement of AI in health care may serve different interests including not only more accurate diagnostics but also more efficient (time) and more cost-efficient diagnostic procedures and so on. Any specific organizational implementation of an AI system in health care will be a balancing of such purposes and interests. Although a patient may share some – perhaps all – of these interests, the patient may not necessarily share the balancing of these interests in an actual organizational implementation of AI. Bob may be rather narrowly focused on getting the most accurate diagnosis, whereas the clinic may pursue the most accurate and cost-efficient procedure. On the assumption that in the present state of affairs increased diagnostic accuracy can only be achieved by combining the efforts of AI system and healthcare professionals, Bob may come to be diagnosed by an AI system embedded in organizational setup that will provide less accuracy than (1) what he could have achieved in an alternative organizational setup with AI and healthcare professionals, perhaps even less than (2) what he would have achieved under normal circumstances without the use of an AI diagnostic system.

A suboptimal organization of AI-supported diagnostics may obtain in the absence of conflicting interests. If increased diagnostic accuracy requires fruitful collaboration of man and machine, then it is of cardinal importance that healthcare professionals retain their ability to make their own independent diagnostic judgments and decisions. Yet, there is evidence indicating that clinical decision support systems may lead to the deskilling of healthcare professionals and automation bias, i.e., overreliance on the performance of such decision support systems [32–38]. If healthcare professionals likely substitute their own judgments with those of an AI system, then Bob and other patients may end up being de facto diagnosed solely by an AI system regardless of the organizational setup. However, there is also evidence suggesting that decision support systems may improve practitioner performance [39, 40]. Interestingly, one possible explanation of these differences in findings is that they reflect organizational differences between the contexts in which the influence of AI decision support on the

performance of healthcare professionals is being studied. Thus, these studies may ultimately be evidence in support of the more fundamental claim that the organization and the division of diagnostic labor do affect the quality of the diagnostic procedure.

The potential variations in diagnostic quality due to variations in organization raise questions related to the patients' right to distributive fairness and their right not to be harmed and the corresponding right to protect these rights. A setup, which in terms of diagnostic accuracy may leave patients worse off than what they could have been or than what they would under normal circumstances be (prior to the implementation of the AI system), is a setup that may be challenged on grounds of its distributive fairness. A setup that may affect diagnostic accuracy – and thus be the cause of over- and under-diagnoses and eventually over- and undertreatment – is a setup that may be challenged on grounds of its potential harm. We believe that patients should be able to defend themselves against distributive unfairness and harm by contesting the division of diagnostic labor between healthcare professionals and AI system in a specific organizational setup. In order to do so effectively, patients should have access to information about the (1) the role of the AI system in the diagnostic process, (2) the role of healthcare professionals in the diagnostic process, and not least (3) information about the objective/legal responsibility for the diagnostic procedures.

Further Issues and Aspects of the Right to Contest

By taking the right to contest as the fundamental reference point for the transparency requirements of AI diagnostics, we are taking a patient-centered approach. It is the right of the patient being subjected to concrete AI decision-making in a particular clinical setting to contest that determines the transparency requirements. As outlined in the introduction, there are alternative frameworks grounding transparency requirements. Thus, one may take a democratic approach grounding transparency requirements in the need of the wider public to be able to have informed discussions

about and hold decision makers accountable for the distributive principles embedded in AI systems and the power exercised over citizens by the use of AI. We believe, however, that the patient-centeredness of the right to contest is primary for two closely linked reasons: firstly, because democracy so to speak starts with an individual's right to contest decisions that may harm them or violate their rights. The right to contest is part of a set of rights establishing the ideal of a sovereign and autonomous individual that is "later" at a societal/communal level protected through the institutions of democracy and particular democratic rights. Bob's rights as citizen in a modern democracy starts by his right to protect himself whenever he is subjected to decisions that may violate his rights. Secondly, because the transparency requirements entailed by the right to contest seem to constitute the core of transparency requirements grounded in the protection of democracy. Public deliberations of the distribution principles of AI systems and the power they exercise over citizens would arguably exactly require insights into the personal and sensitive data used by such systems, the potential biases, the performance, and the organization and division of diagnostic labor between AI system and healthcare professionals. This is obviously less surprising if we are right that democracy starts by protecting the sovereignty and autonomy of the individual.

The scientific approach to transparency would in its purest form focus on algorithmic transparency and perhaps extend that to humanly understandable explainability. It is not only researchers or healthcare professionals who can find this approach valuable, but patients may also have an interest in this deeper understanding of the inner workings of the black box. However, focusing on algorithmic transparency and explainability is by definition a focus on the AI system in isolation and thereby excludes the many contextual factors that come before, during, and after the use of the AI system. It also potentially obscures those instances of bias that are not easily identifiable in the algorithm itself.

While a patient-centered and value-based right to contest AI decisions in health care may be appropriate, there is certainly need of further

work. Two issues are particularly relevant for further work and discussion. On the one hand, the question of the completeness of the information requirements laid out in this chapter. We have tried to show the relevance of particular types of information for Bob's right to contest. These conceptual links may be disputed. Moreover, there are other types of information that is vital and more pertinent for Bob's ability to contest the AI diagnostics in particular circumstances. On the other hand, the practical implications of the right to information about AI involvement in the diagnostic process. We have argued for the right to access to information, but who is responsible for retrieving and making this information available to patients, and how should it be made available? If the right to contest should have any practical relevance for patients, the information must be made available in ways taking into account their ability to and interests in processing such information and by extension the ability of healthcare professionals to process and communicate the information. However, we contend that the regulatory power of a right to contest – the influence of this right on the development and use of AI in health care – does not come solely from patients exercising this power, but from the very existence of this right, i.e., from the possibility that patients may request information about an AI diagnostic system and on this ground contest its decisions. We do not doubt, however, that patients in a number of cases will be motivated to contest diagnostic decisions or treatment choices. Bob may be one such patient.

Abstract

Providing accurate diagnoses of diseases and maximizing the effectiveness of treatments requires, in general, complex analyses of many clinical, omics, and pathological data. Making a fruitful use of such data is not straightforward, as they are usually stored in electronic health records (EHRs) that need to be properly handled and processed in order to successfully perform medical diagnosis. In recent years, machine learning and deep learning techniques have emerged as powerful tools

to perform specific disease detection and classification using EHRs data, thus providing significant clinical decision support. However, approaches based on such techniques suffer from the lack of proper means for interpreting the choices made by the models, especially in the case of deep-learning ones. In this chapter, we describe clinical and omics data along with the popular processing operations performed to improve the medical analyses. We present the most common used algorithms in automatic medical diagnosis and the advance in explainability of machine learning-based systems to validate healthcare decision-making.

Introduction

A large amount of patient-related information is collected by healthcare operators in their everyday activities, which span over a wide spectrum of medical processes, such as wellness check-ups or examinations at healthcare hospitals or medical offices, just to name a few. For instance, when a patient undergoes a medical examination for the first time, the physician usually creates a patient file including his medical history, current treatments, medications, diagnosis, and other relevant information [1]. Considering that disease diagnosis is crucial for health condition monitoring, it is natural to envisage that such large amount of data can be profitably used to guide data-driven disease classification tasks in the quest for early and accurate diagnoses, taking care of the complex interactions among clinical, biological, and pathological variables. Indeed, with the aim of identifying the best services and treatments for the patients, recent advances in medicine have proposed various models for personalized, predictive, and preventive medicine that make use of electronic health records (EHRs) and high-dimensional omics data [2]. In particular,

the use of EHRs facilitates healthcare delivery, by possibly contributing to improving healthcare quality with more accurate decisions. However, accessing and using EHRs and omics data can be rather challenging in practice, because they are heterogeneous and usually stored in different data formats. Therefore, these data need to be collected, cleaned, and stored in a proper way. On top of the consolidated data, relevant and meaningful knowledge for patient care can be then extracted by means of advanced Artificial Intelligence (AI) methods and Machine Learning (ML) approaches.

In this chapter, we focus on the definition of precision medicine and precision health based on clinical and omic data, by considering in particular disease prediction and prevention. We present a survey of recent and novel works in medical diagnosis, along with a detailed discussion about the relevance of the explainability of the results to validate the treatment. In particular, we firstly focus on medical applications based on EHRs. Then, we present recent advances in omics technologies (i.e., genomics, transcriptomics, epigenomic, proteomics, and metabolomics) to enable personalized medicine [83].

The remainder of the chapter is structured as follows. A detailed description of the salient features of clinical data is provided in section “[Clinical Data](#).” Different techniques used in data processing are detailed in section “[Data Processing](#).” Then, emerging applications in Medical Diagnosis are discussed in section “[Existing and Emerging Applications in Medical Diagnosis](#),” while the problem of providing explainable results is detailed in section “[Explainability of Results](#).” Eventually, a number of future perspectives are sketched in section “[Future Perspectives](#).”

Clinical Data

Health-related information usually refers to clinical data, and it is associated with regular patient care or it comes as a part of a clinical trial program. Clinical data represent an important resource to enable and guide the acquisition of novel knowledge (for instance, to provide outcome and therapies predictions) and best practices

(for instance, to ensure data completeness, reliability, and correctness) in healthcare [3]. Clinical data are also important to seek timely treatments and appropriate care to the patient, and to enable a (sort of) self-learning system that is able to continuously improve quality of care. Indeed, by considering the importance of health condition monitoring for early and accurate medical diagnosis, learning from practice is crucial. Clinical data are collected and translated into EHRs; these include administrative and demographic information, diagnoses, treatments, prescription drugs, physiologic monitoring data, and other health information, as reported in section “[Electronic Health Record](#).” The use of EHRs in clinical research studies provides several advantages, such as defining the most suitable treatments, reducing hospitalization cost, and providing personalized medicine. In particular, EHRs are used for various data science and machine learning studies, including statistical analysis of diseases, risk prediction for breast cancers [4], classification of heart disease and diabetes [5], and diagnosis of rare pathologies [6].

In the last decade, different studies have shown that it is possible to discover relevant information and distinctive attributes related to specific diseases by properly analyzing and combining omics and EHRs data [7–10]. Omics studies are used to analyze types of molecules in samples which can be measured in terms of character and quantity as a whole, with the aim of investigating the patterns or relations to the sample attributes [11]. Thanks to the comprehensiveness of these data, it is possible to generate or confirm hypotheses on biological or medical conditions [12] and to provide a basis for precision medicine [13].

Precision health, an evolution of precision medicine, combines omics data with lifestyle, clinical data, and environmental factors. These data can be used to identify and predict disease diagnosis, treatment, prevention, and individualized early diagnosis [14]. In particular, a personalization of medical treatment based on specific patient characteristics is possible by improving the understanding of the physiological and biological mechanisms of disease, responsible for the spreading of omics data, and by developing patient-based algorithms [15]. Thanks to these

advances, the work on precision health is growing quickly, thereby allowing an improvement of outcomes and reducing unnecessary treatment. However, clinical data as well as omics data present several issues that can have a substantial impact on study results, especially in terms of quality, such as incompleteness (e.g., missing information), inconsistency (e.g., information mismatch between various or within the same data source), and inaccuracy (e.g., nonspecific, non-standards-based, inexact, incorrect, or imprecise information) [16, 90].

In this context, Omics Data Management (ODM) and Clinical Data Management (CDM) play a crucial role in generating high-quality, reliable, and statistically sound data from clinical trials [17]. On the one hand, considering that omics data usage provides a prominent opportunity for diagnosis, or predictions of future diagnoses, ODM is used to address the uncertain or unexpected findings, many of which may have relevant impacts in medical diagnosis (e.g., the collection and processing of genome data that are not sufficiently standardized or valid); on the other hand, the main goal of CDM processes is to provide high-quality data by reducing the number of errors and missing data to improve data analysis [17].

In general, data management is the process of collecting, cleaning, and processing data according to standard rules. With this aim, the use of specific software applications and best practices can lead to data completeness and reliability. Sections “[Electronic Health Record](#)” and “[Omics Data](#)” report a detailed description of electronic health record and omics data, respectively, by highlighting the main characteristics and issues.

Electronic Health Record

Electronic health records (EHR) build the digital version of a person’s medical information and history, which is maintained over time by a healthcare provider. EHRs are used to timely and consistently collect patient information to provide more extensive and accurate clinical care, and in predicting future outcomes based on both individual-related and population-related data. It has been shown that a proper use of EHRs can

improve healthcare quality, with benefits including secure long-term storage, consistency, standardization, and accessibility of patient information [18]. EHRs can include structured and unstructured data such as demographics, medical and surgical histories, diagnoses and procedures, patient examinations, and results from various clinical studies, as listed in Table 1. Structured data use a uniform format in the EHRs system with a controlled vocabulary and pre-determined values that make these data consistent and easily extractable. To the contrary, unstructured data do not use a standard format; indeed, healthcare providers can include free text regarding, for example, additional health information and details on clinical examinations, along with comments by the operators. Then, the same clinical information can be recorded in EHRs in different ways depending on the user, hence posing important challenges to computer analysis because of (1) heterogeneous data formats, (2) abundant typing and spelling errors, (3) violation of natural language grammar, and (4) rich domain-specific abbreviations, acronyms, and idiosyncrasies [13]. The unstructured data requires the use of additional tools, such as natural language processing (NLP), to standardize, codify, and extract relevant information [23].

Omics Data

Understanding of human health and diseases requires a proper interpretation of molecular interactions and variations at multiple levels such as genome, epigenome, transcriptome, proteome, and metabolome [24], which together go under

the name of omics data. In other words, omics refers to the collective technologies used to explore the roles, relationships, and actions of the various types of molecules that compose cells of an organism [25] and, potentially, are responsible for specific disease or condition [26]. The omics data and the description of each molecular profile are listed in Table 2.

The use of high-throughput data acquisition such as next-generation sequencing (NGS) and mass spectrometry (MS) allow to perform fast accumulation of omics data. These data can be used to identify medical biomarkers by cleaning raw data generated by NGS or MS, extracting molecular profiles, identifying statistically significant molecules, or defining models able to explain molecular interactions in a specific context. Specifically, genomics approaches have been used to identify the genes and genetic loci involved in the development of human diseases [27], epigenomics to find epigenetic markers [28], proteomics for proteins and peptides [29], and metabolomics for low-abundance metabolites [30]. These data, which are composed of a huge amount of data points, require standard data formats and publication guidelines [31] to improve data sharing, acquisition, analysis, and usage. The use of standard formats ensures unambiguous communications, clear experimental designs, treatments, and analyses with the aim to support the conclusions, guarantee an independent reproduction [31] and facilitate the creation of standardized public data repositories. The current state-of-the-art counts different methods to facilitate better exchange and integration of data such as the Minimum Information About a Microarray Experiment (MIAME) [32] to define a guideline

Table 1 Example of structured and unstructured data available as EHRs at patient-level

EHR data type	Category of data	Example of data
Structured	Demographics	Age, name, gender, contact information
	Allergies	Drug allergies and adverse reactions
	Vital signs	Height, weight, temperature, heart rate, pressure
	Diagnosis codes	International Classification of Diseases (ICD) used as diagnostic tool for diseases classification, health status monitoring and clinical purposes
Unstructured	Clinical notes	Progress notes, hospital admission notes, physical therapy, history and physical examination

Table 2 Some domains of omics standards are listed. The domain indicates the type of experimental data. Genomic measure DNA molecules, epigenomic, transcriptomic,

proteomic, and metabolomic studies the chemical states of DNA and its binding proteins, RNA, proteins, and metabolites, respectively [11]

Domain	Description
Genomic	The genome is the complete sequence of DNA in a cell or organism. Genomic is a technique used to improve diagnosis through identification of genomic conditions, which could improve clinical management, prevent complications, and promote health [7]
Transcriptomic	The transcriptome is the complete set of RNA transcripts from DNA in a cell or tissue. Transcriptomic is a technique used to measure the chemical states of DNA and its binding proteins, RNA, proteins, and metabolites, respectively [11] and study an organism's transcriptome, the sum of all of its RNA transcripts. The information content of an organism is recorded in the DNA of its genome and expressed through transcription, which is also used in disease diagnosis and profiling [19]
Epigenomic	The epigenome consists of reversible chemical modifications to the DNA, or to the histones that bind DNA. Epigenomic is a technique used to study the complete set of epigenetic modifications on the genetic material of a cell, known as the epigenome. Epigenetic patterns are potential useful biomarkers to detect cancer cells and to classify different disease types [20]
Proteomic	The proteome is the complete set of proteins expressed by a cell, tissue, or organism. Proteomic is a technique used to study proteins, which are vital parts of living organisms, with many functions. Proteomic methodologies enable the detection and quantitation of protein profiles associated with the disease state [21]
Metabolomic	The metabolome is the complete set of small molecule metabolites found within a biological sample. Metabolic is a technique used to study and monitor the presence and concentration of specific metabolites associated with a particular disease. Metabolomics methodologies provide the opportunity for the identification of clinically relevant biomarkers as it best mirrors the human phenotype [22]

for the minimum information required to describe a DNA microarray-based experiment, the Minimum Information About a Proteomics Experiment (MIAPE) [33] to define guidelines for proteomics studies, and the Minimum Information about a high throughput SEQuencing Experiment (MINSEQE) [34] to define guidelines for sequencing study.

Diagnostic-Related Information and Treatment Information

Diagnostic-related information can benefit patients in receiving the right treatment, helping healthcare operators to provide the most appropriate preventive interventions and therapeutic strategies [35]. Diagnostic information can help to avoid or shorten hospitalization, reducing inappropriate use of drugs and, consequently the economic cost, bringing to more efficient use of resources [23]. Although diagnostic information can help clinicians to identify certain biomarkers in the body, they do not allow any identification of insight into the interaction among information and the environment responsible for the disease.

The vast amount of digital data captured in EHRs in combination with the emergence of omics data offers novel research perspectives and opportunities in health systems to improve health management and enable the study of personalized medicine and treatment information. In this scenario, the use of omics data becomes necessary to transform the understanding and treatment of many diseases, helping doctors to customize therapies to the molecular profiles of individual patients. These data represent a crucial element in predicting biomarkers, in determining predisposition, diagnostic, and prognostic and identifying modifiable risk factors with the main objective to improve the traditional symptom-driven practice of medicine [36].

However, integrating clinical and omics data is a challenging task due to the difficulty in knowledge extraction from large and complex datasets. Such issues can be tackled through machine learning algorithms that can be adapted to specific settings and omic types [37]; indeed, a high number of researches have been carried out to examine the application of machine learning and deep learning techniques in the area of diagnostic-related and treatment information; some existing and emerging applications are described in section

“Existing and Emerging Applications in Medical Diagnosis.”

Data Processing

Omics and EHRs data can be difficult to analyze and computationally expensive to process due to high-dimensionality. In particular, omics data are composed of many dimensions/features much larger than the number of samples available, while EHR data usually contains a large sample size of high-dimensional data, but each individual sample is sparsely populated [13]. Also, these data can suffer from information quality problems, making data not really suitable for clinical research. In order to tackle these issues, data quality assessment and dimensionality reduction are needed to remove irrelevant and redundant data and preserve the characteristics of the original data. An overview of the data processing operations is shown in Fig. 1.

In the following, we first describe techniques used to handle missing values in section “[Missing Value Imputation](#).” Then, we illustrate dimensionality reduction technique in section “[Dimensionality Reduction](#).” And, eventually, we present further pre-processing approaches that are used to deal with omics data in section “[Different Omics Processing](#).”

Missing Value Imputation

In order to maximize the performance of data analysis, the quality of each omic and EHR data

must be carefully assessed to ensure that measurements are reproducible. Since missing values can affect the quality of the results, several approaches were proposed to tackle this issue. One of the most common approaches is called single imputation, which relies on the removal of the missing rows, by ignoring subjects with incomplete information or replacing the missing items with plausible values (e.g., means of the observed cases). This procedure presents some limitations due to the high proportion of subjects discarded [38], the distortion of the distribution of the variables, and the introduction of additional biases [39]. More robust approaches were presented in the state-of-the-art such as multiple imputation [39], inverse Probability Weighting [40], expectation-maximization [41], Multivariate Imputation by Chained Equation [42].

Dimensionality Reduction

Feature extraction and selection methods are used to maximize performance analysis and improve result understandability. **Feature Selection** selects features in input that contains relevant information for solving the particular problem. Instead, **Feature Extraction** is used to transform the input space into a low-dimensional subspace that preserves the most relevant information [43].

Feature selection techniques consist of filtering, wrapper, or embedded methods [13]. In the **filter** approach, each feature is evaluated individually using its general statistical properties [44],

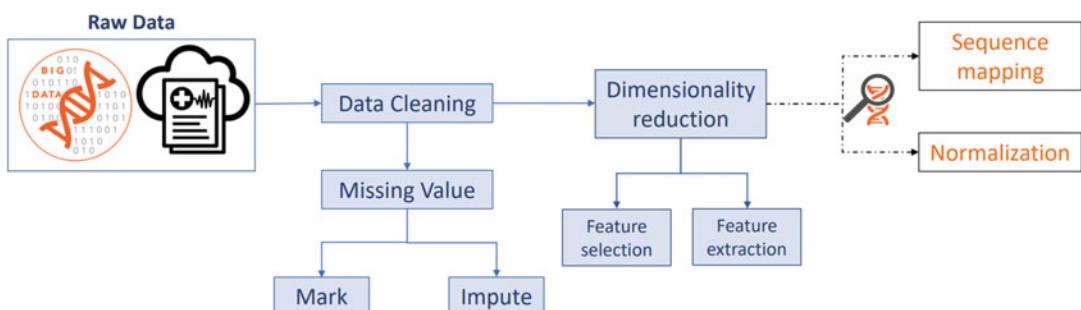

Fig. 1 Workflow of data processing steps. Data cleaning and dimensionality reduction are performed on raw data. Sequence mapping and normalization are usually used to handle the complexity of omics data

making the approach faster, without explicit class labeling [13]. Among several filter approaches, we selected and described the most common. Mutual Information (MI) measures the level of dependence between two random features (i.e., the amount of information that variable V1 knows about another variable V2) [45]. Information Gain (IG) evaluates the gain of each feature to a certain class, by computing the entropy (i.e., level of impurity), such that the feature with higher information is the much related, while the unrelated feature offers no information [46]. Minimum Redundancy Maximum Relevance (mRMR) [44] iteratively selects features with the maximum relevance, decreasing the redundancies within each class, such that any mutually exclusive features are selected [47].

The **wrapper** approach uses learning techniques to select the optimal feature subset. This approach typically requires high computational costs and it is affected by the risk of overfitting, but it shows better performances than the filter approach [48]. Genetic Algorithm (GA), Ant Colony Optimization (ACO), and Particle Swarm Optimization (PSO) are examples of wrapper approaches inspired by natural evolution, ant colonies and flocks of birds, respectively, to generate a population of features that optimize the solution.

The **embedded** method integrates machine learning algorithms with recursive feature elimination [13]. These methods are less computationally expensive and less prone to overfitting than the wrapper ones. An example of an embedded method is Support vector machines (SVM), which is a supervised machine learning algorithm used to search for a hyperplane that optimally divides the tuples from one class to another. Therefore, SVM allows us to identify the main features used in classification and remove the not important ones [49].

Among the various feature extraction techniques, principal component analysis (PCA) is a commonly used method. PCA is an orthogonal linear transformation that converts variables into a new smaller set, called principal components. The number of principal components is less than or equal to the number of original feature variables [50].

Different Omics Processing

Depending on the objective being defined and on the dataset itself, other preprocessing approaches may be appropriate to handle the complexity of omics data, such as (I) sequence mapping and (II) normalization.

(I) **Sequence mapping** is the process of comparing millions of sequences generated, for example, by NGS against the reference genome to obtain one alignment between each read and the genome. Mapping is fundamental in NGS and MS analysis, representing the basis for further analysis, e.g., to estimate the abundance of transcripts and variant detection [51]. The common NGS mapping tools are based on a hash table or index-based algorithms, while heuristic-based aligners are demonstrated to be less expensive in terms of computation [51], such as Genomic Mapping and Alignment Program (GMAP) [52] and Burrows-Wheeler Alignment (BWA) [53]. In MS data, peak alignment can correct drifts to ensure accurate mass across samples. Indeed, without alignment, the same peak (e.g., the same peptide) can have different values of mass-to-charge ratio (m/z) across samples [84].

(II) **Normalization** plays an important role in the omics data preprocessing to remove unwanted systematic bias while maintaining real biological differences in the observed datasets. In this context, different methods have been used based on several statistical models (e.g., unit norm, median, and quantile), scaling methods (e.g., auto-scaling, range scaling, Pareto scaling, vast scaling, and level scaling), and data transformation (e.g., log and power) [54]. Other approaches are used to normalize the samples by adjusting their variability. For instance, Locally Weighted Scatterplot Smoothing (LOWESS) algorithm [55] is used to remove the bias present in the data which frequently shows a deviation from zero for low-intensity spots. Normalization also enables the comparison of different samples in MS, by considering that the absolute peak values of different fractions of the spectrum could be incomparable. Normalizing spectrum allows us to identify and remove sources of systematic variation in MS data which can depend, for example, on varying amounts of sample or variation in the instrument detector sensitivity.

Existing and Emerging Applications in Medical Diagnosis

Recent improvements in machine learning (ML) and deep learning (DL) approaches provided useful techniques to recognize patterns from clinical and omics data and to predict future outcomes of the patients. A conceptual model to illustrate the diagnostic process is shown in Fig. 2. In fact, several works have already shown the validity of these methods to provide improved and more generalizable risk prediction models: by taking advantage of high-dimensionality data, such as EHRs or omics data, these algorithms can effectively determine the combinations of variables that are able to predict a reliable outcome.

In this section, we will describe the latest advances in ML and DL on EHRs and omics data, with the latter being considered from the molecular profiles perspectives: genomics, transcriptomics, epigenomics, proteomics, and metabolomics.

Clinical Data Application

Several works have been proposed to perform diagnosis prediction using clinical data collected during a single medical check-up. Corey et al. [56]

defined different machine learning algorithms including penalized logistic regression, random forest models, and extreme gradient boosted decision trees to identify high-risk surgical patients from EHRs [85]. The experimental analysis showed that the best result was produced by penalized logistic regression models with an AUC value of 0.92. Instead, a DL-based approach was proposed by Miotto et al. [57]. They used a deep neural network composed of a stack of denoising autoencoders to process EHRs in an unsupervised manner that captured stable structures and regular patterns in a variety of clinical risk-prediction tasks, including, for example, diabetes mellitus with complications, cancer of rectum and anus, cancer of liver and intrahepatic bile duct, congestive heart failure (non-hypertensive). The proposed approach outperformed state-of-the-art methods based on raw EHR data (i.e., no feature learning applied to EHR data). A limitation of these approaches is, however, that they did not rely on temporal information to improve the performance of predictive models, making them not applicable in real clinical settings.

To tackle time dependencies in EHRs, Rohit et al. [58] presented a continual prediction framework based on logistic regression to predict acute kidney injury (AKI) before the development of disease at any time during the hospitalization. In

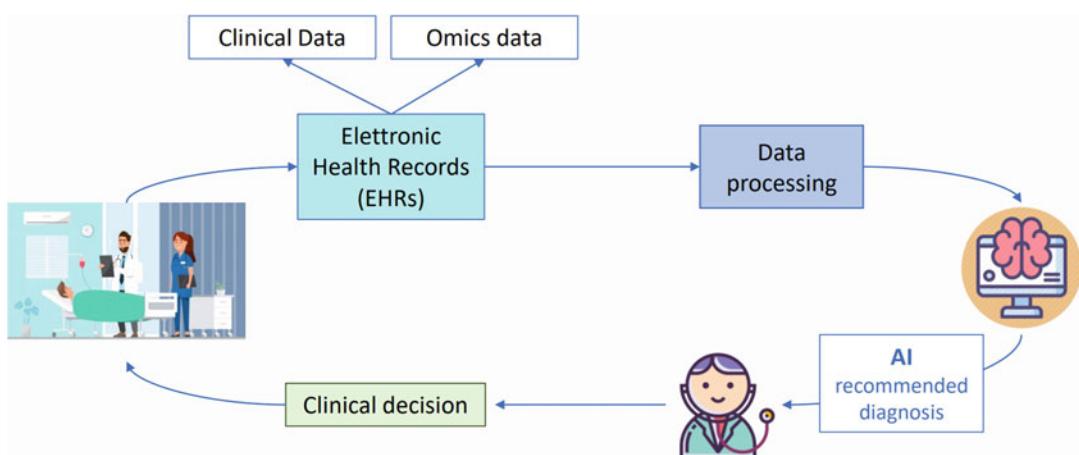

Fig. 2 EHRs are composed of clinical data and omics data that are collected during medical examinations. Data processing operations are performed to prepare data for AI

techniques. The output is used by healthcare providers to improve the diagnosis and provide a clinical decision

particular, the proposed model continually predicts over the entire hospital stay whenever any patient variable changes (e.g. AKI occurrence). A limitation of the work is related to the data used to predict the disease; indeed, the model was obtained by using only the structured part of EHR, discarding the unstructured component. Mehak et al. [59] proposed a recurrent neural network (RNN) architecture with long short-term memory (LSTM), which learns the patient representation from the temporal data collected over various visits of the patient, to predict future obesity patterns from childrens' medical history. Jeong et al. [60] proposed a similar approach called multi-scale temporal memory (MTM) with the aim of modeling clinical events at different time scales in EHRs. Thanks to MTM, information about past events on different time-scales are collected and used to perform on-the-fly prediction. The authors showed that the approach, combined with different patient states, can cover different temporal aspects of patient states, achieving an accuracy improvement of 4.6% than baseline approaches and of 16% the prediction based on LSTM approach. A limitation of these approaches is related to the limited size of the observation windows in the EHRs data. Finally, Che et al. [61] develop a variation of the recurrent GRU cell (GRU-D) which handles missing values in clinical time series by incorporating time intervals directly inside the GRU architecture. Indeed, missing values are considered as one of the principal reasons for the loss of precision. Their GRU-D networks showed an improvement of AUC on two real-world healthcare datasets for classification and mortality prediction tasks.

Omics Data Application

Genomic data: DL technologies can be used to predict gene expression and to study interaction between genomes and diseases. Chen et al. [62] exploited a DL method to infer the expression of target genes from the expression of landmark genes. They used the microarray-based Gene Expression Omnibus dataset to train the model, achieving a performance that is significantly

better than logistic regression, with an improvement of 15.33% on mean absolute error. Chen et al. [63] developed a DL-based approach to explore genomes and disease relationships. They performed jointly supervised classification, unsupervised clustering, and dimensionality reduction on high-dimensional genomic data to identify cancer subtypes. This approach was tested on breast cancer and outperformed the existing methods, identifying more robust subtypes using fewer genes. A limitation of the work is related to generalization capability. The performance decreases in predicting other types of cancers where molecular subtypes have not yet been well established. Bruno et al. [64] presented a framework for automated diagnosis based on high-dimensional gene expression. They performed data reduction to transform high-dimensional representations of data into a lower-dimensional space. Eventually, they relied on different data visualization techniques to convert complex pieces of information into 2-D images, which are in turn used to perform DL-based diagnosis. They also tested the framework on clinical data to perform diagnosis. The approach obtained a good performance, showing a prediction recall value between 0.91 and 0.99. However, performances decrease in predicting patients that share similar variations in gene expression or clinical information.

Transcriptomic data: DL technologies can be also used to identify the association between RNA and disease. Thomas et al. [65] proposed a deep belief neural network (deepBN) to perform the classification of pre-miRNAs. DeepBN is composed of an unsupervised stage with hidden layers pre-trained as restricted Boltzmann machines (RBMs), followed by a supervised tuning of the network [86]. The approach achieved a level of accuracy of 0.97. Bobak et al. [66] presented a data analysis framework that directly integrates multiple publicly-available expression array datasets to identify a gene signature for the diagnosis of tuberculosis. The authors evaluated different machine learning algorithms including random forest, support vector machine with the polynomial kernel, and partial least square discriminant analysis. According to the analyses,

the authors proved that the best result was obtained using random forest with an accuracy value of 0.95.

Epigenomic data: In the context of predict epigenetic effects of DNA sequence alterations (e.g., chromatin accessibility, DNA methylation and histone modifications), DL methods can be used too [87]. Quang et al. [67] proposed a hybrid approach based on Convolutional neural network (CNN) and LSTM to predict the chromatin effects of noncoding DNA sequence alterations [87]. This approach allows to simultaneously learn motifs and a complex regulatory grammar between the motifs. The authors showed that the approach outperforms other methods for predicting the properties and function of DNA sequences across several metrics, including AUC. A limitation of the approach is related to the dimension of sequence data used to train the network; indeed, it can only process sequences of constant length with static output. Yin et al. [68] proposed a DL approach for integrating sequence information and chromatin data with the aim to perform prediction of modification sites specific to different histone markers. The architecture is composed of three modules corresponding to a DNA sequence, chromosome accessibility, and a joint module, respectively. The approach outperformed several baseline methods in a series of comprehensive validation experiments [68]. The authors did not incorporate recurrent neural network architecture, such as long short-term memory units, that, considering the sequential natural DNA fragments, may improve the performance.

Proteomic data: DL technologies are also effective in the identification of protein structures and protein contact map prediction. Wang et al. [69] presented a new DL method to improve protein contact prediction by integrating both evolutionary coupling (EC) and an ultra-deep neural network to preserve sequence information. The approach achieved the highest F1 score on protein structure prediction (CASP). The prediction accuracy could be even better if the authors train a model with more layers. Liang et al. [70] proposed DL algorithms with stacked autoencoders for the analysis of FLT3-ITD mutation in acute leukemia patients. The authors relied on a dimensionality

reduction algorithm to reduce the number of proteins. The approach achieved an accuracy of 0.97.

Metabolomic data: Finally, DL technologies can be used to capture the metabolic features of complex traits and predict metabolic pathways. Stamate et al. [71] relied on several state-of-the-art algorithms, such as DL, Extreme Gradient Boosting (XGBoost), and Random Forest (RF), to obtain high accuracy models to predict Alzheimer's disease (AD) versus cognitively normal (CN) with metabolites as predictors. The implemented framework captured metabolic complexity in Alzheimer's disease (AD), achieving an AUC value of 0.88 and 0.85 using the XGBoost and DL-based approach, respectively. A limitation of the study is that the authors did not include an external validation due to the size of the cohort. Baranwal et al. [72] proposed the use of the RF classifier for metabolic pathway prediction. The input of the classifier was extracted from molecular structures in SMILES format using graph convolutional networks (GCN). This approach achieved 95% accuracy in predicting metabolic pathways. The authors showed that the approach is able to estimate the relative contribution of metabolites in distinguishing pathway classes.

Explainability of Results

Managing clinical and public health decision support systems requires to face several challenges. One of the main challenges is the lack of sufficient explanation of diagnostic and therapeutic solutions and interventions. Indeed, ML and DL-based methods can be more difficult to explain and justify to human users when compared to classic analytical models [73]. Indeed, although a great predictive ability, most of these techniques output complex information networks, which makes the decision process difficult to explain (i.e., the well-known “black box problem”) [74].

Recently, several approaches were proposed to understand the behavior of ML and DL-based systems, referred to as Explainable Artificial Intelligence (XAI). XAI is an important tool in medicine and health care to ensure that the results

obtained by AI methods are sound, correct, and justifiable in order to help healthcare providers in making better decisions [73]. Thus, providing an explainability in the process of making qualified decisions can improve and justify the treatment and health intervention, and help in translating inferred knowledge into particular hypotheses that can be tested with real-life experiments.

Among several approaches, the attention mechanism is one of the most widely used in Deep Learning research in the last decade, which is a method used to analyze the models capability and highlight the most relevant information used in the prediction task. Park et al. [75] proposed a novel disease prediction method named EHR History-based prediction using Attention Network (EHAN). The approach was based on the recurrent neural network (RNN) to predict vascular disease from EHR data. They included a gradient-weighted class activation mapping (Grad-CAM) [88] to visualize the class-specific attention-weights and to provide interpretable results by explicitly weighting significant features and visualizing them. Similarly, Bruno et al. [76] proposed the use of GradCAM and Guided-GradCAM to analyze the internal processes performed by a neural network during the task of automatic medical diagnosis based on images representing the high-dimensionality of gene expression and clinical data. Hu et al. [77] proposed an attention-based deep learning framework, named DeepHINT, to provide mechanistic explanations on accurate prediction of HIV performed on the genomic sequence data. This approach was used to reveal important sequence positions from prediction results and thus provide important insights about the observed genomic. Choi et al. [78] introduced a reverse time attention model (RETAIN), which uses two attention models to detect significant clinical variables within past visits (e.g., key diagnoses). RETAIN is able to preserve interpretability, mimic the behavior of healthcare providers, and incorporate sequential information.

Other approaches are focused on analyzing the level of contribution of the input features to the output prediction to provide interpretability to ML models. Shrikumar et al. [79] presented Deep

Learning Important FeaTures (DeepLIFT), which is a backpropagation-based interpretability approach. In particular, the approach calculates the output prediction of a network on a specific input by backpropagation algorithm to discover the importance of each feature. Lundberg et al. [80] proposed SHapley Additive exPlanations (SHAP) framework which uses a combination of feature contributions and game theory for breaking down the prediction with the aim to show the impact of each input feature. The overall rating of the feature contribution to the model is then achieved by aggregating the SHAP values over observations [89].

Future Perspectives

In order to improve healthcare assistance, clinicians need to make decisions with a high degree of certainty. AI models emerged in the literature as very promising approaches to improve the quality of prognostic and to support the whole diagnostic process. However, since correct clinical decision-making can influence the prognosis and affect treatments, healthcare providers need to be able to understand and trust the predictions and recommendations made by AI-based systems. But this is rather challenging in practice, since AI models pose even questions about their (human) interpretability. Investigating methods to clearly interpret (and then trust) the result of AI algorithms (especially, based on deep learning approaches) constitutes a very important avenue of further research.

Furthermore, although AI-based systems can provide promising results, many patients do not respond to drug treatment due to the complexity of diseases, which can be characterized by different and altered information among patients with the same diagnosis [81]. For this reason, the diagnosis, as well as the treatment plan, can be prone to error. In this context, the use of Digital Twins (DTs) shows promising results to improve the precision of the treatments, for it enables a virtual representation of the human body and with its organs where the effects of drugs and treatments can be studied. The use of DTs allows us to

integrate the information relevant to pathogenesis, with the aim of predicting the outcome of specific procedures by synthesizing and tracking patient data. Moreover, DTs can provide assistance in determining the proper treatment and the best drug among the thousands possible to treat a certain disease [82]. So, it is not hard to envisage that in the future, DTs and AI-based systems will help clinicians to properly and accurately optimize the performance of treatment plans based on specific patient characteristics.

Conclusion

This chapter reported a survey of the current status of research and literature related to AI-based applications in precision medicine and health via clinical and omic data. Thanks to these techniques – such as ML and DL it is possible to find insights into diagnostics, care processes, and treatment variability, identifying disease-related biomarkers and improving patient outcome.

The ongoing research shows very promising perspectives to enhance disease prediction and prevention and paves the way to digital representations of patients (i.e., the use of *Digital Twins* in healthcare) which could be essential for tasks like defining customized treatment decisions, predicting outcomes, identifying the best drugs among all possibilities for a certain disease, virtually testing several treatments (in advance), thus reducing impact on patients and risks. In future, Digital Twins and AI-based systems could significantly help clinicians to properly optimize the performance of treatment plans, based on specific patient characteristics.

Abstract

There are three pillars of evidence-based medicine (EBM): the evidence itself (e.g., data from clinical studies), clinical expertise, and patient values. EBM is therefore a systematic approach to decision-making that integrates

these three inputs. It involves evidence production (design and conducting of clinical studies), synthesis (collecting, appraising, and combining data to answer clinical questions), implementation (e.g., through clinical practice guidelines based on these syntheses), and evaluation (monitoring the quality of care, including adherence to evidence-based recommendations).

EBM faces many challenges that artificial intelligence can help solve. It can help detect research gaps and avoid funding redundant studies. It can expedite the evidence synthesis process, which currently is slow and costly, leading to outdated and incomplete evidence being used in the decision-making processes.

Supplementary Information: The online version of this chapter (https://doi.org/10.1007/978-3-030-64573-1_43) contains supplementary material, which is available to authorized users.

AI can help engage patients and elicit values (e.g., chatbot-based decision aids) as well as provide coordinated care for patients with multimorbidities.

However, improperly implementing AI can also exacerbate problems in EBM. For instance, if AI-enabled decision support systems fail to incorporate patient values, a return to a model of medicine characterized by low patient autonomy is possible – only this time with a computer in charge.

Keywords

Evidence-based medicine · Natural language processing · Systematic reviews · Screening · Data extraction · Living systematic reviews · Shared decision-making · Clinical practice guidelines · Rapid-learning health systems

Introduction

The term “evidence-based medicine” (EBM) was coined in 1990 at the McMaster University to describe the new approach to teaching the practice of medicine. However, the roots of EBM date back much further, at least to the mid-nineteenth century. Through the 1970s and 1980s, researchers such as Archie Cochrane and David M. Eddy debunked claims of effectiveness of many interventions by pointing out that they didn’t stand a test of a randomized clinical trial. This data-driven approach, in which arguments were based on results of carefully designed experiments (evidence) rather than authority, was a revelation – in large part by showing how often the “authority” was wrong.

The emphasis on cold hard facts was foundational for EBM, and it remains its most visible facet. However, the evidence itself is only one of the three pillars of EBM, the remaining two being patient values and preferences, and clinical expertise. Therefore, evidence-based medicine is defined as “a systematic approach to clinical problem solving, which allows the integration of the best available research evidence with clinical expertise and patient values” [1]. The patient

values and preferences should be considered both on the population level, during the development of clinical practice guidelines, and on the individual level by engaging patients in shared decision-making.

Today, EBM is the widely accepted paradigm of medical practice. Other disciplines, such as management or software engineering, are also adopting evidence-based approaches. However, the implementation of EBM still faces many challenges. According to [2], the effectiveness of healthcare has reached a plateau, in which only 60% of care is in line with guidelines (evidence-based or not), 30% is some form of waste of low value, and 10% is harm. This subpar performance has persisted at least for the last three decades, which is since EBM’s formal inception.

Over the years, many criticisms of EBM have been published [3]. As EBM promotes the use of randomized controlled trials, which often have stringent enrollment criteria, it has been pointed out that the effect estimates may be biased [4]. Moreover, integrating these population-level results with personal clinical expertise and applying them to individual patients is difficult. Some doctors have seen EBM as a threat to their autonomy and their relations with patients. Another limitation that has been cited is that EBM requires thousands of (expensive) clinical trials that answer narrow questions. Finally, a common criticism was that the evidence used for decision-making is outdated, as there is a significant lag between study publication and incorporating it in recommendations.

Artificial Intelligence (AI) becomes an increasingly important tool for tackling these issues. Employing AI to expedite the evidence synthesis process not only opens new opportunities but is quickly becoming a necessity due to the exponential growth of scientific output. Researchers also hope to leverage AI’s analytical capabilities to integrate evidence from previously untapped sources, such as medical sensors, electronic health records (EHRs), and pharmacovigilance databases.

The original vision of EBM included trained clinicians who had tools and skills to incorporate the best available evidence with their internal expertise and patient’s values and preferences.

The implementation remains challenging, as this task requires integrating objective, population-level data with the personal needs of a patient. AI is a transformative force capable of solving these issues. Improperly used, it can also create problems of its own [5].

From PICO Questions to Systematic Reviews

The building blocks of EBM are clinical questions. The most common type is the PICO (Population Intervention, Comparison, Outcomes) question, which compares the effects of two interventions applied to a health problem or population as measured by a set of outcomes (e.g., mortality, average blood pressure). Other mnemonics are used for different health problems, such as PECO for environmental exposures. The first step in answering these questions is identifying all relevant evidence, preferably through the systematic review process.

Systematic Reviews (SR) offer a comprehensive and impartial synthesis of all human knowledge on a given topic, resulting from a standardized, transparent, and meticulous process. The primary goal is to maximize sensitivity (recall) – find all relevant studies. At the highest level of generality, the process can be broken down into eight steps:

1. A review protocol is created, which documents the basic assumptions which will guide researchers. Criteria for the inclusion and exclusion of evidence are defined. Both the search sources to be used (publication databases, clinical trial registries, other reviews) and the search strategy for these sources are described. The protocol also contains a description of the methodology for collecting data for review and analysis.
2. Searches are conducted in indicated databases and other sources using the strategy defined in the protocol. The search strategies are expressed as Boolean queries using database-specific syntaxes. The net is cast wide to maximize the sensitivity, so the search often returns thousands

of results. In general, databases contain only bibliographic metadata, titles, and abstracts. Full texts of papers need to be fetched separately.

3. The results are deduplicated and screened by applying inclusion and exclusion criteria to titles and abstracts. Ideally, two reviewers perform this step independently to reduce the number of false negatives (relevant documents excluded by mistake).
4. Full texts of references that pass the first screening stage are then retrieved. Reviewers screen the records by reading the whole text and applying more detailed inclusion criteria – especially concerning information not present in the abstracts.
5. Data is extracted from text, tables, and plots into a structured format (e.g., a spreadsheet), which can be used for quantitative analysis.
6. The results from individual studies are combined, preferably using meta-analysis. Increasingly, questions assess more than two interventions at the same time by leveraging network meta-analysis.
7. A critical appraisal of the evidence is carried out. The most recognized approach used at this stage is the methodology developed by the GRADE Working Group (Grading of Recommendations, Assessment, Development and Evaluations).
8. Due to the continuous progress of medical knowledge (e.g., in cardiology, there are 150 new studies published every week), updating is a critical but often neglected element of the process.

In 2014 alone, MEDLINE indexed over 8,000 systematic reviews. According to some estimates, almost 14,000 are published annually (this does not include HTA reports and internal reports created by the industry). The primary source of costs during the creation of systematic reviews is human labor. Therefore, the total cost depends on the time it takes to create a review, which varies from 6 to 24 months, subject to the scope and complexity. According to the 2013 estimate based on UK rates, a review's total cost is approximately \$100,000 (often just for one question).

These costs grow dynamically every year, which is not surprising given the increase in the number of articles published – over 800,000 papers are indexed annually by MEDLINE; nearly 30,000 clinical trials are registered with clinicaltrials.gov.

Moreover, due to the time and cost required to create or update a systematic review, they cannot keep up with the newly published studies. According to [6], 7% of reviews are outdated at the time of their publication, and after two years, about 23% of outdated reviews will contain conclusions inconsistent with the new medical knowledge.

The situation of the COVID-19 pandemic further amplified both these problems. On the one hand, it required urgent guidance, which would adapt to the changing situation. On the other, an explosion of published research of mixed quality made it difficult to find all relevant studies on time.

Living Systematic Reviews were postulated [7] to address the lack of currency of systematic reviews. These reviews are continually updated, incorporating data from new studies as soon as they appear. However, the help of AI is needed to make this process sustainable.

Automation of Systematic Reviews

As early as 2006 [8], machine learning was applied to selecting studies (screening step in the systematic review process). In 2014, a survey [9] was published that presented examples of 10 automation technologies and discussed future research. International Collaboration for the Automation of Systematic Reviews (ICASR) was established in 2015 to foster collaboration between groups working on review automation. The group holds annual meetings to discuss progress and identify the next challenges of applying AI to the automation of systematic reviews [10].

The primary goal of the automation efforts is increasing the speed and reducing the workload. A recent report describes a systematic review completed in just two weeks using automation tools [11]. However, the introduction of advanced automation tools can also modernize the process

and improve quality. Many of the tasks in the process are tedious and error prone, especially without adequate tool support. Therefore, AI can serve as an additional pair of eyes, which can catch human errors. This application becomes even more relevant in the context of rapid systematic reviews [12]. Such studies are required in situations requiring an urgent response, such as chemical spills or disease outbreaks. One example of the latter is the COVID-19 pandemic [13].

Today, 22 software tools use machine learning in some capacity [14]. They range from small utilities that help with a single aspect of the systematic review process to integrated platforms that facilitate the process from start to finish.

Development of Search Strategies

A Web search engine user is interested primarily in finding the most relevant result on the first page of the results. For this reason, the frequently optimized metric for this problem is P@5 (“precision at 5”) – the proportion of relevant hits within the top 5 results returned by the engine. Conversely, systematic reviews aim to find all relevant studies, achieving perfect recall (sensitivity). For this reason, information retrieval techniques popularized by Web search engines are not directly applicable to systematic reviews. Therefore, the searches are currently performed using manually constructed Boolean queries – they are logic sentences combined with AND, OR, and NOT operators (detecting a term’s presence or absence).

The existing tools that aid in searching can be broadly classified as:

1. Increasing sensitivity of the search by adding words to a query. This is done based on the linguistic analysis of intermediate results (e.g., SWIFT-Review, BibExcel). There are also systems supporting the selection of keywords and keywords from dictionaries such as MeSH (PubMed PubReminer, Yale MeSH Analyzer).
2. Increasing precision by replacing individual words with word combinations (e.g., TerMine) or clustering results and identifying features to exclude some hits (AntConc) safely.

3. Supporting search in many databases by translating between syntaxes (e.g., Polyglot).
4. Automatically generating a search strategy based on a set of seed articles – records identified as relevant by experts.
5. Automated tagging of study designs (RobotSearch) or PICO elements (e.g., PICO Portal, Trip Database, DOC Search) to index references.

The last type of tools come closest to fully leverage the potential of AI for addressing the problem of search. Still, they are currently unable to produce search strategies in the traditional (Boolean) form. The current search strategy format has undeniable advantages: repeatability, syntax compatibility with existing databases, and the availability of tools translating between syntaxes. Moreover, it is possible to perform them on practically all databases in the world (which is essential when searching the so-called gray literature).

Whether the advantages of AI-assisted search will outweigh the problems related to interpretability and portability remains to be seen. The latter problem could be mitigated by better data integration. The reproducibility of searches based on machine learning models' results could be addressed by careful versioning. Some projects are exploring hybrid approaches, in which Boolean search strategies are generated retrospectively to match the results coming from an AI-enhanced search.

Finally, search strategies also need to be monitored. Changes in the corpus contents (the so-called topic drift, e.g., the appearance of a new drug) may result in the current search strategy not finding all relevant documents anymore. It is another use for automation that is currently being explored. Some examples include walking the citation graph (i.e., automatically screening documents that cite studies included in the review) to check if the current search strategy captures them.

Screening

The very need for screening comes from the previous step's specifics. As discussed previously, the execution of a strategy is limited to

determining whether certain words or concepts (e.g., MeSH) appear in the document or not. For this reason, it is not possible to narrow down search results by adding the condition “and there is no word” in a safe manner (i.e., without loss of sensitivity), for fear of a situation where the word occurs in a context different than intended. For example, if one looks for randomized studies, they cannot add the term “NOT observational” to the query, as this term may appear at least in part describing previous studies.

Consequently, search results are characterized by high sensitivity (a small number of false negatives) but low precision (a large number of false positives). The task of separating the wheat from the chaff, that is, eliminating articles that do not meet the inclusion criteria, lies with those who carry out screening of abstracts and then full texts.

Machine learning helps in this process by learning from screening decisions and applying them to yet unscreened references. Typically, the documents are transformed into a review-specific representation, most commonly TF-IDF vectors. Interestingly, document representations resulting from deep learning language models (e.g., BERT) fail to outperform this simpler approach consistently. The references for which decisions are available are used as a training set. The model then predicts the score for the yet unscreened references. This score can be used to rank the records, so the reviewers look at the most promising records first.

This process is most effective when it is interactive, that is, the model retrains continuously on new decisions from users and updates the prioritized list. This scenario is a special case of active learning. The algorithm can query a user (called “teacher” or “oracle”) to label examples that could define the decision boundary. This method proved to be very effective for another text classification task that requires high sensitivity: sifting through legal evidence in eDiscovery [15]. Screening tools that employ some form of active learning include Abstrackr, RobotAnalyst, SWIFT-Active Screener, litstream, DistillerSR, EPPI-Reviewer, Laser AI, ASReview [16].

In the active learning scenario, it is also possible to estimate the current level of recall [17], so the

users can decide when to stop screening, automatically excluding all remaining documents. Such functionality is available, for example, in SWIFT-Active Screener, litstream, and DistillerSR. However, the systematic review community hasn't established a widely accepted stopping criterion yet [18]. Many groups are currently evaluating this functionality to test its robustness across a number of reviews.

Systematic review methodologies (e.g., Cochrane handbook) recommend that screening is performed independently by two researchers to reduce the possibility of human error. If the two reviewers don't agree, they either resolve the conflict in a discussion, or a third reviewer acts as an adjudicator. A common approach for the titles and abstracts screening phase is to include a reference to the next stage if at least one reviewer decides to mark it as relevant.

As many projects lack resources to perform double screening on all the references, a machine learning model can fill this gap and act as a second (or third) screener. To avoid bias, this method is more appropriate for situations where reviewers perform screening without machine assistance. Their decisions can then be split into two folds. The first one is used to train a model, which is then run on the second fold. The folds are then swapped, and the process is repeated. As a result, machine-provided scores are available for all the records and are compared against human decisions to spot any errors.

Classifiers trained on previous screening decisions are also used during review updates and literature surveillance as part of living systematic reviews. It remains to be seen how robust these classifiers are over long periods, for example, to phenomena such as the topic drift mentioned above. During training, the generalizability of these classifiers is commonly evaluated on a held-out set that was chosen randomly, without taking the publication date into account. It may be then a case that if new documents come from a different distribution (e.g., new words for novel interventions appear), the accuracy of these models will decrease. This underlines the importance of monitoring search strategies for their effectiveness.

While most titles and abstracts are available in English, it is not true for full texts. It was especially evident during the COVID-19 pandemic when many early studies were published in Chinese. AI can help here as well, thanks to the high maturity of machine translation. While the final interpretation of results during the data extraction step will probably require a human translator, automatic translation can streamline the screening process, decreasing the number of papers that need to be translated by a human.

While automation of screening has already achieved widespread adoption in several tools and has been successfully applied in many projects, some challenges remain. The major ones connect to the need to achieve almost perfect sensitivity with precision at such a level to reduce the time needed for screening significantly. This task is challenging mainly due to the wide variety of topics of systematic reviews. A serious problem is a large variance in the accuracy of the current tools, depending on the nature of the review [19]. To illustrate this problem, one can think about the levels of autonomy of vehicles. AI models are already capable of driving cars in well-known and controlled environments (e.g., highways), but extending this autonomy level to all roads is a much harder task.

This problem is exacerbated by the lack of interpretability of the results of the model. So far, there is no way to visualize the results of automatic screening, which would allow users to make sure that it is working correctly. A particular challenge here is the number of results for which clear representation (tens of thousands) must be constructed. Moreover, the larger the current NLP models become, the harder they are to understand by researchers and end-users. Without insight into how the model represents the documents and makes decisions, it is difficult for the users to determine if the model is likely to make errors on their data. To extend the self-driving cars analogy, users don't know what driving conditions can make the system fail.

Since most current systems learn only from previous decisions, they struggle with reviews that have very few positive examples (included studies). In an extreme case, systematic reviews

that aim to identify research gaps can find no studies to include. In such situations, classifiers based on previous screening decisions simply cannot be trained. A promising direction for solving this problem is the use of the new generation of few-shot models that could use the search strategy and information on inclusion and exclusion criteria in addition to screened records.

Incorporating the inclusion and exclusion criteria as an input of the model can also address indirect evidence. Sometimes, studies that directly answer the question at hand are scarce or unavailable. Therefore, researchers need to decide what level of indirectness in the population (e.g., different or mixed age groups), interventions (e.g., larger dose), or outcomes (e.g., follow-up length) is acceptable. These nuances may be difficult to capture by a classifier if labels are binary – a study is either included or excluded. Therefore, models that can represent the study text and the query (inclusion criteria) are a promising direction for the next step in screening automation.

Data Extraction

At the highest level of generality, data extraction consists of converting data in semi- or unstructured form (article text, figures, tables) into a fully structured form (data extraction form). Each systematic review can define its unique fields, which will be extracted. Cochrane recommends that 36 categories be considered when creating the data extraction form and that an additional 7 items should be included depending on the review type. This number may be higher depending on the specifics of the question and the types of studies included. For example, teams using the ROBINS-I tool to assess the risk of bias in observational studies will need far more fields than Cochrane recommend. The fields also create hierarchical relationships and appear repeatedly: for example, study arms will be extracted separately for each intervention, measurement results and units will appear separately for each outcome, etc.

This poses difficulties: a list of the fields that will appear most frequently should be drawn up

and defined in such a way (i.e., what information is to be found in them) that it meets the needs of the whole community. Still, every review may feature some fields for which the model was not trained. Therefore, while currently most of the automation tools frame this problem as named entity recognition or classification (if the list of values is controlled), it would be optimal to leverage QA models to allow open-ended (zero-shot) data extraction.

The technical challenge is not only the number of fields but also the rich structure of the annotation. It is not enough to state that a number appearing in the text indicates the size of the study group – it is also necessary to assign this value to a specific group, the description of which appears perhaps in the latter part of the text. Besides, extracted strings of text may be discontinuous and overlapping: for example, the outcomes “bleeding (total)” and “bleeding (serious)” may be represented in the text by the same word “bleeding,” while in the latter case, the determination of the severity appears only a few words later.

Moreover, while some of the data points can be easily found in the study text, others are present only in tables or need to be read from plots. Sometimes the extraction involves some level of interpretation and assessment. Was the randomization performed correctly? When the study authors report mortality in the study, does it include or exclude patients lost to follow-up? These examples may suggest that the goal of AI deployment for this problem is to semiautomate the work – augment abilities of human reviewers, so they can concentrate on critical appraisal of the studies.

To sum up, for a typical question with nine endpoints, for which 19 studies were identified, it is necessary to extract an average of 80 data points per study, that is, over 1,500 per question. If, as recommended, the work is carried out independently by two people, this translates to about 80 working hours, not including discussions about discrepancies. It is a strong argument for the need to improve this process, which at the moment is often performed using spreadsheets.

Time-consuming data extraction also hinders the inclusion of other data sources in reviews. The

European Medicines Agency committed to publishing clinical data, including Clinical Study Reports (CRS), of all products submitted for the market authorization procedure. Although the publication was temporarily suspended in 2019 (with the exception of COVID-19 medicines), this data source is expected to grow in the future. These documents, albeit challenging to process, will be an invaluable source of knowledge for groups analyzing research results.

A statistical model, which can recognize information in the text with great accuracy, is only half of the success. Similar to how it was discussed for screening, the results need to be interpretable. Otherwise, one difficult-to-navigate format (multi-page article text) will be changed to another – a list of hundreds of unordered, extracted text fragments, the correctness of which cannot be judged.

A systematic review of automation tools from 2015 [20] identified a number of systems, which were capable of identifying sentences or individual concepts with high accuracy for simple data types, such as sex or age (F1, a harmonic mean of precision and recall, is the most common metric used to compare systems). In total, of the 52 fields recommended by at least one of the leading standards, only 23 are currently extracted by at least one tool (44%). RobotReviewer, which, in its current version, claims that it can mark all 23 fields, leading the way in this respect.

In 2018, the Systematic Review Information Extraction Track was organized as part of the Text Analysis Conference to develop and evaluate automated data extraction approaches that can assist in the systematic reviews of environmental agents [21]. The track results highlighted the advantages of using deep learning models paired with contextual embeddings (ELMo). This direction has recently seen significant development in the field of Natural Language Processing with models based on the Transformer architecture [22]. It is then expected that the tools for automation of data extraction will see significant improvements. A living systematic review has been started to monitor the progress of the field [23].

New Types of Evidence

The description above concentrates on semi-automation of evidence synthesis from clinical study reports. Two questions may arise. First, why are the results reported as text, which is difficult to find and process? Second, what about other sources of data?

Making Data More FAIR

The first question relates to the idea of FAIR (Findable, Accessible, Interoperable, Reusable) data. Data that is *findable* is indexed in a searchable database using terms that allow its retrieval. Study authors would need to use medical ontologies to map their work to PICO components that systematic review authors use in their inclusion criteria. Precise and consistent coding of these complex concepts by all researchers would be required. The data would then need to be easily downloadable using well-known methods to be also *accessible*. Additionally, the data would need to use standardized formats to be *interoperable*. Finally, it would need to clearly define the semantics of fields and usage license to be *reusable*.

Multiple efforts were made, also by study funders, to improve FAIRness of clinical data. The most extensive database is [clinicaltrials.gov](#), established in 2000 and currently storing information on more than 360,000 studies. However, the vast majority of these records contain only the most basic attributes. Many of the completed trials were not updated with their results. In effect, the registries such as [clinicaltrials.gov](#) are currently used as a source of documents in the screening process, but the study reports need to be retrieved from literature databases as well. To improve the situation, a 2016 federal regulation was introduced that requires all NIH-funded trials to submit summary results information to [clinicaltrials.gov](#). There are also initiatives from evidence producers [24] and synthesizers [25] to develop more advanced formats that adhere to the FAIR principles.

The role of AI in this process is twofold. Firstly, it is a major driver of this change, as improving FAIRness of data makes it easier to feed into AI systems. Secondly, the NLP models developed for systematic review automation can be deployed to help researchers convert their results into standardized formats. One example of such applications would be a system that analyzes a submitted manuscript to prepopulate FAIR representation automatically. Additionally, such tools could be applied retroactively – with human supervision – to produce machine-readable versions of existing papers.

From the resource use perspective, the situation in which authors describe their findings in text so the other researchers can then extract them back into a tabular format seems like a waste. However, the study reports contain much more information than just the effect estimates, which sometimes needs to be read between the lines. The manuscripts are here to stay, as they are easier to write, peer-review, and read than trying to encode the equivalent information in a structured, machine-readable format. Additionally, moving to a more efficient medium for communicating research results requires a critical mass and coordination of researchers worldwide. It is challenging to enforce the standards for knowledge representation in such a distributed scenario. However, the current efforts clearly show that both researchers, funders, and publishers recognize the importance of improving the reporting standards and making data sharing easier. The COVID-19 pandemic once again has a chance to be the catalyst for improved coordination among these actors.

Other Sources of Data

The defining quality of AI is its ability to process large amounts of multidimensional data. It is capable of discovering patterns and detecting correlations between numbers of variables that far exceed human capacity. EBM can leverage these traits to tap into data that was previously impossible to process and analyze [26].

These data sources include electronic health records (EHR), medical claims databases, pharmacovigilance registries, medical sensors, social networks, patient-reported data, and omics (genomics, proteomics, etc.). Sometimes they are called “real-world data” or “real-world evidence” to underline the fact that they come from outside of controlled conditions of clinical trials. However, some find this term misleading by suggesting that other evidence is not “real” [27]. The “real-world” retrospective studies are also tested to see if they can replicate the results of randomized controlled trials on efficacy [28]. However, the most promising direction seems to be integrating different types of evidence, extending the clinical trials’ findings with additional insight from populations that are not typically included.

Firstly, AI allows transforming these streams of data into representations suitable for further analysis. For instance, NLP models are used to extract data from text entries in EHRs and automatically assign medical codes. Similarly, sentiment analysis models are applied to social media posts and patient discussion forums. Machine learning models also help tackle data quality issues by automatically detecting outliers or linking different records for the same patient.

Secondly, machine learning models are applied to connect the dots and find correlations in these vast amounts of data. For instance, studies now explore how patient-reported data can be used [29]. It is natural to expect that advanced data science methods will become indispensable as the number of data points collected increases. However, one needs to remember the old adage that “correlation is not causation.” All hypotheses generated by AI must be evaluated with the same rigor that is fundamental for evidence-based medicine.

Expanding the scope of collected data can also help close the feedback loop in the EBM ecosystem. EHR and patient-reported data can help track quality measures and progress in implementing clinical practice guidelines. Examples of measured outcomes include the rate of postoperative complications, hospital-acquired infections, or

reports on the quality of life. However, these data points cannot be interpreted as is, as the results are subject to many factors, such as patient health status. Machine learning models can help analyze many data points related to the patients to produce more accurate risk-adjusted estimates that correct for these confounders.

Moreover, integrating new evidence sources can help identify research gaps and better prioritize research funds. In general, applying evidence-based practices to the research itself has been postulated [30], for example, by the EVBRES (EVidence-Based RESearch) consortium. Meta-research (i.e., research on research) studies show that the evidence production (including planning and design of new studies) isn't done systematically and transparently. As a result, too many redundant studies are conducted – leading to a waste of time and resources. What is more critical, duplicated studies mean that patients unnecessarily receive placebo or suboptimal treatment, which leads to a waste of health and life. AI for automation of evidence synthesis can help more efficiently detect redundant studies at early stages through its methods for expediting the identification of existing evidence.

Improving Shared Decision-Making

One of the pillars of EBM is to include patient values and preferences in the process of decision-making. GRADE Evidence to Decision framework [31] explicitly considers them one of its criteria for recommendation development. This process is likely to benefit from additional information sources on patient values and behavior (e.g., adherence) as discussed above. However, these recommendations are designed to be further contextualized to the needs of an individual through a process of shared decision-making (SDM). SDM is a process in which patient and physician together take part in the decision-making and agree on treatment decisions. Health care providers facilitate the discussion by presenting possible options (along with their benefits and harms) to patients. The final decision reflects patient preferences as well as their lifestyle and religious and cultural specifics.

The United States Preventive Services Task Force (USPSTF) recommend that patients and physicians participate in shared decision-making. However, patient involvement remains low [32]. Most often, SDM is left to the initiative of the physician. Despite the efforts to standardize this process, the integration of patient values in Clinical Decision Support Systems (CDSSs) is rare [33]. In other words, the technology that is the primary channel of supplying evidence during the clinical encounter is not providing support for patient input.

This issue could be addressed by a new generation of AI-enabled decision aids that provide better user experience, such as chatbots. Additionally, CDSSs can become value-flexible [5] by using decision models and processes [33] that incorporate stakeholder inputs. They can also benefit from including more data in the process – dietary restrictions and genomics, but also experiences of other patients. The latter can be retrieved by applying AI to analyze patient forums [34].

An increasing number of patients suffer from multiple diseases. The management of multimorbid patients is challenging, as the number of risk factors increases with the number of clinical conditions. Unfortunately, few clinical practice guidelines address multimorbidity. Hence, EBM recommendations may lead to conflicts and adverse events, such as interactions between drugs. Coordinated care also involves consideration of individual values and lifestyle characteristics. Guidelines are being converted to machine-interpretable formats to allow CDSSs to reason about their overlaps [35]. Researchers are also working on AI models that can automatically solve the conflicts between the recommendations [36]. If these efforts are successful, a new generation of CDSSs can emerge that genuinely deliver on the promise of personalized medicine.

Summary

In 2007, rapid-learning health systems were proposed [37] to continuously improve the quality and cost-effectiveness by analyzing information collected “on the ground,” for example, from databases of electronic patient data. This idea

has been since implemented in a number of health systems worldwide. Today, AI enables more efficient and faster evidence synthesis, bringing the idea of living systematic reviews closer to the reality. At the same time, use of machine learning enables collecting, curating, and analyzing much larger amounts of data. Together, these innovations can be used to build deep-learning health systems [38].

Deep-learning health systems will put the current, best available evidence at the fingertips of doctors and help them make decisions by leveraging AI-enabled decision support systems. The information on the clinical outcomes would then be fed back into the system, allowing it to learn – very much the same way as deep neural networks learn through backpropagation. At the same time, value-insensitive decision support systems present a potential threat to shared decision-making, because the individual patient's values and preferences are considered only as an afterthought. Instead, AI needs to be used in a way that embraces deep medicine [39] – in the way that makes medicine human again.

Abstract

Artificial intelligence (AI) in medicine prefers rationalism. Medicine not only imposes higher requirements on the rationality of the AI but also provides a restricted domain for AI that is relatively easy to make breakthroughs. This chapter introduces research work c) in electronic health records (EHRs) carried out by the Web Intelligence Laboratory (WI Lab) under the guidance

of scientific theories such as cognitive science, complex network, and machine learning. To build the entire research work on a solid foundation of cognitive science, the authors first propose the symbolic-connectionism cognitive architecture theory and then explain representative research works such as medical corpus construction, natural language processing (NLP), and information extraction (IE) at the data tier; knowledge representation and medical ontology construction at the knowledge tier; and disease diagnosis, electronic medical record quality control, overtest detection, disease risk prediction, chronic disease management, and dermatosis diagnosis at the application tier. A rationalist

Introduction

The development of deep learning not only pushes AI to an unprecedented height but also significantly promotes its applications in the medical field [1]. However, the latter is constrained by its two inherent properties: first, since deep learning techniques originate from a neural network, its processing power is limited to classification, while most of the thinking process in medicine is reasoning [2]. Second, the principles of deep learning have not been revealed, and their effectiveness is not reliable so that their applications in medicine still face many legal and ethical issues.

To delve into AIM research, it must be acknowledged that **AIM prefers rationalism**. It is not just because medicine is a matter of life and death so that the techniques it accepts should always avoid leading patients' condition to uncontrollable or unpredictable stages, but reasoning itself is a topic of AIM. Modeling of cognitive capabilities beyond classification, such as reasoning and decision-making, must be included in the scope of research. On the other hand, medicine provides reasoning with a restricted domain, whose complexity is greatly reduced compared to the open domain.

For AIM research of WI Lab, rationalist route has dual meanings: first, mining medical knowledge to reason is the primary research topic of the laboratory. Second, researchers should base all research on solid cognition science, complex network, and machine learning theories and try to propose white-box methods.

To build work on the solid cognitive science theory, the authors first propose a symbolic-connectionism cognitive architecture. The framework, trying the possibility to unify symbolism and connectionism, which have always been an important branch of AI research [3], is derived from the latest achievements of cognitive science. The purpose of their attempt is to provide a solid foundation for all their research work, and then, under its guidance, research work that the laboratory carried out based on the principles of cognitive science, complex network, and machine learning is illuminated.

The Symbolic-Connectionism Cognitive Architecture

A cognitive architecture is a general proposal about the representations and processes that produce intelligent thought. The most influential cognitive architectures are either rule based, using if-then rules and procedures that operate on them, or connectionist, using artificial neural networks [4]. **The symbolic-connectionism cognitive architecture takes the higher-order predicate-argument structure as the basis of representations and takes systematic similarity computing as the basis of processes** [5].

The predicate-argument structure has always been the primary semantic representation of the sentence in semantics [6]. Representing objects by higher-order predicate-argument structure is one of the theoretical requirements of the structure mapping theory [7]. However, the higher-order predicate-argument structure is redefined by classifying objects into three types: attribute, entity and relation, and those formed phylogenetically from attributes to an entity, from entities to a relation, and from relations to a relation in the systematic similarity model [4]. Such phylogenetic representation brings many benefits: first, following Jeff Hawkins' comments on the characteristics of human intelligence [8], image and language have a unified semantic representation. Second, placing the attribute object in the leaf node of the tree structure of the higher-order predicate-argument structure not only conforms to the

“downgraded predicate” phenomenon that people have already discovered in semantics [6] but also satisfies the priority order of structure mapping [7]. Furthermore, it is even in line with the principle of cognitive economy [4]; that is, the attributes stored in a leaf node can be shared by all its ancestors, which is a storage scheme with the least storage redundancy. There are many other pieces of evidence that also support higher-order predicate-argument structure and similarity computing as the foundation of human cognitive architecture [9, 10]. Synthesizing these new developments in cognitive science, the authors can arrive at the following conclusion: the higher-order predicate-argument structure defined in Ref. [5] is the basic representation of cognitive architecture, and the essence of language understanding is the computation of systematic similarity (and hence is the basic process of cognitive architecture).

In the higher-order predicate-argument structure defined in Ref. [5], attributes, entities, and relations are all concepts. Marked by symbols and referring to objects, concepts are the names of the categories that exist in the human cerebral cortex. By combining multiple argument concepts, a new concept can be formed with the help of a predicate concept or without it. In the former case, the number and semantic roles of arguments are determined by the predicate concept, forming a particular fixed structure, while the latter degenerates into a whole made up of parts. Attribute, entity, and relation may correspond to three different types of neurons that send signals to one another in the cerebral cortex, and a concept is redundantly stored in a certain dendrite or axon of a neuron. In this sense, a network of tens of billions of neurons, which are composed of attribute, entity, and relation neurons, is the representative goal of cognitive architecture [11].

As the primary stage of cognition, the formations of entity concepts, that is, various attributes obtained through the sense organs aggregate to derive the category of a thing, are the processes of perception. After an entity concept forms, the entity combines with other entities and other relations to form a variety of higher-order relations. Since the human learning mechanism is a lifelong continuous learning (regardless of whether one

intends to do so), with the constant growth of human experiences, the processes of combining multiple concepts to form new concepts continue to produce, enrich, and evolve. People learn concepts through analogy, and Bayes’ rule also plays a vital role in concept learning.

The result of learning is the cerebral cortex: a complex network composed of tens of billions of interrelated neurons, which is the massiveness characteristic of the human brain. The relation structures are always updated and changed with the increase of one’s life experience; this is its dynamic nature. It also has concurrency nature, which is confirmed by the fact that people can do multitasks at the same time. Knowledge is always incomplete. Probability is the glue to express the unknown and bond the known.

The symbolic-connectionism representation can give a qualitative interpretation of the effectiveness of deep learning. In the conceptual world, a lower-order structure will always be a component of some higher-order structure so that its value may affect the higher-order structure that contains it. Such systematic characteristic happens to be captured by deep learning with deeper layers of neural network. The systematicness of conceptual space may be the internal reason for the effectiveness of deep learning. Deep learning models the process that multiple attributes form an entity. The result of deep learning training is likely to be infinitely close to a vector that quantifies the attributes necessary to determine an entity.

The knowledge graph is one of the current hot spots in AI research. The most common knowledge in the knowledge graph is head-relation-tail triplet, which is the skeleton of the higher-order predicate-argument structure. Nowadays, the knowledge graph can only be accessed as a static table, so it can only play a minimal role, such as supplementing query information. Under the framework of symbolic-connectionism representation, the tendency of changing from a small static table into massive dynamic concurrent structure drives the development of this technology. Only if the interaction effect mode between a head entity and a tail entity is revealed and a higher-order relation through which the attributes of multipieces of knowledge interact one another

is explored can the potential of the knowledge graph be fully released.

The massive dynamic concurrent probabilistic complex network of conceptual relations is the representation part of the cognitive architecture the authors want to construct, whose complexity is dramatically reduced by the medical field. Combining with the process part, the symbolic-connectionism cognitive architecture can be illustrated using the following concentric circle diagram (Fig. 1).

The authors use the concentric circle diagram to emphasize that the process of outer layer constitutes not only the specific process procedures of its own layer but also the process procedures of all its inner layers. The forming and usage of the representation of symbolic-connectionism architecture lies in the innermost core of the diagram. Systematic similarity computing, as the first usage of the representation, is the basic role of the outer more advanced thinking process. They believe that the research scope of their trying in AIM lies in the core and the first, second, and third layers of the diagram.

Based on the principles of symbolic-connectionism cognitive architecture, treating medicine as the restricted domain, the authors have started a rationalist route towards constructing the virtual brain for clinical reasoning and decision-making, as is fulfilled by (1) defining the knowledge of medicine domain, that is, determining the categorization of entity and entity relation in medicine and researching and realizing IE techniques that are capable of extracting medical entity and medical entity relation automatically from EHRs and other medical data sources; (2) determining medical knowledge representation: the higher-order predicate-argument structure requires head-relation-tail triplet as the basic knowledge representation form; (3) building a medical knowledge base that contains a mass of medical knowledge triplets – researching and realizing complement and expansion methods of the knowledge base based on Bayesian inference, analogy, systematic similarity computing, and lifelong continuous learning methods of continuous knowledge expansion; (4) building reasoning or classification engines based on the knowledge base; and

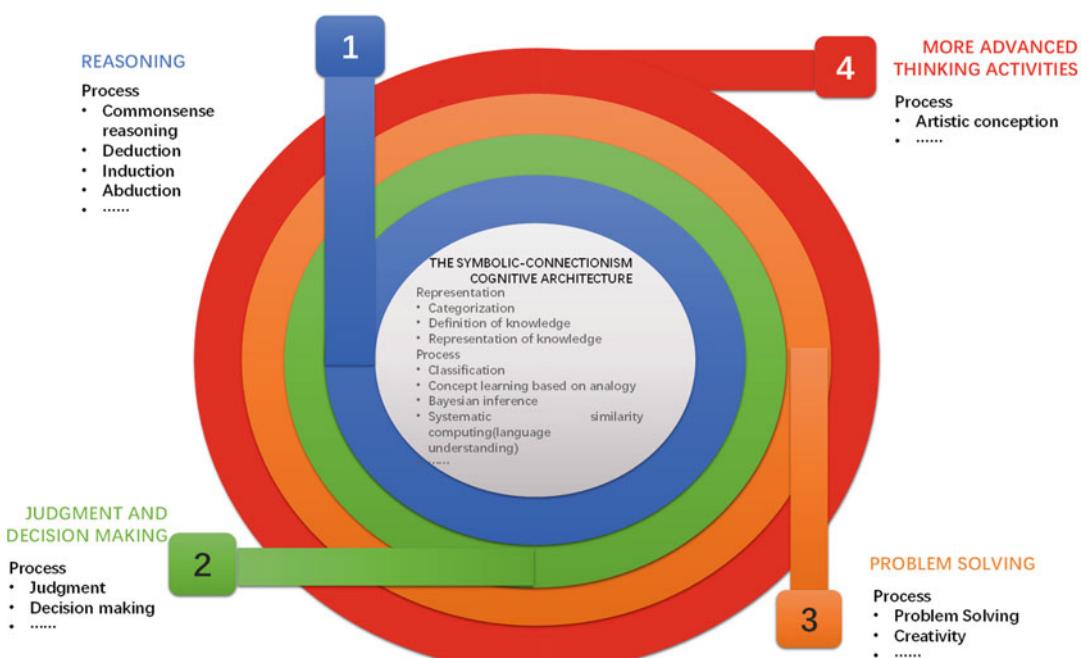

Fig. 1 Hierarchy of thinking

(5) developing applications using these reasoning or classification engines.

The Holistic Framework of Research Work of WI Lab in AIM

Data sources for AIM research include EHRs, medical professional books, medical literatures, medical-related websites, etc. These data sources are collectively called “medical big data” in this chapter. EHR mainly refers to electronic medical record (EMR) in this chapter, that is, the semi-structured digital document that consists of data elements about the medical and treatment history of the patients. EHR also include other structured or semi-structured digital documents prepared by health professionals, such as diabetes nutrition medical record (DNMR) and blood examination records (BERs). The authors use “EHR” and “EMR” interchangeably in the following text. The medical knowledge contained in these data can be divided into empirical knowledge and common sense knowledge according to whether they come from doctors’ medical practice or their education and learning. EMR is a typical data source of empirical knowledge, while the other sources contain both. Clinical text in the unstructured parts of

these data sources shows both generic language features and sublanguage features. Sublanguage features, which are major language features in EMR, denote the language features that are only existent in the unstructured text of the document of some specific types, such as EMR. For example, clinical text in the EMR in Chinese (CEMR) contains such sublanguage features as a number of medical terms, shorthand words and special symbols, templated narrative, occasional ungrammatical expressions, long sentence narrative, etc. Special attention must be paid to deal with these features in NLP or IE tasks.

As shown in Fig. 2, the holistic framework of research and development (R&D) work in AIM can be divided into data tier, knowledge tier, and application tier. Medical entities and entity relations are defined, annotated, categorized, and extracted in the data tier. These basic elements of symbolic-connectionism cognitive architecture are prepared for knowledge tier, where medical knowledge representation and medical ontology construction are implemented. A mass of head-relation-tail triplets, which is the main medical knowledge representation form currently, constitutes medical ontology. These pieces of knowledge are employed by applications in the application tier for classification, reasoning, or decision-making tasks.

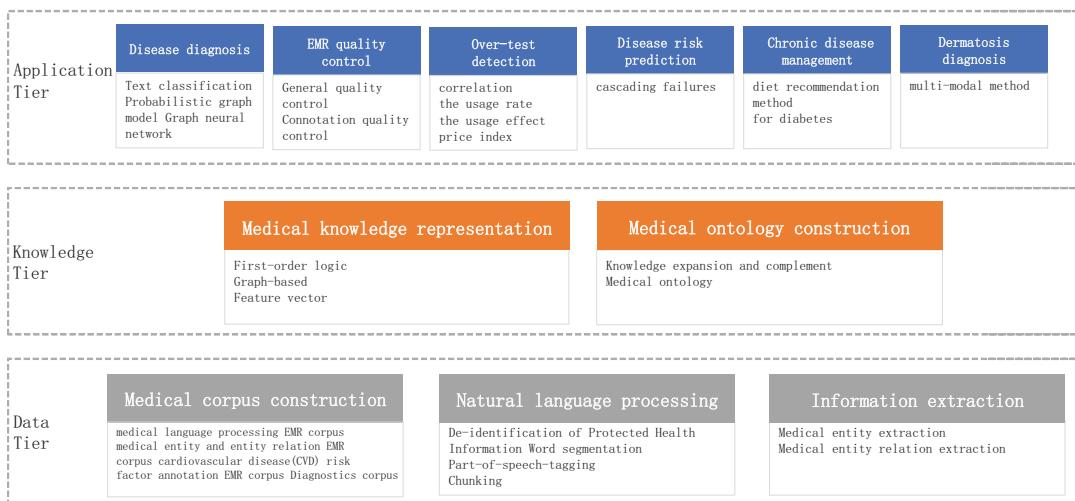

Fig. 2 The holistic framework of research work of WI Lab

Data Tier

Mining the fundamental elements of medical knowledge from medical big data is accomplished in the data tier, as is carried out by three tasks. In the medical corpus construction task, categories of medical entities and medical entity relations must be defined and annotation guidelines and tools must be presented, then medical corpora can be constructed. In NLP task, protected health information (PHI) should be removed firstly, then word segmentation, part-of-speech (POS) tagging, and chunking should be done for the feature extraction of IE. In IE task, medical entities and relations are extracted for knowledge representation. Although IE is usually regarded as a component of NLP, the authors list it separately to highlight its nucleus position in knowledge acquisition.

Four medical corpora, together with their knowledge definitions and annotation guidelines, were constructed by medical professionals (<https://github.com/WILAB-HIT/Resources/>). They are medical language processing EMR corpus [12], for training NLP models for IE; medical entity and entity relation EMR corpus [13, 14], for training IE models for EMR; cardiovascular disease (CVD) risk factor annotation EMR corpus [15], for training CVD risk factor extraction models for EMR; and diagnostics [16] corpus, for training IE models for medical books. The annotation adopts an iterative process to ensure annotative consistency, as shown in stage 2 in Fig. 3.

A risk factor is a pattern of behavior or physical characteristic of a group of individuals that increases the probability of the future occurrence of one or more diseases in that group relative to comparable groups without or with different levels of the behavior or characteristic [17]. Risk factors of CVD, including specific signs such as hypertension and hyperglycemia/diabetes, unhealthy lifestyles such as smoking and alcohol abuse, and other factors such as age and family history, can have prominent effects on the progress of CVD. CVD risk factors have attributes such as indicators, temporal attributes, and assertions that were explicitly or implicitly contained in the records. Besides CVD risk factor itself, these attributions should also be mined. We have built the first annotated corpus of CVD risk factors in

CEMRs, the guideline of CVD risk factor annotations, and the associated IE method to extract them [18]. The risk factor status of a patient can be employed for a personalized modeling of diet recommendation in chronic disease management.

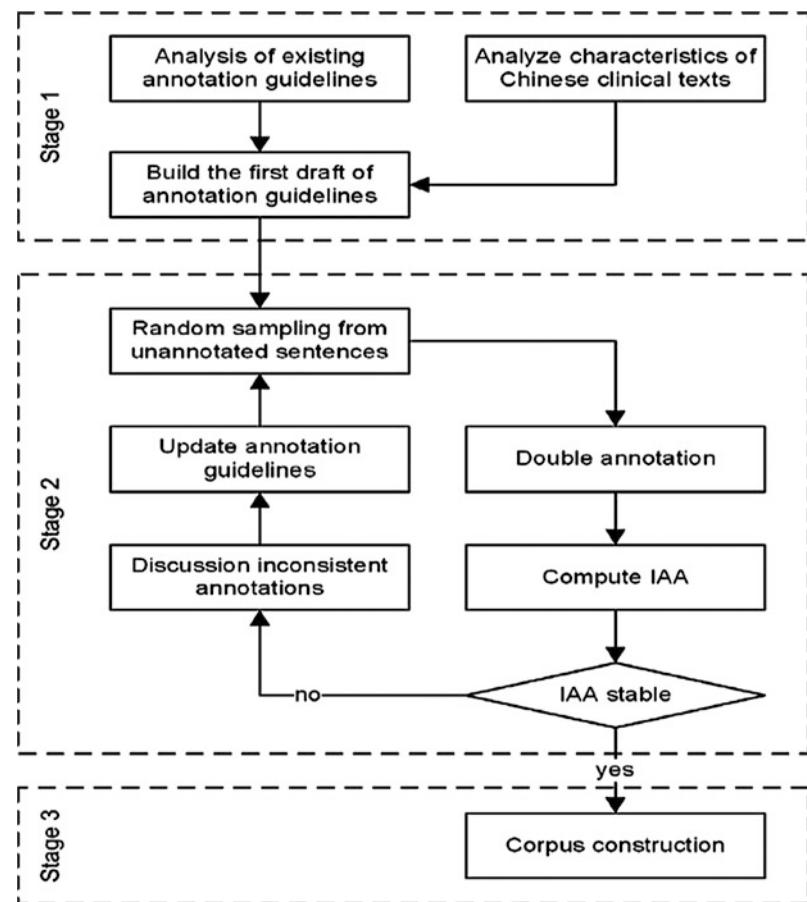

Knowledge Tier

People have tried a variety of methods to define medical knowledge in the diagnosis system. The form of medical knowledge representation is usually inseparable from the diagnosis model. Early attempts include rule based and model based. In recent years, with the development of medical big data, medical knowledge representation has also evolved from the formalization of medical experts' knowledge to automatic acquisition from medical big data. The research of medical knowledge representation is also gradually focused on three aspects: (1) first-order logic based, degenerated from rule-based approaches; (2) graph based, developed from the model-based diagnostic reasoning model; and (3) feature vector based, developed from deep learning. The advantages of first-order logic and its associate reasoning engine are flexibility and powerful expressive ability, but dependence on human labor and low efficiency of reasoning constrain its extensive use. Graph-based representation is a compromise between acquisition difficulty and reasoning efficiency. Feature vector is usually trained by deep learning models and used in classification tasks.

Graph-based representation has been adopted in the researchers' disease diagnosis model in the medical knowledge base that organizes a massive scale of medical triplets. The researchers have also tried the hybrid form of these knowledge representations [19]. And first attempt on the completion and expansion of the medical knowledge base is done [20].

To get close to the symbolic-connectionism cognitive architecture, they have begun their medical ontology construction work, as is carried out, first, by proposing a universal ontology guideline integrating empirical knowledge with common sense knowledge. According to the semantic scheme of the Unified Medical Language System (UMLS) [21] and the annotation guidance of 2010 i2b2/VA

Fig. 3 Iterative annotation method for guideline development and corpus construction. IAA, interannotator agreement

Challenges [22], integrating all the guidelines the researchers put forward before, they design their ontology guideline (<https://github.com/yang1992samantha/MOCG/>). As shown in Fig. 4, they finally define nine kinds of the medical concept – disease, symptom, test, drug, operation, germ, body, department, and health risk factor – and 19 kinds of their relations and attributes. Second is by distinguishing concept and instance. An instance in the medical field refers to a distinguishable and independent medical entity that is in clinical practice. Specifically, entities extracted from the EMRs are called instances. A concept refers to a collection of instances with the same characteristics. The concept of the medical field refers to a collection of summarization and generalization of examples in the medical field with generalization capabilities. The entities extracted from books are called concepts. Concepts are organized in a hierarchical way by a

“subclassOf” relationship, and instance should also belong to the corresponding concept connected by “instanceOf.” Third is by introducing more and more ontological elements into the medical knowledge base. The main feature that distinguishes a medical ontology from a medical knowledge base is the axiom system in which all concepts are defined by formal (description) logic so that any relationship between any two concepts can be derived out by a reasoning engine. The researchers have begun their attempts in this direction. Their current medical ontology contains 82,556 entities and 530,000 pieces of knowledge.

Application Tier

As shown in Fig. 2, the authors have conducted preliminary explorations in six medical applications. Among them, by exploring disease

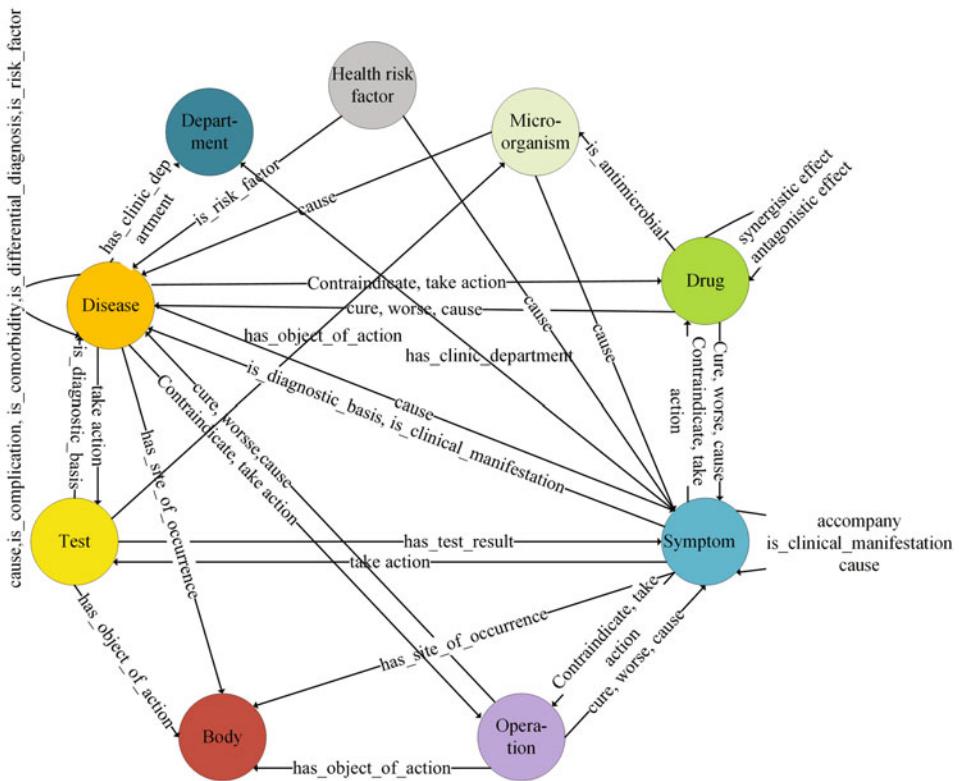

Fig. 4 Medical concepts and their relationship

diagnosis, EMR quality control, disease risk prediction, and dermatosis diagnosis, they study reasoning from different perspectives such as probabilistic reasoning model, application, prediction, and multimodal machine learning, and treat prediction as reasoning on time series data; by exploring overt test detection, they study medical-related decision-making; by exploring diet recommendation methods for diabetes, they study knowledge-based personalized recommendation in chronic disease management.

Disease Diagnosis

Diagnosis is a process in which medical professionals determine the disease from the patient's symptoms or signs. Since clinical reasoning runs through the diagnosis activities, the modeling of clinical reasoning is the most crucial topic of AIM. Nowadays, people's research interests are gradually focused on using classification or reasoning models based on medical knowledge automatically obtained from medical big data.

Classification is one of the most widely researched topics in disease diagnosis. Decision tree, support vector machine, and Bayesian network are designed with a distinct methodology for solving the diagnostic problem, respectively. For improving the accuracy of disease diagnosis, the existing studies have mainly focused on extracting more effective features and exploring more comprehensive pretraining methods while ignoring the importance of domain knowledge.

The probabilistic graphical model is an appealing research direction for reasoning. Many researchers have applied it to disease diagnosis in recent years. In this type of model, the basic knowledge is usually triplets, which can also be regarded as simple first-order logic rules. These pieces of knowledge are then incorporated into a probabilistic reasoning framework such as Markov network, which usually contains a complete theoretical training and probabilistic reasoning process. When these pieces of knowledges are medical knowledge extracted from EMR, a

probabilistic graph model for disease diagnosis is born [23].

The graph neural network is a newly appeared model that shows effectiveness in disease diagnosis. By vectorizing nodes of the knowledge graph, it enriches the interconnectedness between knowledge nodes and provides more ways to reasoning, thus can often bring out more precise disease diagnosis results.

The authors propose an improved probabilistic graph model as a disease diagnosis model and also try graph neural network method to improve the accuracy of disease diagnosis further.

EMR Quality Control

The conventional method of EMR quality control is labor intensive and resource consuming. Using AI technology to raise the effectiveness of quality control has received widespread attention. Beyond some systems, which only pay attention to general quality control like time sensitivity, consistency, and completeness, the researchers' quality control system focus on a more challenging aspect, connotation quality control, that is, the rationality of disease diagnosis.

Under the guidance of “Diagnostics” [16], the researchers summarize three problems to check whether the disease diagnosis in the EMR is reasonable: (1) whether the International Classification of Diseases (ICD-10) codes corresponds to their name – the guidance specifies that each diagnosis must assign its ICD code; (2) whether the principal diagnosis is reasonable – for each EMR, it often contains more than one diagnosis; however, only one or two diagnoses are the reasons for this admission, and they constitute the principal diagnosis; (3) whether the disease diagnosis is complete – each EMR often contains more than one diagnosis. Thus, the researchers need to supplement them according to the content of EMRs.

To solve the above three problems, they construct an EMR quality control system. For each EMR, they first extract all symptom entities and then send them to a disease diagnosis module [23] to achieve a diagnostic list. The diagnostic list contains the top ten diseases and their possibilities. To solve the first problem, they use rules to check whether each disease is assigned to its right ICD code; if not, they return its standard ICD

code. To solve the second problem, they compare the principal diagnosis given by the EMR and the top one diagnosis in the diagnostic list. If they are not consistent, the researchers return their top one diagnosis and let doctors recheck their diagnosis. To solve the last problem, the researchers supplement all diagnosis in the diagnostic list whose possibilities are higher than a predetermined threshold to the EMR diagnosis. Their system now can check the rationality of 20 kinds of respiratory diseases.

Overtesting Detection

Overtesting has become a common phenomenon in the process of reaching a diagnosis, despite the fact that it can cause severe harm to the resources of medical institutions as well as patients' property and health. The authors propose a clinical decision-making framework to determine the appropriateness of diagnostic tests recommended by physicians automatically [24].

Under the guidance of physicians, they first analyze the clinical thinking process and design the unified implicit evaluation criteria to subjectively determine the existence of overttesting for different diseases. And then the implicit evaluation criteria can be modeled by four evaluation strategies, which are the correlation between complaint symptoms and diagnostic tests, the usage rate of diagnostic test t under the condition of related diagnosis, the usage effect of diagnostic test t under the condition of related diagnosis, and the price index. Finally, the four evaluation strategies are carried out through a clinical decision-making framework based on statistical methods integrating a multi-label classifier with a binary classifier.

Disease Risk Prediction

Different from the traditional risk prediction based on time series analysis, the object of disease risk prediction is the occurrence of disease, and disease, especially chronic disease, is often a systemic functional failure rather than a local accidental event. Therefore, the systemic risk prediction method should be used to predict the occurrence of disease, that is, constructing the dynamic evolutionary model of multigranularity and multifactor large-scale complex network to predict the systemic risk of disease.

In progressively serious events, cascading behaviors are considered to be the core driver of risk outbreak, which means failure in one single component would consequently lead to the collapse of the entire system. Inspired by the universal cascading phenomenon, the human body system can also be regarded as a complicated physiological network, in which the interactions between physiological functions maintain the balance of the system. Once one part or function of the physiological network fails, the steady state will be broken, leading to a more significant and more dangerous failure, or even the collapse of the entire network until death, such as complications, infections, immune disorders, etc. To model the physiological domino effect, cascading failures may be a feasible theoretical basis to simulate the deterioration of patients' conditions dynamically.

Chronic Disease Management

Most people will experience two or more chronic diseases during their lives. Nutrition management is an important part of chronic disease self-management. The authors begin their attempt in AI-guided chronic disease management from diet recommendation for diabetes based on nutrition medical records.

For the controlling of CVD risk factors, diabetes is an obstacle that cannot be gotten around. Diabetes, one of the CVD risk factors, is more related to lifestyles, especially diets, than others. The famous Daqing Impaired Glucose Tolerance (IGT) and Diabetes Study proved that positive dietary intervention plays a positive role in the intervention of diabetes and even cardiovascular disease. Diet recommendation is an important way of diet intervention, which can provide patients with a diet plan, closely influence people's daily decisions, and produce long-term significance to health. It is a key technique in the transformation from disease-centered treatment mode to prevention-centered healthcare mode. The authors reviewed the current health recommender system (HRS) research and show that HRSs provide a tool for diet management with health concerns [25].

Diabetes nutrition medical record (DNMR) is a kind of medical record that note documents

medical activities such as inquiry, examination, and treatment of diabetic patients conducted by nutrition doctors. Structurally, DNMR consists of five major components: general status, disease status, laboratory examination, past dietary history, and dietary treatment plan. According to the characteristic of DNMR, as there exists minimum operable quantity (MOQ), which means the minimum quantity of food that can be operated by patients in daily life, the diet recommendation to a patient can be transferred into a multilabel classification problem. Including age, gender, weight, and risk factors, 38 features selected from the DNMR were applied to a random forest-based model. Experiment on 1258 records shows that the method has 0.8448 accuracy of diet recommendation for diabetes. This is the first study that concerns diet recommendation for diabetes based on DNMR. The diet recommendation system has been put into operation in the Nutrition Department of the First Affiliated Hospital of Harbin Medical University. While improving the accuracy of the doctor's treatment, the doctor's treatment time for each patient is reduced from about 15 min to about 5 min (Table 1).

Dermatosis Diagnosis

The difficulties of AIM are not only in research, development, and application; the most challenging point is to become a living AIM application, which means it must become a new positive factor in the ecological environment to which the application field belongs and permanently bring positive effects to all participants in the ecological environment. Taking AI disease diagnosis as an

Table 1 The minimum operable quantity of seven types of food in DNMR

Food type	Minimum value of doctor's advice	Maximum value of doctor's advice	Minimum operable quantity
Staple food	150	375	25
Milk	0	500	50
Egg	0	120	60
Meat, fish, and shrimp	0	100	25
Bean product	0	100	25
Vegetable	50	750	50
Oil	10	35	5

example, a live AI disease diagnosis application must free doctors from tedious daily tasks and increase the reputation and the number of patients of doctors; it must be able to safely and accurately determine patients' diseases and give correct treatment suggestions; it can also bring business opportunities to related industries such as pharmaceuticals and cosmetics and bring benefits and continuous development power to AI application developers. If one of these conditions is not met, it will bring resistance to its own development, which will gradually lose its vitality. Therefore, the application point must be carefully selected to make AI disease diagnosis a living application.

Dermatoses diagnosis is an option with these conditions. Many dermatoses, such as acne, are high-incidence and non-fatal disease. High-precision diagnosis can be achieved only with a photo captured by a mobile phone so that telemedicine on acne is both possible and convenient to accommodate diagnosis AI. At the same time, the multimodal models which combine disease images and texts to make diagnosis is a hot spot of AI researches. The authors have begun their research on acne diagnosis with the support of the department of dermatology of Heilongjiang provincial hospital.

Selected Research

Corpus Construction

To build a comprehensive corpus covering syntactic and semantic annotations of Chinese clinical texts, He et al. [14] propose several annotation guidelines and an annotation method for Chinese clinical texts, providing a foundation for the further study of applying NLP techniques to Chinese texts in the clinical domain. Figure 5 shows the framework of corpus construction on clinical text.

In this work, a comprehensive corpus was built containing annotations of POS tags, syntactic tags, entities, assertions, and relations. Consequently, an IE system was developed based on the annotated corpus. The syntactic corpus consists of 138 Chinese clinical documents with 47,426 tokens and 2612 full parsing trees, while the semantic corpus includes

992 documents that annotated 39,511 entities with their assertions and 7693 relations. IAA evaluation shows that this corpus is of good quality and the system modules are effective. Importantly, it makes a considerable contribution to NLP research into Chinese texts in the medical domain. This corpus is the first comprehensive annotated corpus of Chinese clinical texts, laying a solid foundation for future research.

Information Extraction

He et al. [26] propose a convolutional neural network (CNN)-based architecture with a multi-pooling operation for medical relation classification on clinical records and explore training objective with a relation-type constraint. The model architecture is shown in Fig. 6. Experiments using the 2010 i2b2/VA relation corpus demonstrate these models, which do not depend on any external features, outperform previous single-model methods, and are competitive with the existing ensemble-based method.

He et al. [27] also propose a unified architecture that exploits the advantages of CNN and recurrent neural network (RNN) simultaneously, to identify medical relations in clinical records.

Knowledge Expansion

To enrich and improve the scale of medical knowledge base, Xie et al. [20] propose an incremental expansion framework, which is applied to construct an expandable medical knowledge graph (MKG) in two aspects: (1) integrating external knowledge, which is extracted from the medical information website, and (2) mining potential knowledge, which is hidden in the existing MKG. Figure 7 illustrates the entire expansion framework. First, the authors premise that the integrating procedure and mining procedure are independent. Once a professional or widely recognized external resource is found, the integrating request will be sent to the processing flow. Then a series of knowledge preprocesses are performed, including knowledge extraction from external resource, normalization of medical entities,

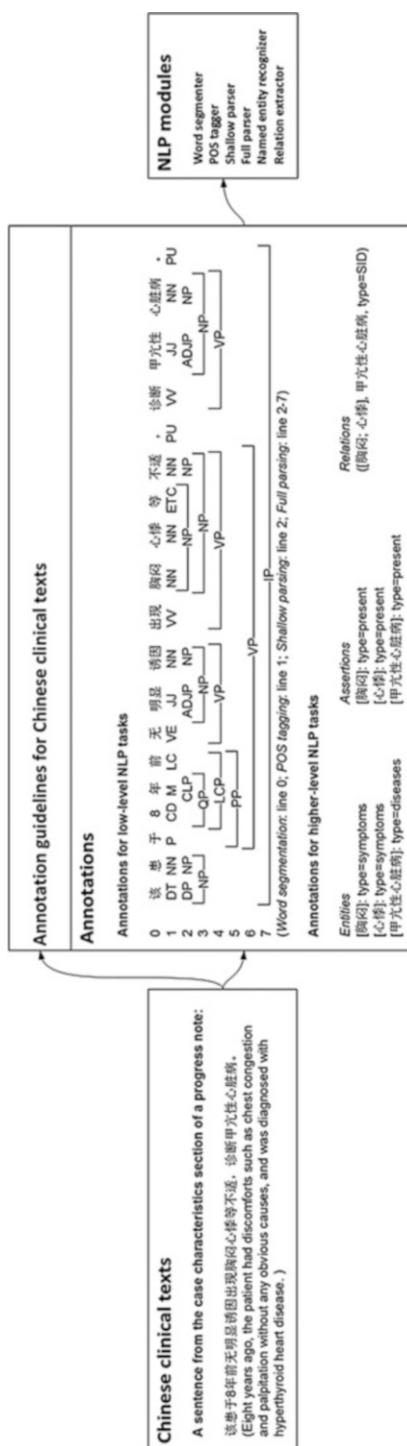

Fig. 5 The framework of corpus construction on clinical text

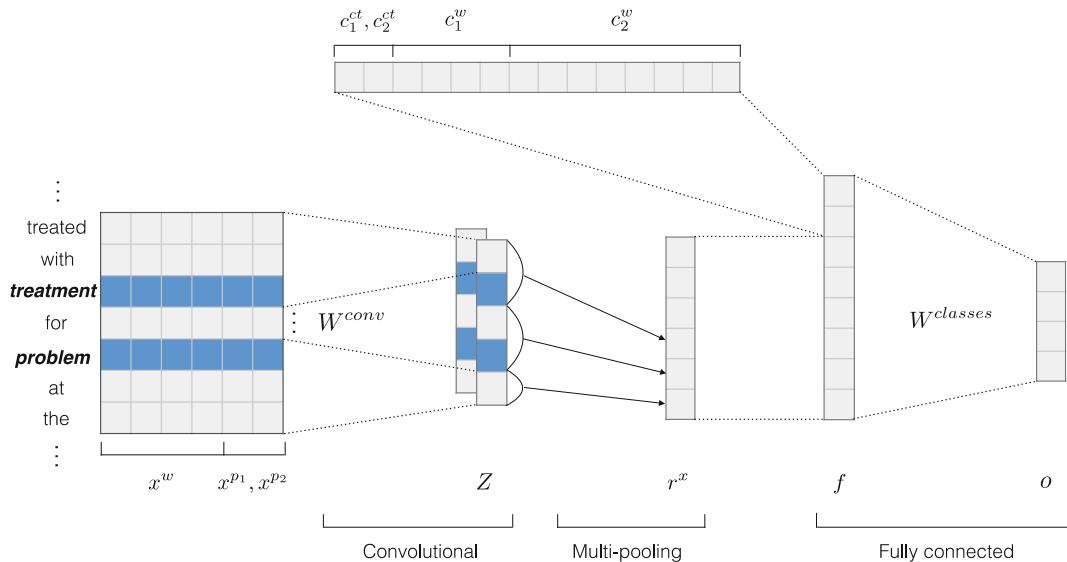

Fig. 6 Architecture of CNN-based model for medical relation classification. Concept contents in the sample sentence “she was treated with [steroids]_{treatment} for [this

swelling]_{medical problem} at the outside hospital, and these were continued” are replaced by their concept types

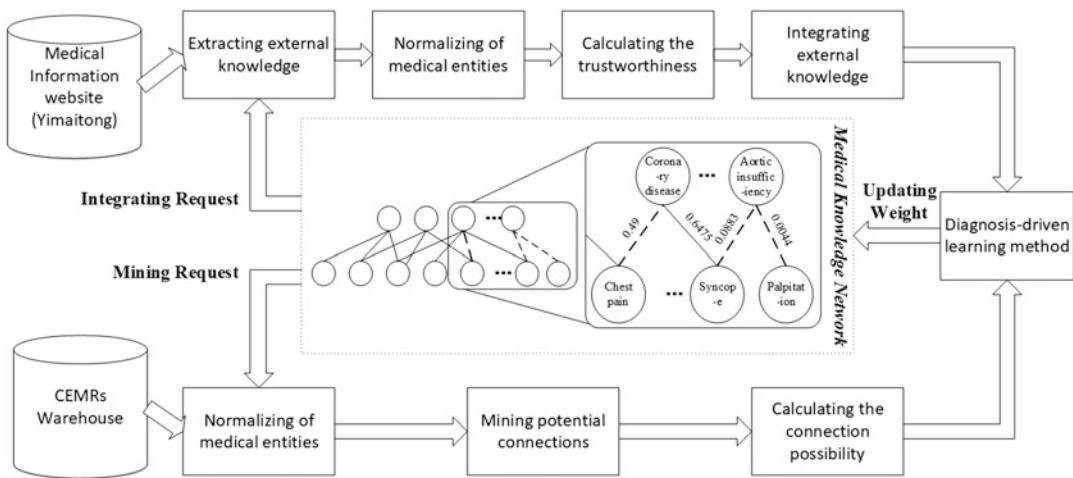

Fig. 7 Workflow of MKN expansion. Solid lines are knowledge from original-MKN, and dotted lines are new expansion knowledge

confidence evaluation of all knowledge, and integration of external knowledge with the Original-MKG.

Integrating External Knowledge

This procedure aims to integrate the disease and symptom entities and their “indication”

relationships with the Original-MKG. When the MKG sends an integrating request, the procedure is performed by four steps: first, by extracting external knowledge. External knowledge is the common sense knowledge that should be distinguished from the empirical knowledge initially. The second step is normalization of medical

entities. Repetitive knowledge will make the network redundant and make diagnostic results biased to the disease which contains more knowledge. Using controlled terminologies (e.g., UMLS) is a regular method to find a medical synonym [28]. All disease entities can be mapped into an ICD-10 code. Considering that most medical synonyms have similar names, the similarity function based on edit distance could be used to normalize these entities [29]. For symptom entities, a symptom vocabulary dictionary is constructed, where symptom concepts with similar semantics share the same code. The third is calculating trustworthiness. To verify the trustworthiness of each candidate's external knowledge, guidelines are collected from the Internet, which have been published over the past ten years and covered most kinds of diseases in different departments. The correlation of the symptom entity S_i and the disease entity D_j is considered as an authenticity index for each external knowledge \mathcal{T}_{ij} . Vector $\mathbf{V}(S_i)$ is constructed to express the state of S_i in clinical guideline set $G = (g_1, g_2, \dots, g_n)$. Disease vector $\mathbf{V}(D_j)$ is formed in the same way. For a candidate knowledge \mathcal{T}_{ij} , the probability $P(S_i, D_j)$ of this knowledge can be calculated by cosine similarity. The fourth step is integrating external knowledge with Original-MKN. The value of $w^*(\mathcal{T}_{ij})$ for knowledge item (S_i, D_j) equals its weight in the Original-MKG, and $w^*(\mathcal{T}_{ij}) = 0$ if \mathcal{T}_{ij} is not contained. Then the external knowledge is fused with the original knowledge to get a candidate weight $w(\mathcal{T}_{ij})$ for each of them by adopting a simple noisy-OR gate:

$$w(\mathcal{T}_{ij}) = 1 - \prod_{k=1}^n \overline{MS_k} = 1 - (1 - P(S_i, D_j))(1 - w^*(\mathcal{T}_{ij})) \quad (1)$$

A knowledge item is considered to be completely impossible only if it had never appeared in any medical resource.

Mining Potential Knowledge

The mining procedure aims to find more potential relationships between existing entities. To evaluate the confidence of each pair of unconnected entities, it is performed by three steps: (1) normalizing the disease and symptom entities, (2) mining potential

connections, and (3) calculating the connection possibility as the candidate weight. The normalization of entities is same as the previous procedure. A detailed description of step 2 and step 3 are given in the following:

1. Mining potential connections: if there is a strong correlation between the neighbors of a disease node and the neighbors of a symptom node, it implies that a potential knowledge exists between two nodes. It is assumed that the symptom might indicate not only the directly linked disease but also the indirectly linked disease, if these two diseases have many similar connected symptoms. For a valid connection $S_i - D_j$, if a path $S_i \xrightarrow{\text{indication}} D_i \xrightarrow{\text{indication}} S_j \dots \xrightarrow{\text{indication}} D_j$ exists, $S_i \xrightarrow{\text{indication}} D_j$ might be connected directly. The indication strength decreases with the path length increasing. Long-distance links indicate weaker indication relationships. Thus, the reasoning path will be confined within a finite-hop neighborhood.
2. Calculating the connection possibility: to obtain the confidence of potential knowledge, the Katz index is used to calculate their connection possibilities [30]. For each potential connection \mathcal{T}_{ij} , the candidate weight is calculated by finding all possible paths between S_i and D_j and summarizing them with damping factor ϵ :

$$w(\mathcal{T}_{ij}) = \sum_{\text{path}_i \in \text{path}} \sum_D \epsilon^d w(\mathcal{T}_{\text{path}_i}^d) \quad (2)$$

where D is the path length and $w(\mathcal{T}_{\text{path}_i}^d)$ is the d -th linking edge weight in the path $_i$. For a potential knowledge, if it has more linking paths and larger weights of linking edges, the indication relationship is stronger.

Clinical Reasoning Model

Knowledge Representation

Some knowledge representation approaches adopt deep neural network to train a language model and obtain indirectly embedding knowledge, of which the entity and relation are

embedded into continuous vector spaces and capture rich syntactic and semantic features from linguistic phrases. Jiang et al. [19] propose a recursive neural knowledge network (RNKN), which transforms medical knowledge based on first-order logic in a hierarchical tree neural network. The model architecture is shown in Fig. 8. Different from some unsupervised embedding methods, RNKN is driven by a disease diagnosis task, and the knowledge vectors are continuously optimized through a large number of EMRs to achieve best performance during disease diagnosis. By reducing the dimensionality of these trained vectors from 150 to 2 using the t-distributed stochastic neighbor embedding (t-SNE) technique, it reveals the interpretation of knowledge embeddings that medical terms with associated semantics are closer together on the scatter plot.

Disease Diagnosis

Zhao et al. [31] give a formal definition of the medical knowledge network (MKN) model. A bipartite graph is constructed by EMRs and denoted by $G = (X, Y)$. If two entities co-occur in the same record, it indicates that there is a specific association between them. Then the weights of all edges are initialized as 0 and depend on modifiers of two entities in EMRs. If their modifiers are both “present,” the weight will be

increased to 1. If the modifier of one of them is “absent,” it indicates a negative correlation, and the weight is decreased to 0.5. The construction of the MKN is finished until all the training records have been added.

Recall that given the status of some entities X , the goal is to infer the status of the unknown entities Y . This problem can be included in a probabilistic inference framework, where the core problem is to calculate the conditional probability $P(Y|X)$. In order to make MKN fit into the inference framework, a Markov random field (MRF) is applied to treat nodes as random variables. These variables can take real values from 0 to 1 and indicate the degree of these entities on the given patient. The entities with positive assertion are denoted as 1, while those that do not appear or with negative assertion is set to 0. The core part of MRF is to define an energy function f (y, x) and model the signs of each $x \in X$ and each $y \in Y$. When $f(y, x) < 0$, the model prefers that y and x take the same sign, which means that a patient with status x as positive are likely to have status y as positive. Otherwise, it implies that y and x are more likely to have different signs.

There are two different strategies to define $f(y, x)$. The first is to assign a real-valued learnable parameter to each (y, x) pair. The second is to assign a dense vector representation for each nod, and

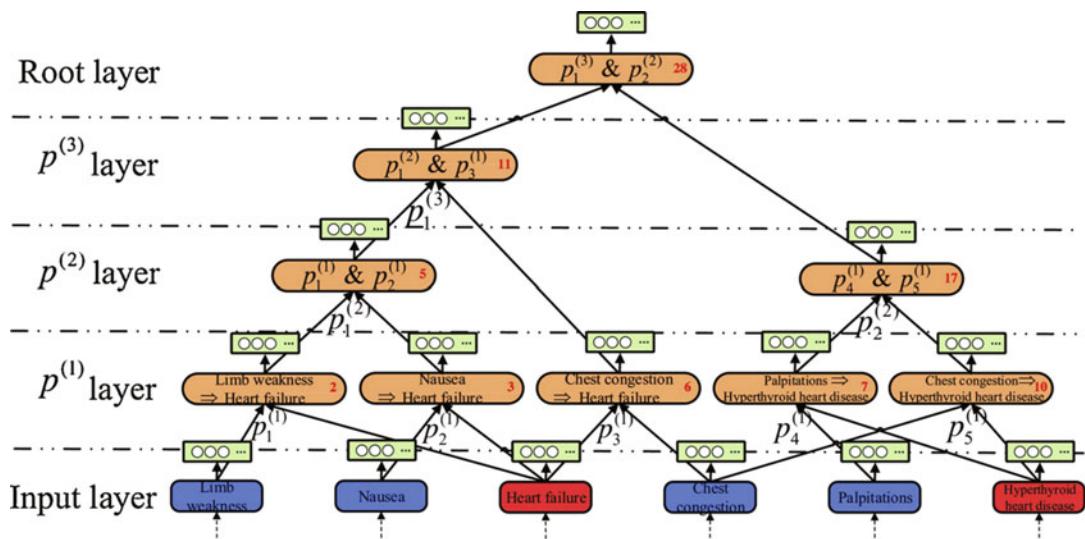

Fig. 8 Huffman tree of the RNKN, representing deep first-order logic knowledge for multidisease diagnosis

calculate the energy function of (y, x) by bilinear transformation or translating distance. Notice that in the first strategy, the parameters are assigned to edges, but in the second strategy node representation is parameterized, which reduces the parameter set from $\Theta(|Y| \times |X|)$ to $\Theta(|Y| + |X|)$. An entire framework is built to learn the parameters from the data and make the inference accordingly.

Jiang et al. [23] propose another multivariate inference methodology that combines a weighted knowledge graph with probabilistic models. By incorporating a Boltzmann machine into the potential function of the Markov network, a joint probability distribution of clinical variables is defined as the following expression:

$$P(X = x) = \frac{1}{Z} \exp \left(\sum_{\substack{i \\ r_i \in R}} \omega_i x_{r_i}^s x_{r_i}^d + \sum_j \left(\sum_{z=1}^n m_z e^{-\sigma} \right) \cdot x_j \right) \quad (3)$$

This joint probability distribution rewrites the potential function of Markov network $\phi(r) = \exp(-\varepsilon(r))$ with a parametric energy function $\varepsilon(r) = \varepsilon(x_d, x_s) = -\omega_{d,s} x_d x_s$, where the medical triplet r consists of a disease entity d and a symptom entity s and x reflects the severity of each entity. In addition, the Gaussian potential function (GPF) is employed to evaluate the potential energy of each node, which is expressed as

$$\varepsilon(x_j) = u_j x_j = \left(\sum_{z=1}^n m_z e^{-\sigma} \right) \cdot x_j \quad (4)$$

where σ represents the distance coefficient between entity j and its neighbor z in knowledge graph and m_z is the quality of neighbor z . According to the definition of joint distribution, two common generic clinical questions are answered in this work: “What is the probability that rule r_1 holds given rule r_2 ?” and “What is the probability of disease d_1 given the symptom vector S ?” In a multidisease

diagnosis task, the experimental results on the actual EMRs and BERs demonstrate that the proposed inference framework significantly outperforms the general machine learning baseline methods such as logistic regression and neural networks. It further proves the effectiveness and promise of the novel knowledge-driven clinical reasoning.

Disease Risk Prediction

The first issue is how to establish an expressive physiological network. In clinical medicine, the abnormalities in vital signs are the internal cause of disease. Meanwhile, disease is the external manifestation of abnormal signs. When a disease emerges, it indicates that some related signs are falling in borderline or abnormal states. Sequentially, if the severity of these abnormal signs exceeds tolerance thresholds of other diseases, it will raise the failure risk of more physiological functions, even cause a chain reaction. Here, the physiological system is formalized as a bipartite network $\mathcal{G} = (\varepsilon_e, \varepsilon_i, \mathcal{R}, \mathcal{W})$, where ε_e and ε_i are the set of disease nodes in subnetwork \mathcal{G}_e and the set of sign nodes (e.g., laboratory examination items) in subnetwork \mathcal{G}_i , respectively. \mathcal{R} is the set of interaction edges between two subnetworks, and \mathcal{W} represents the weight set of triplets. For generality, network X means either subnetwork \mathcal{G}_e or \mathcal{G}_i . If the number of surviving neighbor nodes $k_{s,i}$ that are connected to node i by interaction edges remains greater or equal to tolerance threshold k_i^* , node i with k_i -degree remains functional and transforms its state S_i to 1; otherwise, $S_i = 0$. The tolerance coefficient $r_i(k_{s,i}, k_i)$ can be a step function as

$$r_i(k_{s,i}, k_i) = \begin{cases} 0 & k_{s,i} < k_i^* \\ 1 & k_{s,i} \geq k_i^* \end{cases} \quad (5)$$

a linear function as $r_i(k_{s,i}, k_i) = k_{s,i}/k_i$, or a nonlinear polynomial function as $r_i(k_{s,i}, k_i) = 3(k_{s,i}/k_i)^2 - 2(k_{s,i}/k_i)^3$, which has been used in Ref. [32].

The second issue is how to depict the risk propagation caused by initial failure nodes.

When either of the two connected nodes fails, their interacting edge is also removed; e.g., the emergence of renal failure disease will cause the kidney to lose the physiological function of detoxification. As a result, there is no longer a supply interaction to maintain the physical stability of urine osmotic pressure and plasma albumin. Referring to the cascade analysis of complex network in theoretical physics [33], the generating functions of degree distribution and the excess degree distribution for two subnetworks can be used to measure the robustness of the physiological network at each cascade stage. The generating function of degree distribution [34] in X network is defined as follows:

$$G_X^0(q) = \sum_{k=0}^{\infty} P_X(k) \sum_{k_s}^k \binom{k}{k_s} q^{k_s} (1-q)^{k-k_s} r(k_s, k) \quad (6)$$

where $P_X(k)$ is the degree distribution of X network, q is the probability of a randomly chosen edge, which is connected to a functional node. The generating function of the excess degree [35] is an extension of $G_X^0(q)$ with respect to functional edges:

$$G_X^1(q) = \sum_{k=0}^{\infty} \frac{kP_X(k)}{k_X} \sum_{k_s}^{k-1} \binom{k-1}{k_s} q^{k_s} (1-q)^{k-k_s-1} r(k_s + 1, k) \quad (7)$$

where k_X is the average degree of network X.

Proof Given a randomly connected network, the generating function of the degree distribution $P(k)$ is defined as

$$G_X^0(q) \equiv \sum_{k=0}^{\infty} P_X(k) x^k \quad (8)$$

It follows from Eq. (9) that the average degree of the network is $k = \sum_{k=0}^{\infty} kP(k) = G'_0(x) \Big|_{x=1}$. Following a randomly chosen edge, the probability of reaching a node with k outgoing edges (the degree of the node is $k+1$) is

$$\tilde{P}(k) = \frac{(k+1)P(k+1)}{\sum_{k=0}^{\infty} [(k+1)P(k+1)]} \quad (9)$$

Notice that

$$\begin{aligned} & \sum_{k=0}^{\infty} (k+1)P(k+1)x^k \\ &= \sum_{k=0}^{\infty} kP(k+1)x^{k-1} = G'_0(x) \end{aligned} \quad (10)$$

and

$$\sum_{k=0}^{\infty} [(k+1)P(k+1)] = G'_0(x) \Big|_{x=1} = \langle k \rangle \quad (11)$$

The generating function for the distribution of outgoing edges $\tilde{P}(k)$ is

$$\begin{aligned} G_1(x) &\equiv \sum_{k=0}^{\infty} \tilde{P}(k)x^k = \frac{G'_0(x)}{k} \\ &= \sum_{k=0}^{\infty} \frac{kP(k)}{k} x^{k-1} \end{aligned} \quad (12)$$

Then the given random network (with degree distribution $P(k)$) is replaced by a tree structure. Each of these nodes is in turn connected to $k-1$ neighbors at the next lower level. The levels of the tree are labeled from $n = 0$ at the bottom, with the top node at an infinitely high level ($n \rightarrow \infty$). Define q_n as the probability that a node on level n is functional. Consider updating a node on level $n+1$, assuming that the nodes on all lower levels have already been updated. With probability $\tilde{P}(k)$, the chosen node has k neighbors: one of these is its parent (on level $n+2$), and the remaining $k-1$ are its children (on level n). Each of the $k-1$ children is active with probability q_n . Thus, the node has m active children (and therefore $k-1-m$ inactive children) with probability $\binom{k-1}{m} q_n^m (1-q_n)^{k-1-m}$. The probability of distribution of its tolerance coefficients is given by function $r(m+1, k)$, and combining the independent probabilities yields the equation for q_{n+1} :

$$\begin{aligned}
q_{n+1} &= G_1(q_n) \\
&= \sum_{k=0}^{\infty} \frac{kP(k)}{k} \sum_{m=0}^{k-1} r(m+1, k) \binom{k-1}{m} q_n^m \\
&\quad (1 - q_n)^{k-1-m}
\end{aligned} \tag{13}$$

The final issue is how to model a general process of cascading failure in the medical field. If a fraction $1 - y_{G_e,1}$ of nodes is removed from ε_e to indicate the emergence of disease, the fraction of surviving nodes $y_{G_e,1}$ in G_e will determine the connectivity of the current bipartite network. Considering that another network G_i has not been affected by the first cascade, the functionality of a randomly chosen interaction edge $q_{G_e,1}$ only depends on $y_{G_e,1}$. Thus, the equation $q_{G_i,1} = y_{G_e,1}$ is set up. Applying generating function $G_X^0(q)$ to G_i , the fraction of surviving nodes in G_i will be updated by $y_{G_i,1} = G_{G_i}^0(q_{G_i,1})$. Because network G_e has been damaged at the second cascade stage, $q_{G_e,2} \neq y_{G_i,1}$. The excess degree distribution is used to calculate $q_{G_e,2}$, denoted as $q_{G_e,2} = G_{G_i}^1(q_{G_i,1})$. Through inducting the general cascading mechanism, the recursion relations for stages $l > 1$ can be formalized:

$$q_{G_e,l} = G_{G_i}^1(q_{G_i,l-1}); q_{G_i,l} = y_{G_e,l} G_{G_e}^1(q_{G_e,l}) \tag{14}$$

The fractions of surviving nodes of two sub-networks at l -th stage are

$$y_{G_e,l} = y_{G_e,1} G_{G_e}^0(q_{G_e,l}); y_{G_i,l} = G_{G_i}^0(q_{G_i,l}) \tag{15}$$

In conclusion, the robustness of a physiological network and the characteristics of failed nodes are estimated iteratively by Eq. (14) and Eq. (15) at each cascade stage. If these temporal evolution features are fed into sequential models, such as long-short term memory (LSTM), gated recurrent unit (GRU), and Transformer, the deterioration of patients' condition will be retraced and the health risks can be continuously predicted.

Conclusion and Future Work

Based on EHRs and other medical data sources, the authors have successfully carried out a series of AIM research and development, and some results have been put into actual operation. However, their research is still in an initial state, as is mainly reflected in the following aspects: in knowledge acquisition, the authors have tried medical entity and relation extraction based on deep learning methods, among which entity relation extraction is still a bottleneck that impedes the overall precision. In knowledge representation, triplets are their primary way, but this way has increasingly shown low expressiveness and is not suitable for rich and complex medical knowledge. They need to adopt a more expressive form of knowledge that can be automatically obtained from massive medical big data. In medical ontology building, the total amount of medical knowledge is still relatively small; the axiom system that gives the ability to reason between concepts is under construction. Knowledge complement and expansion method are still in their infancy stage, not to mention concept learning based on analogy and systematic similarity, knowledge complement based on Bayesian inference, and lifelong continuous learning mechanism. In terms of reasoning, the probabilistic reasoning model they proposed can only produce beneficial results from a small amount of knowledge and needs to be further improved in both ability and accuracy. The key to solving these problems is to break through the bottleneck of knowledge representation. From the discussion of cognitive architecture, the authors can understand that the massiveness, dynamics, concurrency, and interconnectivity of the human cognitive architecture are unmatched by the triplet. Therefore, how to overcome the limitation of triplets and study a new medical knowledge representation with characteristics closer and closer to the human brain is the direction of their future efforts. This requires them to propose an entirely new type of medical knowledge representation with innovation in terms of the system architecture.

Abstract

AI has the potential to transform medicine and healthcare, but the value of current applications, often exciting and sometimes helpful, has been overstated. The responsible application of AI, however, especially in advancing medicine as a scientific endeavor, has great potential, which is only just beginning to be tapped. We propose using AI to move from population-wide symptom pattern matching toward individual causal diagnostics, and to advance healthcare from only cost-effective

and population-wide pattern matching toward patient-centered, value-based, predictive, and precision care.

Current Standard of Care and Medical Research

Laboratory tests cost the UK's National Health Service (NHS) billions per year, and according to a recent report, this use of resources by the NHS could be curtailed. For example, up to 80% of the total number of tests are only requested in tandem because of long turnarounds, making doctors reluctant to wait for the result of a first test

before ordering a possible second one, which may turn out not to be necessary in certain cases. Meanwhile, requests for blood test are rising in number as they are the first step in any initial health screening, and this trend is expected to continue during the pandemic.

A General Practitioner spends around 2–3 h a week on average checking patients' blood results, and almost 40,000 additional GPs will be needed in the next 8 years. Thanks to Covid 19 and the NHS' Long-Term Plan, online appointments have been increasing in number. However, many of these patients must still travel to hospital for things like blood tests. In pediatric cancer care, for example, 9,500 children undergo regular full blood count tests once per week, which places a heavy financial and mental burden on these children and their parents. What's more, during the pandemic these children haven't been properly monitored, being vulnerable patients with compromised immune systems.

The current approach to preventing people from having to visit hospitals consists of sending a nurse into the community, which entails significant overhead costs that make it anything but cost effective. On the one hand, not only is the cost of such visits 20 times higher than the cost of, e.g., a blood test, but staff time is taken away from other tasks.

Current approaches also pose obstacles to changing the way blood testing is done because they are based on very expensive equipment that requires specialized operators and comes with very onerous annual maintenance contracts which are usually as or more expensive than the machinery itself. Current technology, which consists of very large, expensive machines that are not user-friendly, are unable to allow the regular testing needed for early diagnosis and proper health monitoring.

Moreover, biology and medicine are heavily multiscale making it difficult to model at any single level [2]. Instead, powerful model-driven approaches are needed in the study of complex diseases [7] to overcome the curse of data dimensionality, with a model able to extract main features and selection to be able to abstract the key elements of a disease diagnosis and prognosis.

However, scientists and clinicians alike are unable to keep abreast of their own areas of expertise, with individual scientists increasingly ignorant of advances not only in all other scientists' fields but even in their own. For example, only between 2003 and 2016 alone, the total number of scientific papers published annually more than doubled [1] and the doubling period is being shortened by about half every 5 years. Things are set to get worse, not better, with today's output at almost 2.5 million papers per year. Only AI could help close this gap by digesting, selecting, and exploiting this information faster.

Eventually, only AI will be able to catch up, leaving human scientists to guide AI on the type of meaningful research that should be conducted, with a focus on what scientists believe is of greatest interest. Most of the work will then be a matter of translating back and forth between humans and AI, providing instructions to AI and interpreting results from AI so humans could understand them.

Current AI Practice in Medicine and Healthcare

While techniques such as machine and deep learning (e.g., deep neural networks) are very effective in performing tasks related to classification, they are only so under highly controlled conditions, and are ill-equipped to deal with basic cognitive functions that we as humans take for granted, including basic logical inference and abstraction for model generation and hypothesis testing.

The combination of symbolic computation and statistical machine learning is thus a powerful combination for tackling complex problems, and a way forward to achieve better and more responsible A.I. This is because it offers interpretable models that correspond to observations, and can be tested, rather than encoded in obscure black-box explanations.

Driven by digitalization and rapid progress in the field of artificial intelligence (AI), and particularly in the field of machine learning (ML), the healthcare industry is undergoing radical changes that are constantly accelerating. The potential for

improvements in healthcare is significant if done properly. The responsible application of AI procedures can derive findings and recommendations for action from the vast amounts of data constantly being produced in digital form (Big Data). This is particularly relevant in cancer research, where new non-invasive imaging technologies are opening up completely new fields of research, and where existing imaging modalities like magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET) are extensively used over the complete cycle of patient care, from the early detection and diagnosis of tumors to the evaluation of treatment responses and follow-up.

One overarching reason for the small number of AI applications that make it to clinical application in general, is the lack of trust in AI-based applications, which are perceived as black boxes producing results on the basis of non-transparent decision making, and produce failures that are difficult to understand and unpredictable. This meta-problem is rooted in multiple individual but strongly related issues with AI development and validation.

Big data-based AI technologies hold still potential but model-driven AI which is explainable and can contribute to medical understanding, can better contribute to value-based healthcare for better outcomes through better prediction, diagnosis, and treatment of diseases.

There is also a lack of methods and protocols for the development, testing, and validation of reliable and reproducible AI-based medical approaches without the traditional hype. There is a non-trivial issue of measuring the degree of AI involvement and its relevance and impact. While quality is commonly assessed using performance measurements, a comprehensive evaluation of the quality of AI-based solutions should consider various other criteria, including robustness, explainability, and actual impact on clinical decisions.

These issues within the current AI development and validation cycle represent enormous obstacles to the practical use of AI outside shallow applications, that is, applications that do not offer scientific insight and are chiefly related to categorization tasks.

To illustrate the limitations of statistical AI, no amount of big data or statistical massaging (no matter how ‘sophisticated’) can make a traditional deep neural network perform a simple arithmetical operation if it has not seen it before, because it has no concept of number or symbol and will treat the whole term as an object.

One of the main problems data scientists face when working with images or medical data in the medical domain is the typically small amount of publicly available data, data being crucial for training and validation of neural networks. Such obstacles are especially challenging to overcome for start-ups and small commercial enterprises (SMEs) lacking the required resources and contacts for scaling their projects and accessing the first healthcare market.

The question is thus how AI can partner with clinicians and patients to improve quality of care. If we want AI and humans to collaborate, it is very important to recognize their respective capabilities and skills. In fact this collaboration began a long time ago, and it was accompanied by certain implicit understandings. For example, when calculators, cash registers, and electric counting machines entered the market, it was because it was acknowledged that these machines performed the tasks they were designed for far better and faster than their human counterparts. With AI as a newly developed computational asset, a similar process is afoot, for example, in the recognition that deep neural networks appear to be in some ways better at categorizing objects than humans. Hence the hype regarding new AI systems able to characterize and categories all sorts of medical images and data often purportedly better than clinicians, and if not always better, then faster. However, some subtleties are worth noting. While deep learning classifiers are faster once trained, they are also several orders of magnitude slower at learning or training, require much more data, and more importantly, are currently far less robust than their human counterparts. Humans build models based on function or highly abstracted features. Take, for instance, a school bus. It is its purpose – transporting children to and from school – that is the foremost consideration in its design, and only secondarily its looks, size,

shape, and color. A recognition of capabilities that evolve over time is key to optimally partnering with AI, even as AI improves in areas where its abilities are currently weak.

Model-Driven AI and Causal Diagnostics

One of our main advantages is how we approach AI by combining the best of different approaches: neural networks, that have produced incredible results in classification tasks, and what is called symbolic computation. The best way to understand symbolic computation is to think of a traditional calculator that understands the concept of number to the level of being able to perform arithmetic operations and follow an algorithm, which is something that neural networks find difficult to accomplish. We think this approach is a responsible way to control some variables that are key to being able to better understand and explain some of the decisions that an AI algorithm may take in medicine and health care.

An area that has also seen advances and great interest is explainable AI systems, that is, AI able to explain in human terms what, why and even how they do what they do or go about making a decision.

However, despite the many advances in medical technology, practical clinical diagnosis is still largely based on statistical symptom pattern-matching. The idea that a cluster of symptoms can lead to the correct diagnosis is often an oversimplification. Not only are symptoms not binary (either one has it or not), but complex diseases are multifactorial and can display a wide number of dissimilar effects and confounding signals. To better deal with probable root causes, we propose leveraging the results of years of research in model-driven causal discovery [3–5] by developing the area of causal diagnostics, a cutting-edge and responsible model-based approach to medicine different from simplistic AI approaches based on statistical classification that are typically unable to provide generative models or explanations for their arbitrary choices.

Longitudinal, non-invasive, (quasi) real-time, and cost effective health monitoring is hugely

important if we are to improve public health and deliver on the promise of personalized medicine for timely, accurate diagnosis.

The training and inference engines behind causal diagnosis are based on what is identified as neuro-symbolic computation, a combination of the best AI tools with cutting-edge expert systems that rely on both mind and machine to fight disease.

Causal diagnostics can revolutionize medicine by refocusing on first principles and causal generating mechanisms to redesign treatment and drugs so that they go beyond offering symptom relief. We call our neuro-symbolic computation approach a type of responsible Artificial Intelligence (AI) because it goes beyond current black-box approaches in AI in order to reach a deeper understanding of critical questions relevant to the unveiling of root causes in areas of medicine.

The Opportunity for Precision Medicine

Watson, for example, was at the pinnacle of statistical inference. Its success on the TV show Jeopardy! was never matched by successes in industry, in particular in areas of medicine and healthcare, where IBM initially thought it could be implemented and could make a real difference. Watson may have led to some marketing strategies in IBM's cognitive computation campaign but the methods behind the success of Watson at Jeopardy! were difficult to translate into other areas.

The problem that Watson and other AI approaches have tried to solve is, in our opinion, at once easier and more difficult.

First, the whole area of automation and AI application to medicine and healthcare is underdeveloped, and bringing to bear so much computational power at such a high cost, and overpromising while underdelivering, seems to have been the wrong approach. Instead, we believe that starting simpler is better, and then moving step-by-step, adopting only processes that are already known to work in the field and improving them with AI can prove to be a more robust approach after exhaustive evaluation.

In an application to risk assessment of blood test results, for example, we have developed an innovative score used in our health diagnostics and analytics methods. The score was tested against 100,000 cases, demonstrating that it picks up signals to separate healthy from unhealthy groups, even from noisy sources (the NHANES database from the CDC).

The score introduced in [6] is a numerical score that goes from 0 (healthy) to 10 (unhealthy), quantifying how removed a person's individual values are from reference population values, and is able to separate healthy from unhealthy groups even in the face of noise.

In a further improved version of these risk assessment scores, the scores adapt and learn over time with incremental precision each patient's baseline, allowing the application to flag for deviations smaller than the traditional reference population values, and thereby allowing a level of personalization not available before in the analysis of blood test results.

Once implemented, outlier analysis can flag for rapid changes, even within average healthy population values, and can deal with an important special case in the robustness analysis of AI methods, so-called out-of-distribution samples, that are especially critical in medical scenarios, where they can have fatal consequences. For this reason, model-driven approaches are better when they are shown to be more robust and can stand shallow adversarial attacks, such as single-pixel perturbation.

The methods for explainability implemented in our technology include perturbation and sensitivity analysis to ascertain the impact that changing the model inputs, and the models themselves, impose on their outputs. Using algorithmic probability, models are then ranked by complexity, with models whose explanatory power is in inverse proportion to their simplicity being favored. From visualizations of intermediate network layer activations and learned filters using medical literature, insights about the evolution of patient or user markers that combine all user data and medical literature in a computable form, are exploited to offer a highly informed pre-diagnosis and different disease progression and prognosis models. Traceability during the decision/

classification process can be guaranteed by the causal method through the implementation of a procedure similar to the layer-wise relevance propagation (LRP) method, but applied to non-statistical networks, to ensure that the decisions are supported by both meaningful algorithmic patterns in the input data and medical knowledge ingested by the platform. LRP operates by propagating the prediction backward in a neural network, whereas our platform propagates information back to the disease networks informing the first principles of possible progression, that is then tested against current or new data, to be adjusted and the models updated.

Explainability can also be ensured through the implementation of local interpretable model-agnostic explanations (LIME) at low levels, and at higher levels by a fully rule-based expert system that only uses deep neural networks for representation purposes. Methods and user interfaces should be designed for interpretability, explainability, and confidence, including information about possible failures, inaccuracies, and errors that should be accessible to the expert user for consideration and evaluation.

Conclusions

We propose a phased but responsible use of AI for precision medicine and value-based healthcare that is able to ensure that clinicians and patients understand the reasoning behind AI-based conclusions, enabling them to understand their chain of inference and justify their final call.

Combined, these proposals are designed to create trust and confidence in AI-based reasoning in clinicians, patients, and users, promoting responsible applications of AI that have the potential to transform medicine and healthcare.

Abstract

Artificial Intelligence has played a key role in innovating modern medicine over the course of the twenty-first century. As a result, technology has greatly impacted and revolutionized the field of healthcare. However, despite all the progress that has been made by technology, it must be emphasized that with any form of new technology comes some degree of risk; whether this is from existing technology or from the emergence of future technologies. In order to highlight the security challenges that may derive from increased technological development, we will be drawing upon two prominent and relevant security issues. The

first issue is the development and potential use of human enhancement technologies. It will be explored how the increase of enhancement technologies may lead to further issues and inequalities within society. Drawing from historical case-studies, it will be explicitly highlighted how the use of human enhancement technologies may lead to the irresponsible misuse of technology. To further highlight how technology can increase security risks, it will also be discussed how cyberattacks can impact the healthcare industry. Looking at the use of electronic medical records (EMRs) in healthcare, it will be analyzed how existing technologies can also increase security challenges. The overall purpose of this chapter is to highlight the symbiotic relation between technology and security and to further draw attention to prominent security threats in healthcare.

Introduction

The introduction of technology, particularly Artificial Intelligence (AI) in the form of machine learning (ML), natural language processing (NLP), and deep learning (DL), have become essential and impactful tools in modern medicine. Over the course of the twenty-first century, technology has become conveniently and effectively embedded into all spheres of life through technological innovation across all sectors in society. Consequently, the innovation of technology has greatly impacted and revolutionized the field of healthcare and medicine as a whole. This is evident as currently large corporate giants like Google have created AI that can efficiently and more precisely detect lung cancer than traditional doctors, [1] machine learning (ML) AI can be used to detect schizophrenia [1], and ML and wearable technology can be used to detect the onset of heart disease [1]. The aforementioned examples are just a small selection of technological innovations that demonstrate the impact technology has had within medicine.

While many of these procedures have been beneficial for the vast majority of the population, numerous headlines and bold sweeping statements continue to make headway about the negative impact of technology and how this will be society's greatest pitfall and challenge in the future. Public influential figures such as Bill Gates and Elon Musk have expressed their concerns about the future of technology, with the latter lamenting how technology could be one of the biggest issues we combat in the coming decades. Although many of these headlines are false and plagued with misinformation and clickbait titles, it must be emphasized that with any technology and medical procedure comes

some degree of risk. Therefore, the purpose of this chapter is to provide information about the future security challenges that could derive from the use of technology in medicine, and to further explore the symbiotic relationship between security and technology in a medical context by using real life case-studies and addressing some of the most pressing global security concerns in the twenty-first century.

In order to accomplish this, two prominent and pressing security issues will be discussed at length. The first issue is human enhancement through the use of biomedical technologies. As the future of medicine continues to advance and the application of AI allows doctors, scientists, and genetic engineers to break through biological limits, using technology to enhance human beings is becoming a reality. While this topic has already been heavily discussed from an ethical, moral, and philosophical lens, the aim of this chapter is to explore the potential security and political challenges that could derive from the use of these technologies. Investigating this issue from a security and political perspective is especially important, as in the future the use of these technologies could have severe consequences upon humanity. Beyond debating whether biomedical technologies should be used to enhance human beings or not, it is important to have critical awareness and knowledge on the security challenges that could result from this technology.

The second issue that will be discussed is the use of big data in healthcare and patient privacy. As many healthcare services across the globe now use digitalized and electronic medical records (EMRs) or electronic health record (EHRs), this increasingly poses numerous risks and challenges, as it potentially leaves many healthcare institutions and practices vulnerable of cybersecurity threats. To illustrate this point further, the hacking of the Finnish psychotherapy center, Vaastamo, and the UK's National Health Service (NHS) will be analyzed in great detail. The purpose of this is to shed light on how technology can sometimes be a double-edged sword with real life implications. Although there have been many benefits from the use of technology and AI in medicine, this does not mean that all risk and

security threats are diminished. By assessing the cybersecurity issues that could derive from technology, it better equips the healthcare industry, governments, and the general public of the flaws in the system, so that these issues can be resolved.

Human Perfection and the Security Implications of Biomedical Technology

The future of medicine is one that invites positive innovation and has the potential to benefit many people across the globe. Despite this however, there are still many issues that could occur from the development and employment of such technology. This very sentiment was expressed by Francis Fukuyama, in his book *Our Posthuman future Consequences of the Biotechnology*, [2] in which Fukuyama had expressed concerns about biotechnology, and the consequences that could derive from a posthuman future. In essence what Fukuyama was trying to convey is that, as the future of medicine gets increasingly innovative and technologically adept, this could have profound consequences for humanity. This is because as more research is conducted within certain specialties, for example, within reproductive medicine and genetics, this could lead to further problems as the more our knowledge and capacity to interfere increases, the more we could alter things for the detriment of humanity. Fukuyama discusses this very phenomenon in his book, as he talks about the potential impact of biotechnology and genetic engineering, and hypothesized that it will “dominate government policy in future” [2]. Fukuyama continues by saying that in the future, “the ultimate prize of modern genetic technology will be the designer baby” [2]. A designer baby is one that has been genetically altered to have enhanced features and/or attributes.

Eugenics: The Painful History of an Idea

Throughout history, the belief that certain human beings are better than others has dominated the world. People that possessed certain skin colors, ethnicities, genders, sexualities, and were

from different social classes, that did not conform to the typical societal expectation, were victimized within society. This led to great injustices such as slavery, imperialism, colonization, racism, and sexism, throughout the twentieth century. However, it was not enough to claim someone was inferior when compared to another human being simply by the aforementioned defining factors, it needed to be proven that their genes and DNA meant that they were physically inferior.

This idea of possessing better features or attributes due to “better genes” is often referred to as eugenics [3]. The term eugenics was first coined in 1883 by Francis Galton, the cousin of Charles Darwin [3]. Galton had advocated the idea that couples should marry based on who are the fittest individuals in order to ensure a better human race, when procreating [3]. He also advocated that this idea of marrying individuals that are of a better social standing could be enforced through monetary gain provided by state governments [3]. This idea has set the groundwork for future practices of eugenics, in which selective breeding had become the “underpinnings of state sponsored discrimination, forced sterilization and genocide” [3]. The ideology surrounding Eugenics has been around since the late nineteenth century, [4] with practices occurring across the United States (US) and in Europe. In the US, scientists had worked alongside politicians to theorize and practice methods of eliminating the reproduction of those considered to be of a lesser gene pool, and thus, hereditarily weaker. Increasing reproduction and breeding among those considered to be hereditarily stronger was considered the way forward to promote a better and stronger society [4]. These early eugenic programs in the US are noteworthy to mention as they served as social models for preliminary eugenics programs in Nazi Germany [4].

The advancement of science had played a pivotal role in highlighting this phenomenon and had created further barriers and hierarchies among human beings. Using science to mark the genetic differences among people predates the twentieth century, and can be seen in Arthur De Gobineau’s, *An essay on the inequality of the human races* [5]. The significance of this is that it presents

how science, or rather pseudoscience, has been used to support and validate discriminatory agendas. This idea is crucial as it plays an integral role throughout twentieth century Europe, and led to a number of immoral experiments being conducted on human test subjects.

The most infamous and devastating examples arises from Nazi Germany, under experiments led by Josef Mengele. In Nazi Germany, people from marginalized and socially outcast groups (those of Jewish faith, Polish nationals, Roma, political prisoners, USSR prisoners, homosexuals, catholic priests, and those with physical disabilities) [6] were used as human test subjects without permission or consent, and were subjected to cruel and dangerous experimentation so that doctors could study genes.

Mengele was famous for his fascination with genetics, particularly the genes of twin siblings, leading him to conduct unethical and unorthodox practices to study that phenomenon further [7]. Holocaust survivors and fraternal twins, Irene Hizme and Rene Slotkin recount their experiences of being used as human test subjects in a 1995 interview. In the interview, Ms. Hizme recounts how she was spending a lot of time at the doctor's office and was in and out of hospital. She remembered how she was very sick after the doctors had taken blood from the left side of her neck [8]. She further discussed how she would have to wait for long periods of time to be measured and weighed, and recalled how she would often be injected, without consent, with a mysterious substance that afterwards made her unwell [8]. Likewise, Eva Mozes Kor, who was sent to Auschwitz with her twin sister Miriam, also recalls similar memories. Ms. Kors explains how "the doctors would take their blood and had given them regular injections." After one of those injections, Kors had also become extremely ill [9]. In addition to the morbid fascination and experimentation on twins, other experiments that aimed at human perfection, and forced sterilization in men and women, were also conducted. To sterilize women, the doctors had formulated an "irritating solution to be injected into the uterus" [10] against the will and knowledge of these women. These experiments are particularly important as they highlight the fundamentally

flawed concept of human perfection. To what extent is creating a "perfect human race" worth the lives of innocent people? The experiments were conducted so that the Nazi's could understand how the human body functioned, in order to use this to their advantage. By understanding how to remove and damage reproductive organs of those considered inferior, they hoped it could aid them to reach their goal of eradicating the impure and be a step closer in creating the Aryan race. The study of twin siblings was particularly sinister as doctors wanted to understand how harming one twin would have affected the other, until it led to their eventual death. By analyzing the corpses of twins, the doctors would try to look for anything that supported their hypothesis that certain people are born genetically inferior, allowing these people to then be ostracized and eradicated from society; thus, leaving behind only those considered to be pure and genetically superior. This idea, though it may seem convoluted, has great significance and relevance to the study of reproductive technologies today.

Can "Liberal Eugenics" Really Work? The Relationship Between New Wave Eugenics and Security

At present day, similar studies are being conducted to those practiced in Nazi Germany to see if there are any direct correlations between genes and certain behavioral qualities [2]. What this connotes is that studies are being undertaken to determine if there are links between genes and behavioral attributes such as "intelligence, aggression, sexual identity, criminality and alcoholism" [2]. This is of great importance as if certain genes were found to be "better" than others it begs the question of what could happen in the future if people were to take advantage of this? For example, if wealthy parents in the future could choose specific genes for their offspring and pick certain qualities and features that are deemed "better," how would this impact parents who would not be able to select genes for their offspring, due to financial restrictions? Would this create an unfair precedent in society?

Francis Fukuyama expresses his concerns that human enhancement and designer babies could become a major “political issue that may someday come to dominate politics” [2]. This is because if wealthy parents could alter the genetics of their potential offspring, they would be altering the germline not just of their offspring but also of all future descendants [2]. This could have a profound impact upon humanity, if those with better genes are to be favored or championed in society, while others are discriminated against simply for their genes. Fukuyama claims that the impact of this could someday lead to a “full scale class-war” [2].

A class war in the future, dictated by one’s genes is a haunting reminder of the ideologies and practices that emerged in the original iterations of eugenics. Despite this, some defend the use of genetic engineering and human enhancement through the use of liberal eugenics [11]. Liberal eugenics is a newer version of eugenics in which authoritarian eugenics is rejected, meaning that state governments would have no decision-making role in the process. Instead, individuals would have the liberty and freedom to decide how to utilize these technologies [11]. The fundamental principles of liberal eugenics are that individuals would be well-informed about future technologies and their utility, and thus, can make conscious decisions about how to use them [11]. Liberal eugenics is often defended by likening the choice of using biomedical and enhancement technologies, as having a series of choices in a liberal society [11]. What makes up the core foundations of a liberal society is allowing people to have the freedom and discretion to choose the life that they want and respect the choices of one another [11]. One of the core principles of liberalism itself is “acknowledging the right of others to make choices that do not appeal to us” [11]. Therefore, when applying this liberal notion to eugenics, instead of restricting the freedom of citizens through state-sponsored eugenic practices, it is returning freedom and offering individuals more choices to better their, and their future offspring’s, life. By putting the control into the hands of individuals and allowing prospective parents to make decisions in the best interest of their future offspring, it is believed that enhancement technologies would be used responsibly.

Hence the risks of creating social hierarchies and division in society would be mitigated [11].

While, the idea of liberal eugenics attempts to overcome the negative connotations attached to original eugenics practices, the theory of liberal eugenics has some fundamental flaws. The theory bases a lot of assumptions of responsible use of this technology in an idealized utopic liberal society; however, there are some important issues with this. Firstly, if biomedical technology was available and legal for global use, then it should be factored in that not every country adopts a liberal or democratic social structure. In countries that function through communism, socialism, authoritarian rule, or dictatorship systems, non-state sponsored eugenics would be difficult to facilitate. The theory of liberal eugenics is purely a Westernized concept that would only be compatible for liberal societies. Although approaching eugenics from a liberal approach could work in countries that adopt a liberal system, the theory of liberal eugenics is limiting.

This is extremely important to consider from a security context. If states that employed non-liberal systems instructed citizens on how to use these technologies or encouraged the use of genetic enhancement to create better citizens, this could lead to an array of other problems. For example, this could create chaos in the international community, if in different societies, whole populations were to genetically enhance future generations to be “smarter,” “stronger,” and “attractive,” whereas in some countries these technologies were not accessible to all citizens or were entirely outlawed. Although it is incredibly difficult to measure and predict the exact response of these technologies from different countries, it needs to be highlighted that biotechnology and the power to modify humans carries with it significant risks and challenges to the global order.

Furthermore, the concept of liberal eugenics is also flawed as it could lead to the inadvertent discrimination against certain groups of people within society. The potential of gene editing brings with it many possibilities, as it could result in the eradication of diseases and illnesses in the future. For example in 2018, media reports surfaced that doctors had illicitly used gene

editing technology to modify the genes of two twin girls [12]. The modification was intended to make the twin girls immune to human immunodeficiency virus (HIV) [12]. At the time the news broke, this caused much anger, concern, and controversy in scientific circles as the doctor responsible, He Jiankui, conducted the procedure unlawfully and unethically [12]. By using clustered regularly interspaced short palindromic repeat (CRISPR)-associated system (Cas) technology, [13] Jiankui was able to edit the gene CCR5, that is responsible for causing HIV [12]. This was achieved as the CRISPR/Cas9 system allows it to be possible to locate a certain part of DNA inside a cell that can then be edited [14]. This is possible as Cas9 acts as a pair of “molecular scissors” [15] that is able to cut DNA [15]. Within Cas9 is an enzyme, guide RNA (gRNA), that directs Cas9 to the exact part in the genome that needs to be cut [15]. Once the incision has been made, the DNA will try to repair itself; however scientists can intervene and hack this system and provide the DNA with models to replicate, thus allowing genetics engineers the ability to modify and alter genes [15]. In the case of the two twin girls, Jiankui claims he was able to effectively remove the gene that causes HIV [12].

Although this procedure was orchestrated unlawfully and widespread use of gene editing technologies are still outlawed, the success of such a procedure demands important conversations and considerations. If it is possible to eradicate diseases and genetic mutations, what would this mean for the future of disabled people? As many gene editing technologies focus on “the correction or removal off disabling genetic traits” [16], this raises some questions about whether this would be purposely eradicating those born with disabilities [16]. By trying to “fix” people that would be born with genetic mutations or anomalies, it needs to be questioned what sort of message this would send to individuals that are born and live with disabilities. While having a disability can make some aspects of life harder, it does not mean that the quality of that life cannot be as good, fulfilling, or happy as someone who was not born with a genetic mutation.

Even though liberal eugenics champions the idea of individuals picking genes for their child, this may lead to unconscious biases surfacing in the future, in which those born with disabilities face eradication in the name of modernity and progression. This itself cannot just be viewed as a moral and ethical dilemma but can also be framed as a security issue. Gene editing threatens the future for those that would be born, and currently live with, genetic mutations [16]. It reinforces negative connotations about disabled conditions and risks “reverberating [these opinions] throughout wider society” [16]. In a future where genetic editing technologies are legal in society, the security implications that could entail for different people are imperative to consider. The first wave of eugenics aimed to eradicate members in society that were deemed “less than” and genetically inferior. Liberal eugenics attempts to remedy this by promoting liberal and positive eugenics; however in doing so, this may lead to widespread unconscious discrimination.

Despite the fact that this technology is still not widely implemented within society, and that there is still a long way to go before scientists, genetic engineers, and doctors can perfect and safely use this technology, it is still important to consider the consequences at this moment in time. This is largely due to the fact that some of the technical problems that genetic engineers and doctors have encountered before can largely be resolved with AI and ML algorithms, in the twenty-first century. For example, one of the biggest logistical challenges for engineers and doctors when it came to using CRISPR/Cas9 was ensuring that if they are cutting and replacing genes, what combinations would work when replacing the original. As there can be numerous combinations, it would be difficult to accurately analyze all this information in a short amount of time. However, machine learning algorithms can largely resolve this issue as a computer can be given large datasets and analyze accurately and efficiently the best combination and outcome from previous datasets. Thus, as the reality of GE gets closer, it is imperative to consider every angle of the debate, especially with regard to security.

Exploring the Symbiotic Relationship Between Technology and Security

Over the past decades, technology has fundamentally transformed the field of medicine. Not only have pivotal developments been made through actual medical procedures such as genetic engineering as previously discussed, but technology has also changed the way patient information and data has been collected. Most hospitals and healthcare practices at present use some form of electronic medical records (EMRs) or electronic health records (EHRs) as a tool to accurately collect vast amounts of patient data [17]. EMRs are digitally kept records that contain confidential patient information recorded by healthcare professionals or personnel in a medical setting [17]. Examples of EMRs include lab results, routine check-up clinical notes, prescriptions for medication, and clinical progress reports [17]. EMRs are crucial in maintaining hospital systems and ensuring patient care [17]. The vast amount of patient information available from EMRs can be considered as a form of big data [18].

Big data are mass volumes of structured or unstructured information. In comparison to regular data, big data, as warranted by the name, is bigger in size and can be characterized by volume, variety, and velocity [19]. In recent years, big data has become increasingly important for both the private and public sector due to the important information that can be found within the huge and complex datasets [18]. The information that can be found in these datasets can then be used to study, analyze, assess, and predict trends, patterns, and even consumer behavior. In healthcare, big data is especially important as it can be used to highlight important trends in the medical field and can also be used for biomedical research [18]. This type of data is especially important as it can be used for machine learning purposes. This is because researchers in the field of machine learning (ML) have gained access “to a large quantity of high-quality medical data” [17] that can be used to teach computers about past cases to better equip the technology to recognize future cases.

The reason why this is important to note is because as the healthcare field gets increasingly more digital and employs the use of ML algorithms and other AI tools, this may lead to more complications and potential security threats in the future, since valuable data such as EMRs may be used for malicious intents and purposes.

Hacking Healthcare: The Violation of Patient Data

This very issue pertaining to the misuse of EMRs is not just a hypothetical concern as in recent years the hacking of private and confidential patient data occurred. In 2020, a scandal regarding the hacking of EMRs came to the forefront and garnered public attention after it was discovered that a hacker tried to extort psychotherapy patients after illegally obtaining access to their EMRs in Finland [20]. The Finnish psychotherapy center, Vastaamo, were at the center of the cybersecurity attack when hackers had exploited security breaches in 2018 and 2019, respectively, which had remained undetected at the time [21]. Patients had then received disturbing messages that their private records and clinical notes will be uploaded onto the internet unless they pay €500 in cryptocurrency [21]. The hackers had sent more than tens of thousands of emails to patients demanding money in exchange for their silence [20]. Sensitive information, including confidential clinical notes and social security numbers, were threatened to be published.

Indeed, a similar cybersecurity attack also affected the British healthcare service in 2017, after the UK’s National Health Service (NHS) fell victim to the global WannaCry ransomware attack [22]. The WannaCry attack brought the NHS to a halt after affecting hospitals, practices, and GP surgeries throughout England and Scotland; with thousands of appointments and operations being cancelled [22]. Similarly to the Finnish case, hackers demanded monetary gains in the form of cryptocurrency in exchange for silence over confidential EMRs that they acquired. The hackers had managed to achieve

this large-scale attack by exploiting a preexisting vulnerability in the software. Although the NHS was not a particular target in the mass global attack, the software had left them susceptible to the attack [22]. The NHS was particularly vulnerable to the attack as the NHS at the time used archaic Microsoft systems IT systems thus increasing the likelihood of cyberattacks affecting the NHS altogether [22].

The reason why these cases are important to reference is two-fold, and shall be discussed. Firstly, as patient data continually becomes more digitalized through the use of EMRs/EHRs and is used for biomedical research, ML, or any other use, it must be imperative that patient privacy and data security is ensured and maintained at all times. This is of vital importance as a violation of such personal information could result in a loss of confidence from patients, which could have a profound impact on both the patient and healthcare system. The second reason that this should be considered is because any new technology comes with some form of risk. The two cases in Finland and the UK highlight the dangers of cyberattacks and hackers in the healthcare industry. It explicitly emphasizes the vulnerabilities of technology and the long-lasting impact that it can have. While technology can help to innovate healthcare, it is important to consider that with technology comes certain risks, thus these risks should be examined in a bid to mitigate any potential catastrophes.

In the Finnish and UK case studies mentioned, the violation of patient data presents an emerging human security issue. This is because the theft, extortion, and blackmail as depicted in the Finnish case can have a profoundly negative impact on individuals that threatens their sense of security and trust. In a world where data is considered the most precious commodity becoming even more lucrative than oil [23], the private data of patients and EMRs are incredibly invaluable. The medical data of an individual can reveal private information about a patient that they may not want to disclose publicly, such as illnesses, health conditions, and mental health concerns. The theft of medical data is especially disconcerting as EMRs and EHRs have a longer life compared to other forms of personal data [24]. Compared to other forms of personal data like an individual's

online digital footprint or financial data including credit card and bank details, the lifespan of medical data is imaginably longer as the medical history of a person does not ever change [24], in comparison to other forms of data that may be subject to change. As a result, evidence indicates that stolen EMRs and EHRs are "often sold and resold on the dark web," [24] perpetrating an endless cycle. This makes the theft of EMRs especially unique and dangerous as it has the potential to cause the most lasting damage for individuals. This can lead to further attempts of blackmail, extortion, and fraudulent behavior.

Moreover, the long-term impact of stolen patient information can substantially affect and worsen a patient's health and well-being. The distress of the violation may cause trauma to patients who are contacted by hackers to pay a lump sum of money in exchange for their information. In the Finnish case, patients were reported to have "flooded victim support services" [25] due to the distress of the events. In addition to the trauma faced by patients, this may also encourage a lack of trust in healthcare services and a distrust for technology. Not only would this fundamentally affect patients but it would also impact healthcare services if people do not feel safe and entrust healthcare workers with their medical concerns. This may lead to people not attending routine check-ups and appointments that could be important in ensuring that people stay healthy, and detect the onset of any illnesses or underlying health conditions earlier. As EMRs are increasingly being used to train ML algorithms to detect and identify previous case studies to aid new cases, it is especially essential to ensure the data privacy of patients. Before implementing new technological processes in healthcare, the existing cracks from using technology first need to be resolved.

While the use of technology in medicine has shown increasing benefits it cannot be denied that this also brings a whole lot of challenges and security concerns. As mentioned, the theft of patient data is arguably one of the biggest consequences that could derive from the lack of cybersecurity provisions in healthcare. The relationship between security and technology itself is an interesting albeit turbulent one. As the world becomes more digital and adopts a digital infrastructure,

this increases the likelihood of potential cyber-attacks. Likewise, as the healthcare industry continues to utilize technology, this may also bring with it some unwarranted risks. It is therefore important to explore the link between cybersecurity and healthcare and resolve the vulnerabilities in order to make systems secure.

The healthcare industry appears to be at a higher risk from a cyberattack than any other industry or sector [26]. The impact of a cyberattack not only risks the sensitive data of patients, but it also risks infecting the infrastructure of healthcare practices, costs the health service millions, disrupts workers from doing their job, and affects patient care. Healthcare is suggested to be an attractive target for two reasons. The first reason is that the healthcare industry has an unlimited supply of invaluable data, and the second reason is that protections and defenses against cyberattacks are weak [27]. This makes the target of healthcare that much easier to exploit as a fast way to make monetary gain. Despite the impact that a cyberattack may have on the healthcare industry, evidence suggests that the healthcare industry is still unprepared with the recent 2020 case in Finland. As a result, not only are technological developments needed to improve the field of healthcare but so are enhanced security measures.

Stronger measures such as blockchain systems may be beneficial to employ, as well as other preventative measures. Blockchain is a system that is used to securely store and share information [28]. Blockchain works as data is stored in decentralized transparent blocks that are linked together by cryptographic hashes [28]. Blockchain has the potential to remedy many of the cybersecurity issues the healthcare industry faces, as it is a more secure way to collecting and storing confidential data. Blockchain, with a combination of other security measures such as encrypted emails, adequate staff training to recognize fraudulent and phishing emails, and impenetrable networks, offer increased security.

By identifying the susceptibilities that may derive from increased technological development, this will crucially benefit the healthcare industry. The relationship between technology and security is a symbiotic one as the two unequivocally go

hand in hand. A lack of security allows for technology to be exploited. As medicine continues to advance, the security provisions also need to be held to the same standard and accountability.

Concluding Thoughts

It is better to have principles covering situations that turn out to be impossible than to have no principles for situations in which we suddenly find ourselves [11]

- Nicholas Agar, Liberal eugenics: In defense of human enhancement [11].

The continued implementation of technology in medicine will certainly elevate healthcare and modern medicine. Although, a lot of these breakthroughs will have a positive impact on humanity and within medicine, it is still imperative to explore the relationship between technology and security. This is because sometimes with technology there is still a degree of risk that could derive from the use of it. This was explicitly highlighted throughout this chapter as despite the advances that have been made, there are still some fundamental security concerns.

As AI continues to advance medical practices and paves the way for greater innovation, it is important to critically analyze the purpose of technology and ensure its responsible and safe use. This entails analyzing potential security issues before they arise. In terms of GE, this technology has the power to greatly benefit a lot of people; however, equally it can also bring about a lot of harm if used irresponsibly. Thus, it is wise to have as Agar suggested, security measures for situations that could happen as opposed to no measures or considerations at all. Genetic enhancement has the potential to be misused; hence it would be wise to critically analyze how this could occur and mitigate the possibility of misuse before it is a widely normalized part of society.

Likewise, when analyzing technology and the negative impact that it could have, it is also wise to investigate existing uses of technology and ensure that they are being used safely. As the healthcare industry continually gets more digitalized, it is also important to cover all bases, and ensure

there are adequate security provisions in place. By closely examining the relationship between technology and security, we optimize our chances of having a safe digital future.

Abstract

This chapter explores the differences between association rules extracted using the likelihood mining criterion (LMC) and rules extracted by using frequent item-set rule mining (FRM). LMC provides a change in perspective for rule selection, from a measure of frequency in the dataset to a measure of relationship between the rule items. For illustration, this chapter presents the evaluation of qualitative differences between LMC and FRM rules with three examples: (1) a basic rule mining

scenario to illustrate LMC properties, (2) an analysis relating socioeconomic information and chemical exposure data, and (3) mining behavior routines in patients undergoing neurological rehabilitation. Results show that LMC is capable of extracting rare rules and does not suffer from support dilution. Furthermore, LMC focuses on the individual event generating processes, while FRM focuses on their commonalities.

Introduction

Association rules can model a process by describing the relationship between variables. In a dynamic process, for example, a rule states that a change on an input will cause a change on an output. As the process evolution is stored in a dataset, association rule mining (ARM) can extract the original relationship between the process inputs and outputs. The common approach for ARM is frequent association rule mining (FRM). Rules extracted by FRM, e.g., $X \rightarrow Y$, have support and confidence greater than a user-specified min-support and min-confidence thresholds [1]. Formally, support of an item-set X is defined as the number of transactions T in the database D containing item-set X divided by the number of transactions in the database. Equation 1 shows the support of a rule $X \rightarrow Y$. The rule confidence is defined using support in Eq. 2.

$$Supp(X \rightarrow Y) = \frac{|\{(X \cup Y) \subseteq T_k, (X, Y) \neq \emptyset, \forall T \in D\}|}{|D|} \quad (1)$$

$$Conf(X \rightarrow Y) = \frac{Supp(X \rightarrow Y)}{Supp(X)} \quad (2)$$

The following thought experiment illustrates one of FRM's limitations. Suppose all supermarket receipts from the winter holidays are used for

rule mining. One would expect to see rules that associate the ingredients used for winter holiday meals. Now consider a year worth of receipts from the same supermarket. In the light of the additional data, the winter holiday meal ingredients would not have enough support to be extracted. In other words, the minimum support (min-support) threshold used to extract rules in a small dataset will not work in an extended version of the dataset due to the definition of rule support. In this chapter, min-support's dependency on the dataset size is called support dilution.

A dataset can be viewed as the collection of items sampled from multiple generating processes. However, FRM has the implicit assumption that all items are generated at the same rate. In practice, processes can generate items at different rates. For example, people in Germany occasionally buy white sausages, but when they do, they buy wheat beer too. So the rule “if white sausage then wheat beer” is a rare rule when compared to frequent rules, e.g., “if milk then eggs.” FRM can extract rare rules by using a low min-support threshold. Unfortunately, spurious item associations may create unwanted rules that FRM's threshold cannot eliminate. Filtering out unwanted rules for FRM has been addressed in the past [2, 3]. However, the processing required to separate rules does not generalize [4].

The field of medicine advances by capturing evidence that supports a given hypothesis. As the means to collect data surpasses the current capacity to analyze it, automation is required to extract new knowledge. ARM as a tool provides investigators the ability to sift through data repositories automatically. However, FRM methods are inadequate to extract useful knowledge from medical repositories, if the interest is association quality and not how frequent a certain observation occurs in a dataset. Therefore, this chapter reviews the use of likelihood as a means to select rules with quality measured independently of the dataset size. In particular, the minimum likelihood mining criteria (LMC) is explored and compared to min-support FRM. LMC has been proposed to replace min-support as primary rule selection criteria in ARM [5].

This chapter is organized as follows: section “[Association Rule Mining](#)” presents an overview of ARM algorithms. Section “[Likelihood Mining Criterion \(LMC\)](#)” describes LMC and illustrates

rule selection differences between FRM and LMC by extracting all atomic rules, i.e., rules of the form $X \rightarrow Y$, where $|X| = |Y| = 1$, from five datasets commonly used in ARM literature. Sections “[Basic Rule Mining Example](#)” through “[Rehabilitation Routine Mining](#)” illustrate LMC and FRM in three ARM applications: a synthetic timeseries, a dataset linking socioeconomic variables with health-related chemical exposure information, and a dataset of daily behavior routine annotations of patients with hemiparesis. In each setting LMC and FRM extracted rules are compared and evaluated for quality and usefulness.

Association Rule Mining

ARM algorithms can be generalized to have two stages: (1) search for useful item-sets, and (2) search for adequate rules within these item-sets [6–8]. In the context of ARM, useful item-sets are categorized as passing a min-support threshold and adequate rules depended on a secondary rule selection criterion. As the problem of support dilution became apparent [9], many approaches looked to circumvent the min-support threshold or to define new rule interest metrics, but always relied on support properties to search the lattice of rule candidates. In this section, algorithms that rely on support to select rules are grouped under FRM methods.

Conceptually, there is no correlation between rule frequency and rule interest, as pointed out by Li et al. [10]. Therefore, alternative rule interest metrics have been proposed, inspired by probability

theory, where rules are created based on the relationship between the rule and its conforming items. In this section, algorithms that use probability theory to select rules are grouped under Bayesian rule mining (BRM) due to their use of Bayesian concepts to select interesting rules. LMC is considered a primary rule selection criteria class under BRM. Figure 1 illustrates a summarized taxonomy of ARM algorithms, by mining methodology, primary rule selection criteria, and search type.

The rest of this section provides a brief overview of ARM literature grouped into FRM- and BRM-based approaches.

FRM

High-utility item-set mining is the general approach to extracting useful item-sets. The idea behind high-utility item-set mining is that a utility is given to each item in a transaction. Then, high-utility item-sets are extracted by summing the utility of each item-set across all transactions and comparing them to a min-utility threshold [11]. The advantage of high-utility item-set mining is that items bought occasionally, e.g., white sausages and wheat bear, usually have high utility and are extracted. It has been shown that frequent item-set mining is a special case of high-utility item-set mining, where the transaction utility per item is one and min-utility threshold becomes min-support [12]. Nguyen et al. [13] illustrate multiple approaches to association rule mining using high-utility item-set mining. The challenge with high-

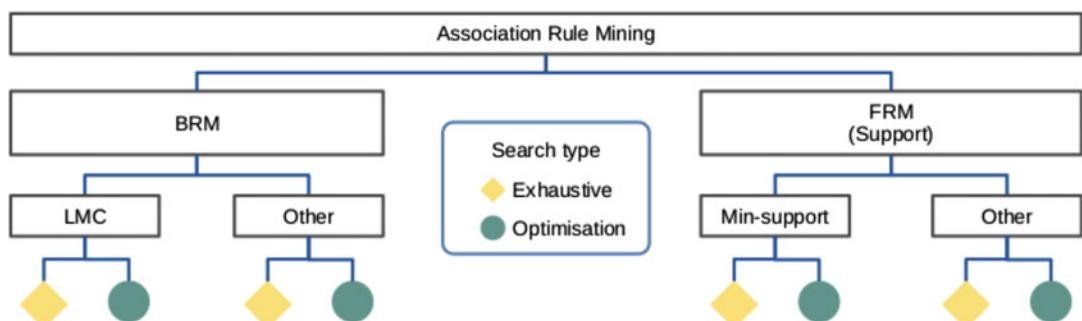

Fig. 1 Extended taxonomy of association rule mining. FRM and BRM rule mining methods represent different concepts related to the rule selection process. FRM employs support properties while the yet less established

BRM uses probabilities. In this chapter, LMC and min-support FRM are compared. LMC is considered a primary rule selection criteria class under BRM

utility mining is that the utility of an item is not always available as in the supermarket case. Therefore, the chapter's scope is limited to compare ARM based on LMC with FRM without utility.

In general, the two-stage approach to ARM requires min-support as primary rule selection criterion, and a secondary selection criterion such as min-confidence threshold. Seminal work in ARM, like the Apriori [1] or ECLAT [14] algorithms, introduced the min-confidence threshold as the main mechanism for creating association rules. As ARM was used to solve real-world problems, the threshold on confidence was producing rules with no prediction power [15]. Therefore, several interest metrics were introduced, such as lift [16], conviction [17], relative confidence [18], information gain [19], and others [20]. Alternatively, rule grammars and machine learning approaches have been presented as alternatives of the downward-closure property of support to restrict the rule search space, and extract more interesting rules. For example, Padillo et al. [21] used rule grammar and map reduce to optimize the mining process in large datasets. In timeseries, Guillam-Bert et al. [22] proposed the TITARI algorithm. They used decision trees to improve rule description and temporal specificity. However, these interest metrics were used as secondary rule selection criterion, and depended on item-sets extracted using a min-support threshold.

Rare rules are defined as the rules with support between a min-rare-support and min-support thresholds [23], where $\text{min-rare-support} < \text{min-support}$. In the rare-rule community, the available work focuses on resource-efficient extraction. For example, Tsang et al. [24] proposed the RP-Tree structure to facilitate rare rule extraction. Liu and Pan [3] proposed RP-VRIM, an extension RP-Tree that uses vertical layout to reduce dataset scans. Borah and Nath [9] proposed the SSP-Tree that enables the search of frequent and rare pattern combinations simultaneously and considers dynamic datasets.

Selecting the correct value for min-support is difficult. Thus, several approaches proposed rule search mechanisms that omit the min-support threshold. For example, *OPUS* [25] is a frequent item-set exhaustive search algorithms that does not use the downward-closure property to traverse

the item lattice. Webb [26] presented an extension that converted *OPUS* into an ARM algorithm. Bashir et al. [6] proposed an exhaustive search algorithm for frequent item-set mining, which starts by selecting n item-sets. Then, their algorithm selects the smallest support values of the chosen item-sets, and prunes the search space using the downward-closure property. Fournier-Viget and Tseng [27] proposed the TNR algorithm where the top n nonredundant rules were extracted. Both TNR and Bashir et al.'s algorithms required min-confidence to be specified.

Support dilution is a common ARM problem in dynamic databases. Cheung et al. proposed FUP [28], the first algorithm to consider efficiently updating extracted knowledge after adding new transactions to a database. Tobji and Gouider [29] extended FUP for different user-given support thresholds after adding transactions. Aqra et al. [30] proposed the Aprior algorithm to improve rule maintenance under append, update, and remove operations over the dataset. All these methods have in common that the min-support threshold needs to be manually updated in order to maintain interesting rules.

Although Tian et al. [31] proposed the use of probabilistic metrics of rule interest based on Bayes theorem, their methodology is based on a frequent item-set extraction, and proposes the Bayesian confidence and Bayesian lift as secondary rule selection criteria.

BRM

Bayesian methods for ARM are still less frequently investigated, nevertheless offer elegant features and complementary properties to FRM. The following review summarizes key contributions to BRM.

Li et al. [10] introduced local support as primary rule selection criteria in medical datasets. Local support is an approximation of the likelihood probability based on data observations. Gay and Boullé [32] have used Bayes and Information theory to select rules with the best classification power. Their proposed *level* sets a boundary for extracting interesting rules, with a preference for simpler models, i.e., shorter rules. However, the

level does not have a monotonic or anti-monotonic property that can be exploited to minimize the search space. Therefore, their methodology looks for locally optimal rules. In contrast to *level*, LMC has the anti-monotonic property [5], which reduces rule search space. Lopera G. et al. [33, 34] used increasing belief in the recursive application of Bayes theorem as rule selection criterion. Increasing belief can be simplified to a threshold on the likelihood. LMC differs from increasing belief by using a fixed minimum likelihood rather than the rule's premise probability as threshold value.

When LMC is used to replace min-support in FRM algorithms, existing interest metrics can be used as secondary rule extraction criteria, including Bayesian confidence and lift. As LMC extracts rules from the entire support range, min-support and min-rare-support thresholds can be defined after mining rules to label LMC rules as rare, e.g., following the FRM definition of rare rules. Although LMC requires data representations like SSP-Tree to maintain item-set counts, in dynamic datasets, LMC does not require the maintenance of thresholds between dataset updates. Unlike min-support, LMC does not depend on the dataset size.

Likelihood Mining Criterion (LMC)

When considering data supporting a hypothesis, Bayes' theorem is a useful tool to measure the change in belief when new data becomes available. In general, Bayes' theorem states the relationship between posterior and likelihood scaled by the prior of the data and the hypothesis. The posterior is defined as the probability of the hypothesis H being true given the data D . The likelihood is the probability of observing D given that H is true. The priors are the respective probabilities of D and H . Equation 3 illustrates the relationship.

$$P(H|D) = \frac{P(D|H)P(H)}{P(D)} \quad (3)$$

The ARM task can be restated as finding the association such that an item-set D provides evidence to an item-set H in the form $D \rightarrow H$. Using

this new formulation, and approximating probabilities from data, it follows that confidence is equivalent to the posterior $P(H|D)$, and local support is equivalent to the likelihood $P(D|H)$. In this chapter, LMC is designed to find atomic rules when the likelihood is at least 50%, describing associations that are better than random choice for the item in H . Equation 4 illustrates LMC for a rule of the form $a \rightarrow b$, where a and b are items in the dataset.

$$\text{LMC} : P(a|b) \geq 0.5. \quad (4)$$

LMC–FRM Comparison

Difference between FRM and LMC mined rules were evaluated using five datasets commonly used in ARM literature: the Chess, Accidents, Retail, Mushrooms, and T40I10D100K available at <http://fimi.ua.ac.be/data/>. A miner extracted all possible atomic rules from each dataset, and illustrates which rules pass FRM and LMC criteria. To extract all atomic rules, the miner scanned each dataset once and recorded all pairwise combinations, keeping counts of rule appearances, and individual item appearances. For example, given a transaction $T_k = \{a, b\}$, atomic rules $a \rightarrow b$ and $b \rightarrow a$ were extracted. Subsequently, rules were selected by applying LMC after each dataset was scanned. Any possible rule in the dataset follows that $\text{Conf}(r) \geq \text{Supp}(r)$, as the $\text{Supp}(X) \leq |D|$ generating a triangular rule region in the support/confidence plane. Figure 2 illustrates the triangular rule region with the boundary support = confidence. Furthermore, Fig. 2 illustrates the FRM region delimited by the min-support, min-confidence thresholds, using the following values for best visualization: min-confidence = 0.5, min-support = 0.1, and min-support = 0.002 for the Retail and T40I10D100K datasets. Fig. 2 also shows all the atomic rules available in each dataset, and highlights rules that pass LMC. Depending on the dataset, LMC can extract rules from any part of the triangular rule region, where FRM is bound to the rules made available by the min-support and min-confidence thresholds. Although all LMC rules might not be of use, the

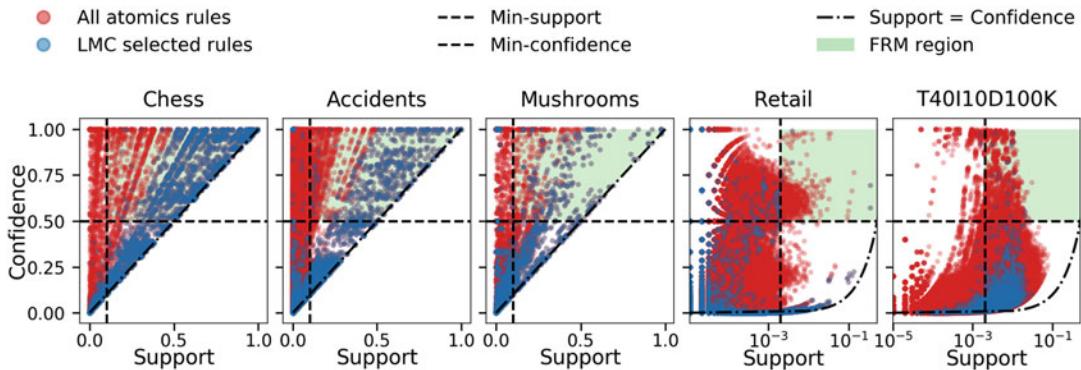

Fig. 2 Distribution of all possible atomic rules in each dataset. Rules in the FRM region pass the min-support and min-confidence thresholds. LMC rules are highlighted, and depending on the dataset, LMC rules can come from any

location on the triangular rule region. Log scale is used to display the support axis for the Retail and T40I10D100K datasets

exploration of space provides the user with information about the application and helps to guide the knowledge extraction process, and recorded all pairwise combinations, keeping counts of rule appearances, and individual item appearances. For example, given a transaction $T_k = \{a, b\}$, atomic rules $a \rightarrow b$ and $b \rightarrow a$ were extracted. Subsequently, rules were selected by applying LMC after each dataset was scanned. Any possible rule in the dataset follows that $\text{Conf}(r) \geq \text{Supp}(r)$, as the $\text{Supp}(X) \leq |D|$ generating a triangular rule region in the support/confidence plane. Figure 2 illustrates the triangular rule region with the boundary support = confidence. Furthermore, Fig. 2 illustrates the FRM region delimited by the min-support, min-confidence thresholds, using the following values for best visualization: min-confidence = 0.5, min-support = 0.1, and min-support = 0.002 for the Retail and T40I10D100K datasets. Figure 2 also shows all the atomic rules available in each dataset, and highlights rules that pass LMC. Depending on the dataset, LMC can extract rules from any part of the triangular rule region, where FRM is bound to the rules made available by the min-support and min-confidence thresholds. Although all LMC rules might not be of use, the exploration of space provides the user with information about the application and helps to guide the knowledge extraction process.

Basic Rule Mining Example

This example compares LMC and FRM miners. The goal is to cluster items from a synthetic timeseries according to their generating process, including the extraction of rare rules.

Methodology

A timeseries generator simulates processes emitting common and rare items. Using an observation window of fixed size, two miners extracted all atomic rules created by pairing the first item of the observation window with all remaining items. Then, each miner is applied a primary and secondary rule selection criteria and graphs are created using the resulting rules. When independent subgraphs formed, each subgraph was considered an item cluster that represented a generating process. For primary rule selection criteria one miner used LMC. For comparison, the FRM miner used a min-support threshold that was set using heuristics to 0.1. The selected heuristic assumed all items were equally likely to appear, i.e., 1/7, and rounding down to one decimal point.

The timeseries generator mixed two processes: (1) a common process $p_r(t)$ that frequently emitted random items and (2) a rare process $p_c(t)$ that occasionally emitted a specific pattern of items

denoted as a chain. The process $p_r(t)$ sampled vocabulary $V_r = 0, 1, 2, 3$ using a uniform distribution. In contrast, $p_c(t)$ used vocabulary $V_c = 10, 11, 12$ to emit the chain $10 \rightarrow 11 \rightarrow 12$. Chain items were always emitted in the same order, but the timing between items varied uniformly, sampled from the integer interval [1, 10] items. The timeseries generator filled the gaps between $p_c(t)$ emissions with items from $p_r(t)$, resulting in a dense timeseries. Additionally, the timeseries generator used 1000 sampled items from $p_r(t)$ and 20 chains from $p_c(t)$. $p_c(t)$ chains were uniformly distributed throughout the timeseries and could not overlap. Equation 5 shows an excerpt of a generated timeseries ts , with the items emitted from $p_c(t)$ highlighted.

$$ts = [\dots, 0, 2, 3, \mathbf{10}, 2, 0, 0, \mathbf{11}, 2, 2, 1, 1, \mathbf{12}, 2, 2, 2, \dots] \quad (5)$$

Following FRM's two-step process for rule mining, to improve the subgraph separation, the FRM miner used the following secondary rule selection criteria: (1) a min-confidence threshold of 0.5, matching the threshold on $P(a|b)$ defined in LMC, (2) a selection criterion based on the Bayesian factor, and (3) selecting rules with the highest confidence for each conclusion. Except for the min-confidence threshold, the secondary rule selection criteria were chosen to avoid additional thresholds. Equation 2 shows the estimation of rule confidence where $X = \{a\}$ and $Y = \{b\}$ confidence. The Bayesian factor was estimated using Eq. 6, where the rule $a \rightarrow b'$ denotes atomic rules in the miners final rule set A that have premise a and items other than b as conclusion.

$$\begin{aligned} \frac{P(b|a)}{P(b'|a)} &= \frac{\text{Supp}(r)}{\text{Supp}(a \rightarrow b')} \\ \text{Supp}(a \rightarrow b') &= \sum_{\forall a \rightarrow x \in A, x \neq b} \text{Supp}(a \rightarrow x) \end{aligned} \quad (6)$$

Evaluation

In accordance to the generator's characteristics, performance was evaluated by grouping extracted

rules into the following categories: (1) R_r contained all possible atomic rules that use V_r items, ($|R_r|: |V_r|^2 = 16$) (2) R_c contained all atomic, time-ordered, decompositions of the chain $10 \rightarrow 11 \rightarrow 12$, i.e., $10 \rightarrow 11$, and $11 \rightarrow 12$, ($|R_c|: 2$) (3) R_{rc} contained atomic rules of the form $i \rightarrow j$, where $i \in V_r$ and $j \in V_c$ ($|R_{rc}|: |V_r| * |V_c| = 12$) (4) R_{cr} contained atomic rules of the form $j \rightarrow i$, where $i \in V_r$ and $j \in V_c$ ($|R_{cr}|: |V_r| * |V_c| = 12$), and (5) R_{cv} contained atomic rules which were created from all possible pairwise combination of V_c items and are not in R_c , ($|R_{cv}|: |V_c|^2 - 2 = 7$).

Process separation occurred when miners only extracted rules from the categories R_r , R_c , and R_{cv} , as no rules bind items from the two generating processes. Rules in R_{cv} were not generated by $p_c(t)$. Thus, they are considered a separate category. Rules in R_{cr} and R_{rc} connect the items from $p_c(t)$ and $p_r(t)$ and no process separation is possible. R_{cr} and R_{rc} were defined as independent categories to evaluate LMC's effect on item association between frequent and rare items, when considering their position in the rule. The mining performance metric quantified the extraction rate for a rule category R with size $|R|$ as shown in Eq. 7, where A is the mined rule set.

$$\text{Extraction rate} = \frac{|\forall r \in A \cap R|}{|R|} * 100[\%] \quad (7)$$

A parametric search looked for observation window sizes in the range between [2, 500] items in one item increments. One hundred timeseries were generated for each observation window size. The following evaluation steps used a window size that minimized the chances of extracting rules from categories R_{rc} , R_{cr} , and R_{cv} . The selected window size also ensured that the miners always mined all rules from the R_c and R_r categories. The secondary rule selection methods required the generation of a new batch of one hundred timeseries. Each miner processed the new timeseries and produce results using the secondary rule selection criteria. The performance evaluation measured the average number of times items were correctly separated into generating processes $p_r(t)$ and $p_c(t)$, respectively.

The evaluation found that the FRM miner could not retrieve the items from V_c as their support was around 0.01. Therefore, any atomic rule from $p_c(t)$ will also not pass the min-support threshold of 0.1 due to support's downward-closure property. In addition, sampling extra items from $p_r(t)$ caused $p_c(t)$ chain's support to dilute. In contrast, LMC does not depend on the number of items in the timeseries. Therefore, LMC always retrieved the $p_c(t)$ chain.

Figure 3 illustrates how the rule categories were extracted as a function of the observation window size. Using an observation window larger than the expected item timing of $p_c(t)$ of five samples, LMC always extracted all rules from the R_r and R_c categories, which are needed to separate items according to their generating processes. Rules in R_{cv} were extracted when at least two partial chains were seen by the observation window. An observation window size in the range [5, 8] prevents the extraction of R_{cv} rules. Rules from R_{rc} meet LMC because the rule support is similar to the conclusion support. Thus, $P(X|Y) \approx 1 > 0.5$ and R_{rc} rules are always extracted. In contrast, R_{cr} will never pass LMC and are ignored because the rule support is smaller than the conclusion support, $\approx 20/250$, which illustrates that under LMC, rare premises cannot associate with frequent conclusions. In the LMC miner, the generating process separation task needed to remove

R_{rc} rules from the final set A using a secondary rule selection criterion. The min-confidence threshold always correctly separated the items into generating processes. The Bayesian factor only selected $p_c(t)$ rules and no items from $p_r(t)$ are grouped. Finally, the best confidence per conclusion criterion failed to separate items into two generating processes, because $p_c(t)$ item 10 is always associated as conclusion with $ap_r(t)$ item.

Census and Chemical Exposure Database Mining

The following example compares LMC and FRM miners in a database mining task. The database is the publicly available dataset from Huang et al. [35]. The dataset comprises US census tract information from the American Community Survey (ACS) 5-year summary files for the 2010–2014 period. Moreover, the dataset contains health-related chemical exposure data generated from the 2011 National-Scale Air Toxics Assessment (NATA), specifically air pollutant exposure concentration.

Methodology

Huang et al. reported results for two mining scenarios: (1) mining rules using the socioeconomic variables as premises and chemical exposure variables as conclusions ($S \rightarrow C$), and (2) mining rules within the socioeconomic dataset ($S \rightarrow S$). Huang et al. used min-support of 0.1 and lift ≥ 1 as thresholds for FRM-based rule selection. Here their atomic rule findings are replicated with an exhaustive search, min-support, and lift FRM algorithm and compared the extracted rules to LMC results. Lift is defined in Eq. 8

$$\text{Lift}(X \rightarrow Y) = \frac{\text{Supp}(X \rightarrow Y)}{\text{Supp}(X) \times \text{Supp}(Y)} \quad (8)$$

Huang et al. categorized variables as follows: socioeconomic scores were divided into deciles, chemical variables into quartiles, and age group used the ranges: (0–20), (20–30), (30–35),

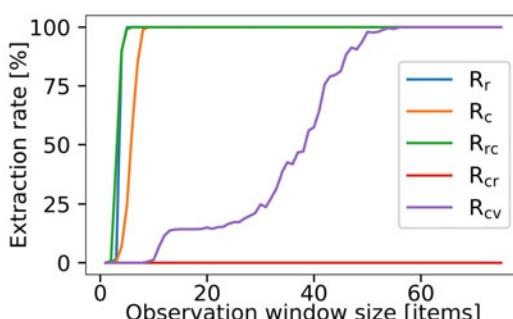

Fig. 3 Search results of observation window sizes for all atomic rule categories. LMC extracts all rules from the R_r , R_{rc} , and R_c categories when the observation window size is greater than the expected value of $p_c(t)$'s item timing. As the observation window grows, LMC extracts rules from R_{cv} , which are innocuous for the generating process separation task

(35–38), (38–40), (40–50), and (50–150). The poverty score was computed as the percentage of population per track that had a ratio between income and poverty level below 1.5. Additionally, deciles seven through ten were combined. Education score was calculated as the population percentage per track that had demonstrated education beyond high school level. Deciles eight through ten of the education score were merged. Finally, the race score was calculated as the percentage of non-White population per track.

Evaluation

Huang et al. [35] analysis provided a relevance criterion to interpret the extracted rules within their field. Therefore, the evaluation goal was to measure how many of Huang et al.’s criteria were extracted by the LMC miner.

For any newfound rule, the odds ratio (OR) was computed using a 95% confidence interval (CI).

The CI was calculated using 10000 runs of bootstrapping, following Huang et al. [35]’s evaluation of rule relevance. Table 1 lists the mined rules from Huang et al. [35] S → C scenario, with their respective support and lift. The LMC miner extracted only five rules from Huang et al.’s 13 rules.

Table 2 lists mined association rules in the S → S scenario. LMC found two out of the six rules reported by Huang et al. Additionally, LMC found three rules, highlighted in Table 2, that did not pass the min-support and lift criteria from Huang et al.

Table 3 shows the odds ratio (OR) and estimated 95% confidence interval (CI) for rules exclusively extracted by LMC in the S → S scenario. The OR analysis showed that the new rules had higher OR than the rules from Huang et al., whose OR ranged from 1.75–3.56. Rules that passed LMC had the largest OR in both mining scenarios. Thus, LMC rules are more likely to appear in a repeat experiment, and therefore LMC rules may be deemed more desirable.

Table 1 LMC’s extraction of socioeconomic and chemical exposure association rules (S → C). LMC mined five rules out of the 13 extracted using FRM. LMC rules had the highest lift

Rules	Support	Lift
Race score = 1 → Diesel = Q1	0.144	1.783
Race score = 1 → Butadiene = Q1	0.142	1.805
Race score = 1 → Toluene = Q1	0.138	1.746
Race score = 1 → Benzene = Q1	0.130	1.653
Race score = 1 → Acetaldehyde = Q1	0.126	1.596

Table 2 LMC extracted five rules in the S → S scenario. Two rules correspond to the FRM mined rules with highest lift, and three rules (in bold) did not pass Huang et al. [35] min-support threshold

Rules	Support	Lift
Age group = 40–50 → Race score = 1	0.172	1.585
Race score = 1 → Age group = 40–50	0.172	1.585
Poverty score = 1 → Education score = 8	0.038	3.919
Poverty score = 1 → Education score = 7	0.034	3.210
Race score = 1 → Age group = 50–150	0.015	2.227

Table 3 Odds ratio (OR) and confidence interval (CI) for LMC extracted rules in the S → S scenario. The 95% CI was estimated using 10,000 bootstrapping iterations

Rule	OR	Est. 95%	CI
Poverty score = 1 → Education score = 8	11.18	10.49	11.94
Poverty score = 1 → Education score = 7	6.74	6.35	7.17
Race score = 1 → Age group = 50–150	5.68	5.10	6.39

LMC rules provide meaningful insight, in particular on rarely, but consistently occurring relations, which may provide application experts new hypotheses to investigate. For example, as seen in the $S \rightarrow S$ scenario of the database mining examples, LMC provided additional rules that hint to a predominantly White ageing population (Race score = 1 → Age group 40–150), and to a correlation between low poverty score and high education levels (poverty score = 1 → education score = 7 or 8).

Rehabilitation Routine Mining

The following example illustrates how LMC can be used to interpret patient behavior during stays at a day care rehabilitation center. LMC and FRM miners try to classify patients into physically active and sedentary groups. However, results show that FRM represents the cohort's average behavior and thus fails to assign patients to groups.

Methodology

The rehabilitation routine mining examples used activity labels from the longitudinal stroke rehabilitation study of Derungs et al. [36]. The study was approved of the Swiss Cantonal Ethics Committee of the canton Aargau, Switzerland (Application number: 2013/009). There were 11 patients in the study, aged 34–75 years, among them five female and four used a wheelchair. In addition, data from a patient excluded from the original rehabilitation study [36] was added to the dataset, for a total of 12 patients.

Patients visited the day care center for approximately 3 days per week over 3 months to participate in individual and group training sessions, socialize with others, and follow personal activity preferences. Some training sessions available to patients were physiotherapy, ergotherapy, and training in the gym. Patients performed activities of daily living, including walking, eating and drinking, setting the table, writing, and making coffee. Behavior of each

patient was recorded for up to 8 h on 10 days at the center by two observers accompanying patients. In addition, body motion was recorded using inertial sensors attached to wrists, upper arms, and tight positions. During the observation time, the examiners annotated patient activities using a customized annotation tool on a smartphone, resulting in a total of 16,226 activity labels. Therapists scored patients for their ability to execute activities of daily living independently using the Extended Barthel Index (EBI) [37]. The EBI consists of 16 categories. Each category receives a score within the range zero to four, where zero means that the patient requires full support, and four means the patient can live independently.

Miners used the start of activity labels as timestamped items and a 20-minute observation window to create candidate rules by pairing the first item of the observation window with remaining items. The miners extracted atomic rules using their respective primary selection criterion. The same secondary criterion was used to filter the resulting rule sets and the remaining rules were assembled into graphs. Each resulting independent subgraph was considered a routine and a study observer assigned a label. The FRM miner's min-support threshold was set to 0.0038 with the goal of selecting the same number of rules as the LMC miner.

Evaluation

Miners were evaluated by submitting their extracted rules to the same post-processing two stage procedure: (1) secondary rule selection criterion and (2) graph-based routine classification. In the secondary rule selection stage, three methods were evaluated: Bayesian factor (Eq. 6), min-confidence threshold of 0.5, and best confidence per conclusion. With the retained rules a graph was constructed and routines extracted as independent subgraphs. For each mining method, the goal was to find the secondary rule selection criterion that provided a balance between activity label count per graph and the number of independent graphs.

A patient's contribution to the resulting routines was analyzed using a patient exclusion process (PEP), where a patient's data was removed from the dataset and resulting routines were compared with routines mined using all patients.

Based on the type of the majority of activities in the routine, a study observer named LMC routines as socializing, eating, using the phone, and intense and balance training. Whereas, FRM routines were named mobility, eating, and cognitive-motor training. Preliminary results showed that FRM routines lacked emphasis on activities related to socializing.

The *Primary Criteria* column in Fig. 4 shows the resulting graphs based on atomic rules extracted by LMC and FRM miners. Activities in both graphs are hyperconnected, i.e., multiple edges connect activities. However, for FRM, there are nodes with one edge. FRM rules do not describe the flow from one activity to another, but rather, the associations of repeating events, e.g., repetitions of an exercise. In contrast, LMC looks for successive activities, and the respective low count of activity transitions vs exercise repetitions does not affect the rule selection. For both mining algorithms, the hyperconnected graph yielded no useful routine information.

With a Bayesian factor ≥ 1 , LMC mined rules focus mostly on self-referencing activities, e.g., walking \rightarrow walking, resulting in single activity

subgraphs. In contrast, the Bayesian factor criterion removed most of the FRM rules. The resulting subgraphs had too few activities to consider them as routines. For FRM rules, the confidence secondary rule selection criterion reduced the graph size, but it was unable to create independent subgraphs. However, with LMC rules, the confidence secondary rule selection criterion selected many self-referencing rules creating two more subgraphs than the Bayesian factor, containing four activities each. Nevertheless, there were too many single activity subgraphs to consider the split as routines. The best balance was obtained between the number of subgraphs and activities per graphs using the best confidence per conclusion criterion. After secondary rule selection, LMC-mined rules yielded five routines, whereas FRM-mined rules yielded only three. Figure 4 illustrates the resulting subgraphs for each mining algorithm and secondary rule selection criteria.

Figure 5 illustrates an example of the changes in routine graphs when removing patients with active and sedentary behavior. For both mining algorithms, when removing one patient, the routine's activity composition varied, but the assignment of routine labels by the study observer did not vary. In the PEP analysis, using the best confidence per conclusion secondary criterion, LMC mined routines that grouped patients into

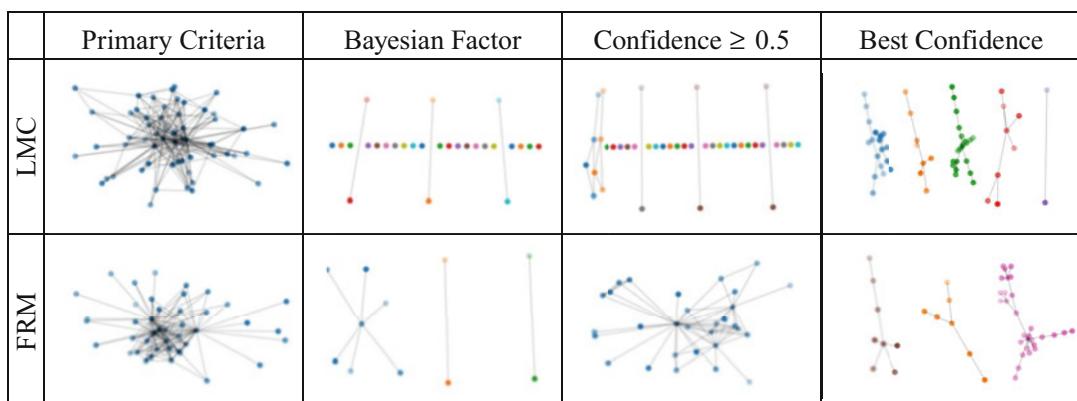

Fig. 4 Graphs constructed using rules derived by LMC, FRM, and different secondary rule selection criterion. Without a secondary rule selection criterion, both LMC and FRM produce a single graph and no useful routine

information is extracted. A balance between activity count per graph and number of independent graphs was achieved using the best confidence per conclusion secondary rule selection criterion

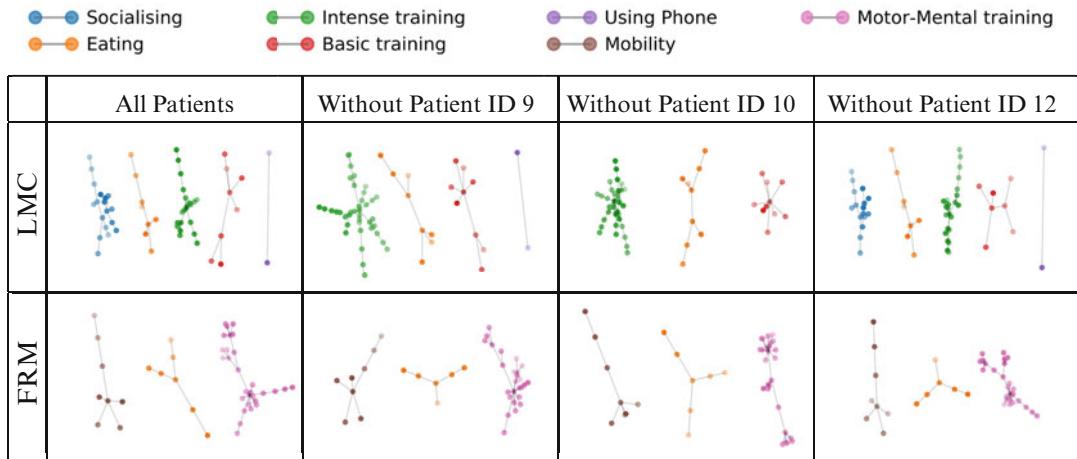

Fig. 5 Routine graphs when patients are removed from the dataset, i.e., PEP method. LMC's focus on rare rules highlights the importance of each individual patient's contribution to the graph representation. With PEP analysis,

physically active and sedentary groups, as indicated by the study observer. Removing patient ID 10 made the routine *using a phone* disappear. Apparently, patient 10 received calls while playing with the phone. The physically active group contained patient IDs 2,4,6,9, and 10. The physically active group refers to patients following their rehabilitation schedule closely. No relation to activity intensity or EBI score was found. The active patient group consisted of one wheelchair rider, patients with different EBI starting points, and some patients, where the EBI score did not change. When a patient from the active group was removed, the extracted routine number reduced to four and *socializing* was always missing. The result appears counterintuitive, as the sedentary group has been likely involved in socializing, but could be explained by the chosen 20-minute observation window, which causes LMC to focus on transitions between activities of at most 20 min duration. Sedentary patients would perform individual activities for periods longer than 20 min. Therefore, their socializing activities would not be associated into rules.

For comparison, PEP analysis for FRM-extracted routines using rules with the best confidence per conclusion found that the removal of any one patient did not affect the extracted

the LMC miner was able to separate patients into active and sedentary behavior groups. In contrast, the number of FRM-mined routines did not change under PEP analysis and no further insight was derived

routines. Therefore, FRM provided no further insight to classify patients into active or sedentary groups.

The rehabilitation routine mining examples illustrated the difference between both association rule mining criteria. Routines mined with FRM did not change during PEP analysis. FRM mined routines that were common to the entire population. With LMC, the routines changed during PEP analysis, grouping patients into active and sedentary groups. Hence, FRM answers the question: Which routines are common among patients?, and LMC answers the question: What types of patients are there?

Conclusions

FRM algorithms can be converted to use LMC by simply replacing the min-support threshold. As most algorithms exploit the support's closure property, and LMC has the same computational complexity as the calculation of support or confidence, there is no complexity penalty on any migrated algorithm. Albeit, the extracted rules will be different.

One limitation of LMC is the sporadic association of frequent premises with infrequent

conclusions into irrelevant rules. A secondary rule selection criterion can help remove irrelevant rules. However, the secondary rule selection criterion of choice depends on the application. For example, in the basic rule mining example a confidence threshold was used to separate items into generating processes, best rule confidence per conclusion worked for the rehabilitation routine mining task, and for the database mining example, no secondary rule selection criterion was needed.

Part of the motivation to introduce secondary rule selection criteria, other than confidence, is that association rules should provide some predictive power [15]. For LMC, rules have a predictive power of at least 50%. In other words, items in the premise of an LMC rule are colocated with items in the conclusion in at least 50% of the transactions. Although LMC was chosen to have better predictive performance than random chance for atomic rules, the 50% threshold used by LMC might be too restrictive. Lower threshold values might be necessary when considering categorical variables in the conclusion or conjunctive rules.

BRM, and in particular LMC, are not a replacement for FRM. The application should drive the choice of algorithm. For example, suppose a dataset contains symptoms, health-related behaviors, and disease outcomes. FRM is better suited to answer questions like “Which behaviours are most conducive to sickness?”. Whereas BRM is better suited to answer questions including “Which symptoms and behaviours correlate to a specific disease?”. The difference between ARM branches is summarized as follows: FRM focuses on extracting rules that describe commonalities between generating processes. In contrast, BRM looks for rules that describe each process.

This chapter showed that LMC does not suffer from support dilution, and that LMC is capable of extracting rare rules. The basic rule mining and socioeconomic examples illustrated how LMC extracted frequent and rare rules. In the rehabilitation routine mining examples, LMC was used to mine rules, create routines, and group patients into active and sedentary groups. Only LMC rules provided patient grouping information. As new medical datasets are investigated, LMC is a

powerful tool when considering ARM for knowledge extraction.

Acknowledgments The authors are thankful for the permission to utilize the datasets used for illustration in this chapter.

Abstract

Artificial intelligence (AI) is making a global impact on various professions ranging from commerce to healthcare. This section looks at how it is beginning and will continue to impact other areas such as medical education. The multifaceted yet socrato-didactic methods of education need to evolve to cater for the twenty-first-century medical educator and trainee. Advances in machine learning and artificial intelligence are paving the way to new discoveries in medical education delivery.

Methods

This chapter begins by introducing the broad concepts of AI that are relevant to medical education and then addresses some of the emerging technologies employed to directly cater for aspects of medical education methodology and innovations to streamline education delivery, education assessments, and education policy. It then builds on this to further explore the nature of new artificial intelligence concepts for medical education delivery, educational assessments, and clinical education research discovery in a PRISMA-guided systematic review and meta-analysis.

Results

Results from the meta-analysis showed improvement from using either AI alone or with conventional education methods compared to conventional methods alone. A significant pooled weighted mean difference ES estimate of ES 4.789; CI 1.9–7.67; $p = 0.001$, $I^2 = 93\%$ suggests a 479% learner improvement across domains of accuracy, sensitivity to performing educational tasks, and specificity. Significant amount of bias between studies was identified and a model to reduce bias is proposed.

Conclusion

AI in medical education shows considerable promise in domains of improving learners' outcomes; this chapter rounds off its discussion with the role of AI in simulation

methodologies and performance assessments for medical education, highlighting areas where it could augment how we deliver training.

Keywords

Artificial intelligence · Medical education · AI in surgical education · Performance assessment · AI in dermatology education · AI in ophthalmology education · AI in surgical education · AI in simulation · Deep learning · Neural networks · Machine learning · Meta-analysis

Introduction

The origins of modern-day medical education can be traced from Alexandria in Egypt, dating back to 3000 BC, to Ancient Greece and the works of Hippocrates and Greco-Roman doctors like Galen of Pergamon who developed an understanding of human and animal anatomy and would encourage his students to examine the bodies of those who had perished in gladiatorial combat. Fulton provides a more detailed account of the history of medical education [1]. In many ways, medical education has not changed very much over the centuries; however, the demands and necessities of modern life make it increasingly apparent that technology will play an ever more important role.

Similarly, concepts of thinking machines have centuries of history, from Descartes discourses in 1637 to Babbage's analytical engines [2]. The automaton was also explored well before antiquity, with biblical references to the times of King Solomon. But according to the Royal Society's archives, Jacques de Vaucanson, an eighteenth-century mechanician from Grenoble, devoted much of his attention to the exploration of

automata, unveiling public depictions of these autonomous machines [3, 4]. These depictions sparked considerable public interest, rhetoric and criticism about mechanical creations. That Voltaire credited Vaucanson as a rival of Prometheus “in his ability to steal fires in his search to give life” encouraged and illustrated the need to educate the public about the origins of machine learning – the medical community is no different needing a shift in our thought process and approach to AI and its applications [5]. From Friar and Marshall’s assembled oeuvre on the motives of de Vaucanson, one particular quote highlights the importance of this viewpoint [6].

...One such motive might be the desire to understand how some part of the natural world actually works. Derek de Solla Price [5] and Silvio Bedini [6] have recently argued that many early gadgets and machines were neither ‘trivial toys’ nor ‘immediately useful inventions.’ Rather, they were simulacra. That is, the devices were models of a very special sort, models ‘... whose very existence offered tangible proof, more impressive than any theory, that the natural universe of physics and biology was susceptible to mechanistic explication.’ [7] This leads Price to reverse the usual interpretation of the relationship between high technology and ‘pure science’ in the Hellenistic and Roman world. It is not the case, he suggests, that ‘... certain theories in astronomy and biology derived from man’s familiarity with various machines and mechanical devices.’ On the contrary, ‘... some strong innate urge toward mechanistic explanation led to the making of automata, and ... from automata has evolved much of our technology ...’ [8]. Another alternative might, of course, be that this urge toward mechanistic explanation led both to the construction of automata and to our practical technology....

In the 1950s, Alan Turing posed the question of whether machines could think, fundamentally forming the Turing test. This test involves a human interaction with a machine, and if an assessor human cannot differentiate between the human and the machine, then the machine is said to be thinking. Ashrafian et al. modified this test in 2014 for more medical implications for machine intelligence [7]. AlphaGo by DeepMind has shown that artificially intelligent agents can learn to become highly adept at certain tasks and show superior intelligence in domain-specific facets that previously were deemed beyond their

intelligence [8, 9]. Failures in how an AI is trained have also surfaced in modern times with one example being the Microsoft Tay, an AI agent that was designed to interact with Twitter users, but which unfortunately inherited chauvinistic tendencies based on the approach used in its training [10]. AI has considerable potential, but like any child starting to learn, it will require the correct type of data and the right guidance to become effective for it to be useful in education. Training when the premise of learning is flawed becomes suboptimal, and so too will the eventual outcome and educational approach. Education here has a twofold self-fulfilling philosophy: training the AI to learn how to educate the medical community and the medical community themselves learning about how the AI learns to teach it to learn optimally.

As this chapter was written during the global COVID-19 pandemic, our current approach to delivering education must evolve to keep up with twenty-first-century lifestyles. The imposed restrictions have also brought into focus the need to recalibrate improvements in work-life balance. However, the introduction of working-time directives has also affected training time and reduced the time to gain the required clinical experience to be deemed an expert in one’s specialty of interest. Therefore, there is an argument for leveraging other approaches to supplement the lack of experience by evolving how training is delivered using a trans-specialty and multidisciplinary approach. AI is a candidate that can support this notion of personalized medical education through agent-based modeling and similar paradigms.

The recent debates surrounding machine learning and artificial intelligence can also be extended to include medical education for clinicians in low- and middle-income countries, thus opening a synergistic global education platform to a wider audience from different cultural demographics. There is also the opportunity for the joint education of members within the clinical multidisciplinary team. By learning together, the team members can foster more of an appreciation for how each member’s role impacts the team-working dynamics and the individual clinical challenges that each must overcome for optimal patient care. This is

paramount from a human factors' perspective not just for effective learning delivery to an ever-changing workforce, but also to safeguard our patients and ensure better outcomes.

Fictional anthropomorphisms for AI have mainly dominated public discussions about their impact on humanity, altering perspectives, be it in a positive or negative way. However, little has been explored for the fact that learning about and understanding the human body and interactions with AI may have aspects where anthropomorphic AI applications become warranted. A prime example being areas related to *in situ* medical simulation where an AI agent may be useful to automate a specific task to improve fidelity and timing and enable fine adjustments to be made to help guide the trainee to the optimal management approach for a task.

Another area that is worth considering, which adds a challenge to AI for medical education, pertains to the various learning style models that exist in education theory. David Kolb's model of experiential learning states that some individuals learn continuously in a process that strengthens specific areas and weakness in our knowledge acquisition. This gives rise to four areas of preferential learning styles: 1) accommodating, 2) converging, 3) diverging, and 4) assimilating. Accommodators prefer a hands-on approach to experiential learning; convergers adopt and test out problems through abstractions to help them better learn; divergers prefer using their own personal experiences to develop widely applicable theoretical frameworks to guide their learning; and assimilators like convergers develop abstract concepts into their own original theories [11–13].

Similarly, Honey and Mumford evolved Kolb's model to four main learning styles – 1) activists, 2) pragmatists, 3) reflectors, and 4) theorists [14, 15] – clearly elucidating that individuals might fall within one or more of these categories. Others such as Gregorc and Butler's mind style model looks into how we think or frame our thought processes, categorizing us into a spectrum of either 1) concrete sensate thinkers or 2) abstract idea generators versus either 3) sequential logic-based linear thinkers or 4) unpredictable

and multidirectional random thinkers [16]. Adding another dimension to the challenge of classifying learning styles, Barbe and colleagues' VARK model highlights important differences between the approaches for 1) visual, 2) auditory, and 3) kinesthetic learning styles [17]. Although some of these models have consistent similarities, each applies to various individual learners, which lends itself to considering a personalized approach to medical education.

Thus, it is unsurprising that our current methods of medical education remain ill-equipped to cater for all these types of learners. Often the status quo attempts to place a learner into a particular style, perhaps due to inherent resource constraints or because the situation being dealt with dictates a particular approach be adopted that may not be suitable to that individual or the organization for that matter. Nevertheless, the best educators and educational systems can identify the needs of the learner and what type of learning style suits them best in a cost-effective way. This is where AI algorithms could potentially augment medical education, and this remains an area of active research [18] as Table 1 summarizes. Identifying the specific needs of the learner and providing decision support that allows them to be effective at what they are learning could lead to a productive workforce with complementary skill sets.

Another point worth mentioning is that most practitioners have genuine concerns about whether AI algorithms will replace them as educators or as clinicians, while others pragmatically question whether an algorithm can be as good as a human medical teacher. We attempt to dispel some of the myths and allay some fears while keeping the conversation open so that both proponents and opposing ideas can flourish, thus emboldening thought and stimulating the discourse that will move the field forward.

In this section, we explore how AI is being used in medical education, its advantages, and pitfalls and where innovations have been made or could evolve to enhance this for medical practitioners. This will not be in the form of the usual rhetoric of dystopian medical universes but

Table 1 The AI models that have been discussed and useful buzzwords that nonengineering medical communities need to be familiar with in the twenty-first-century artificial intelligence for medical education

Author and year	Countries involved	Study group	AI models and platforms discussed and interesting AI buzzwords	Subspecialty discussed
Bastardot et al. 2019 [20]	Switzerland	Undergraduates, postgraduates	Deep learning	AI for radiology image and in cardiology for ECG interpretation
van der Niet and Bleakley 2020 [21]	United Kingdom and Netherlands	–	Artificial neural network (ANN), actor network theory (ANT), object-oriented ontology, INTERNIST I, MYCIN, CADUCEUS	General Calculated Medical Pedagogy and Genomics CRISPR
Lindqwister et al. 2020 [22]	United States	Residents	K-nearest neighbor (KNN)	Radiology curriculum design, preparation, AI topic interest, use of didactic methods, Journal Clubs, pacing and assessment
Carin 2020 [23]	United States	–	Deep learning	Radiology and image and video analysis in radiology, ophthalmology, and dermatology; deep learning as a tool for quantitative assessment
Clancey 1983 [24]	United States	Students	ATTENDING, GUIDON, MYCIN consultation system, Intelligent Computer- Aided Instructional Systems (ICAI)	GUIDON uses mixed initiative dialogue and the MYCIN infectious disease diagnoses framework developed as a computer-based instruction platform for teaching diagnosis
Bourlas et al. 1995 [25]	Greece	Undergraduates, postgraduates, continuing medical education	CARDIO-LOGOS platform, reference model and AI techniques	AI leveraging the page-turning architecture for cardiology ECG pattern recognition
Voss et al. 2000 [26]	Germany	Undergraduates, postgraduates	LAHYSTOTRAIN, Virtual Reality and Intelligent Tutoring System	Artificially intelligent laparoscopic and hysteroscopy trainer and surgical simulator, general surgery
Stasui et al. 2001 [27]	United States	Students	CARDIOLOG	Artificially intelligent echocardiography tutor for cardiology
Kintsch 2002 [28]	United States	Second- to 4th-year medical undergraduates	Latent Semantic Analysis, Singular Value Decomposition, Dimensionality Reduction, Intelligent Essay Assessor	Clinical case summaries using a semantic space construction approach, for history of present illness, physical examination, laboratory data, differential diagnosis in general medical education and clinical psychology
Caudell et al. 2003 [29]	United States	Undergraduates	Touch Simulation Engine, National Computational Science Alliance AG distributed networking	An AI-powered platform for virtual reality simulation and problem-based general medical education

Author and year	Countries involved	Study group	AI models and platforms discussed and interesting AI buzzwords	Subspecialty discussed
Lang and Repp 2020 [40]	Germany	Students	NeuroTronics, with parallels from biology and electronics	Multispecialty education in the form of seminars, guided discussions, and demonstration and concrete development of algorithms. The content and the organization of the events were coordinated by the SciTecMed/NWTmed projects
Frize and Frasson 2000 [41]	Canada	–	Decision-support tools, such as scoring systems, Bayesian models, neural networks, to cognitive models	–
Masters 2019 [42]	Oman	Continuing medical education	AlphaGo, Psychological Reorientation	Teaching across all levels of medicine including continuing medical education and how it is going to continue to evolve
Holden et al. 2019 [43]	Canada	Postgraduate trainees and experts	Perk Tutor Decision tree and fuzzy rule-based assessment, Naïve Bayes, rule-based learners, zero rule regression, support vector regression, linear regression	A configurable assessment method that performs comparably to state-of-the-art methods and provides useful feedback for training
Mirchi et al. 2020 [44]	Canada	Postgraduate trainees and experts/fellows	Explainable AI platform for simulation education, single processing unit known as the perceptron, linear support-vector machine (SVM), virtual operative assistant	Neurosurgery, virtual operative assistant used for objective structured feedback of performance and skills education for a virtual reality brain tumor resection task
Bissonnette et al. 2019 [45]	Canada	Postgraduate trainees seniors and juniors and medical students	Linear discriminant analysis, k-nearest neighbors, naive Bayes, decision tree, support-vector machine, NeuroVR neurosurgical simulator, leave-one-out cross-validation	Spinal orthopedic and neurosurgery, virtual reality hemilaminectomy task skill discrimination between different levels of trainees. Surgical performance and novel metric analysis
Winkler-Swartz et al. 2019 [46]	Canada and Iran	–	Machine Learning to Assess Surgical Expertise (MLASE) checklist, Supervised and Unsupervised Machine Learning, hidden Markov models, support-vector machines, and artificial neural networks	Use of machine learning to assess surgical expertise in virtual reality simulation; it educates and allows a standardized and robust unbiased reporting metric for AI in publications across medical fields
Wang and Majewicz 2018 [47]	United States	Surgeons, novice to experts	Deep learning, convolutional neural networks, kNN (K-nearest neighbor, logistic regression (LR), novel vector space model (VSM), linear discriminant analysis (LDA), support-vector machine, nearest neighbor (NN), novel feature fusion, hidden Markov model, JIGSAWS, multinomial cross-entropy cost, Xavier initialization method, mini-batch updates of gradient descent	

practical applications of AI in medical education. We begin the chapter by presenting a recent systematic review of the literature looking at AI in medical education and discuss specialty areas where influences in AI for medical education are showing promise.

AI in Various Specialty Delivered Medical Education

Literature Review

To identify work that has already been done in AI for medical education, a systematic search of the literature was performed using the terms “artificial intelligence” and “medical education” in the following databases: Books@Ovid November 30, 2020; Journals@Ovid Full Text December 07, 2020; Your Journals@Ovid, AMED (Allied and Complementary Medicine) 1985 to November 2020; Embase Classic+Embase 1947 to 2020 December 07; Ovid Emcare 1995 to 2020 Week 49; Global Health Archive 1910 to 1972; Health and Psychosocial Instruments 1985 to October 2020; HMIC Health Management Information Consortium 1979 to November 2020; Ovid MEDLINE(R) ALL 1946 to December 04, 2020; Maternity and Infant Care Database (MIDIRS) 1971 to November 2020; and PUBMED.

Inclusion and Exclusion Criteria

Primary articles and reviews that made no specific reference to artificial intelligence and medical education were excluded. Included articles strictly discussed artificial intelligence and medical education, referring to them in their title and abstract. Also considered for inclusion were intelligent tutoring systems, but with a discussion on artificial intelligence in medical and surgical education.

Meta-Analysis

A meta-analysis was performed using R (Version 1.3.1093, RStudio Team (2020). RStudio: Integrated Development for R. RStudio, PBC, Boston, MA) and Stata (Stata Corp. 2017. Stata Statistical Software: Release 15. College Station,

TX: StataCorp LLC). A random effects model was implemented with I^2 to characterize the degree of heterogeneity. Ratio of means was calculated using a standardized difference approach as $(Me - Mc)/Mc$. There was no imputation of missing values. A p-value <0.05 was deemed statistically significant.

Bias Assessment

Bias was assessed using the Cochrane risk-of-bias tool.

Results

The search results identified 3102 publications, screened by KL and JD on the Rayyan platform with AN/HA acting as the tie breaker when necessary [19]. A PRISMA flowchart summarizes the results of the systematic review as shown in Fig. 1.

Results from Screening

Figure 1 shows the PRISMA flowchart for the results of the study. Studies were reported between 2000 and 2020. Twenty-eight studies were reviewed in the qualitative synthesis, and three studies were included in the final meta-analysis with one study presenting incomplete data on its standard deviations.

Bias Assessment Result

A significant risk of bias was seen across all the studies selected for the final meta-analysis (Table 2).

Meta-Analysis

Figures 2, 3, and 4 summarize the meta-analysis performed over 3 main studies with 14 sub-studies reporting on improvement over various domains. Majority of the sub-studies were extracted from Cheng et al. 2020 and looked at facets such as the improvement from leveraging AI for pre- and post-learning sensitivity, pre- and post-learning specificity, and pre- and post-learning accuracy. Cheng also looked at gained sensitivity, specificity, and accuracy, whereas Michael and colleagues explored the improvement in knowledge and performance between pre- and post-test scores. Aleman-Fernandez et al. studied an AI-powered

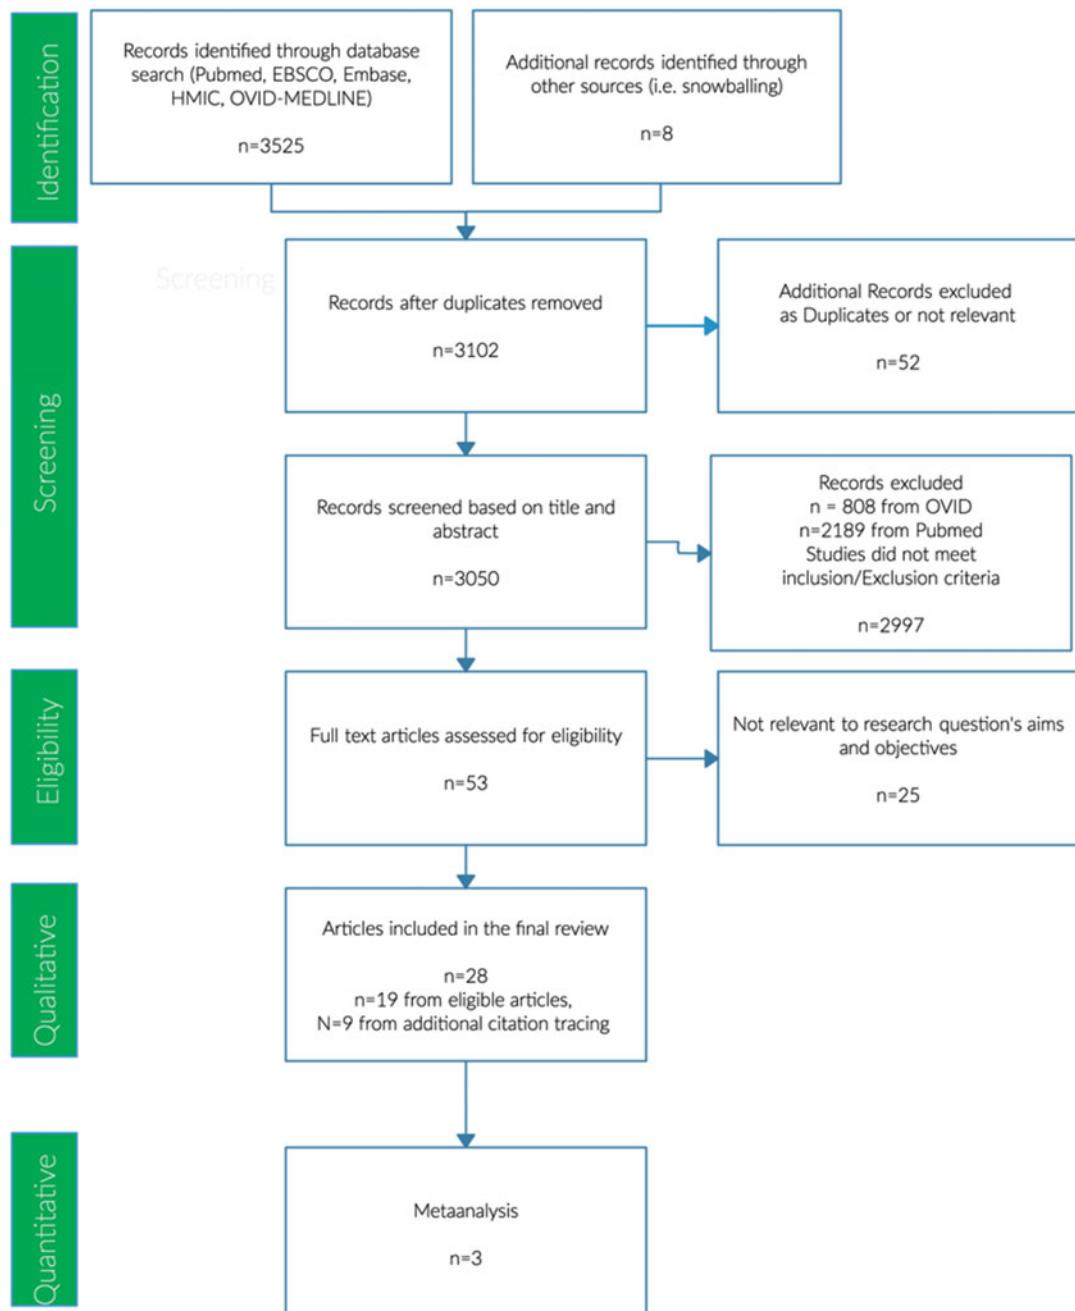

Fig. 1 PRISMA flowchart illustrating the number of articles selected for meta-analysis

intelligent tutoring system compared with a conventional approach.

Improvement from either using AI alone or with conventional education methods compared to conventional methods alone showed 1) a

significant pooled weighted mean difference (WMD) effect size (ES) estimate of ES 478.9%; CI 1.9–7.67; $p = 0.01$, $I^2 = 93\%$; 2) a significant pooled standardized mean difference (SMD) ES estimate of ES 87.8%; CI 0.352–1.404; $p = 0.001$,

Table 2 Cochrane risk-of-bias grid illustrating a high percentage of bias across some of the domains of blinding and allocation. [31, 35, 38].

Table 2 Cochrane Risk of Bias grid	Fernández-Alemán et al 2016	Michael et al 2003	Cheng et al 2020	Final Score
Random sequence generation (selection bias)	High Risk 😕	High Risk 😕	Low risk 😊🏃	66.6% 😕
Allocation concealment (selection bias)	High Risk 😕	High Risk 😕	High Risk 😕	100% 😕
Blinding of outcome assessment (detection bias) (patient-reported outcomes)	High Risk 😕	High Risk 😕	High Risk 😕	100% 😕
Blinding of participants and personnel (performance bias)	High Risk 😕	High Risk 😕	High Risk 😕	100% 😕
Blinding of outcome assessment (detection bias) (Mortality)				
Incomplete outcome data addressed (attrition bias) (Short-term outcomes (2-6 weeks))	low risk 😊🏃	High Risk 😕	low risk 😊🏃	66% 😊🏃
Incomplete outcome data addressed (attrition bias) (Longer-term outcomes (>6 weeks))	low risk 😊🏃	High Risk 😕	low risk 😊🏃	66% 😊🏃
Selective reporting (reporting bias)	low risk 😊🏃	high Risk 😕	low risk 😊🏃	66% 😊🏃

$I^2 = 85\%$; and 3) a significant pooled ratio of means (ROM) ES estimate of ES 94.1%; 0.937–0.944; $p = 0.001$, $I^2 = 100\%$.

Discussion

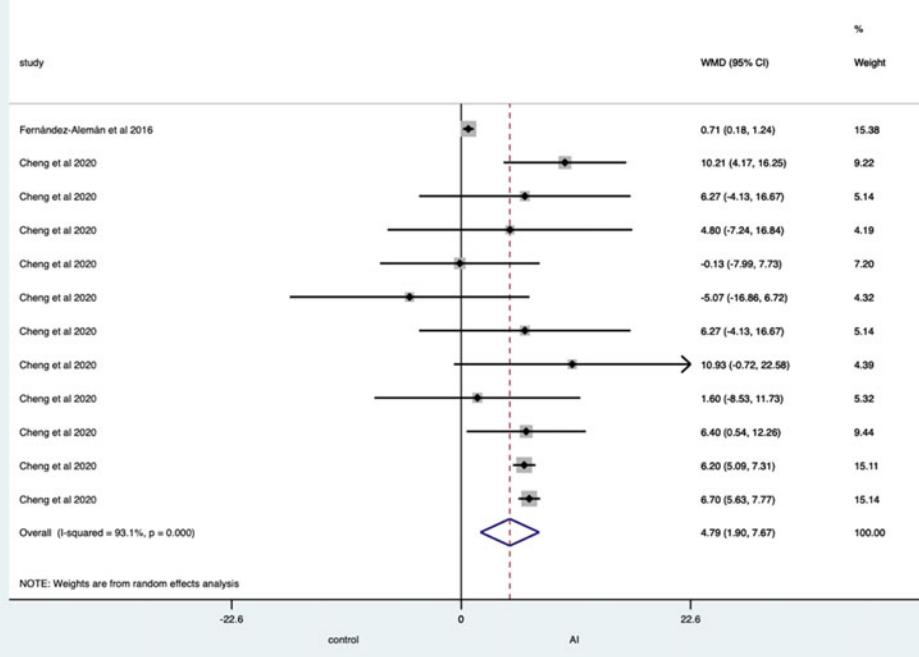

There is sometimes a separatist mentality in the academia of one field being pitched against the other (engineering against medicine with a never shall the two cultures mix attitude), but the boundaries between specialties are starting to blur with the applications of artificial intelligence within medicine facilitating crucial translationally relevant multidisciplinary collaborations. The puritanical practitioners of the latter specialty have on many occasions felt there is no reason to learn a bit about the former and vice versa. Members from the former camp that look at artificial intelligence as purely an engineering and technically demanding concept that only belong to engineers, fail to appreciate that subsets of AI such as deep neural networks derived its inspiration from the latter medical camp. So developing artificial

intelligence was born out of a clinical need to tackle and understand how the human brain works by leveraging either specialties to advance our knowledge, thus creating a cyclical irony of sorts. This chapter considers the interplay between these two specialties to be quintessential to translational innovation that will improve clinician education with the ultimate outcome being improved patient care. And perhaps AI can serve as the glue that unites specialties to answer some of the essential medical education questions and learning theory. Here we performed a very recent addition to the myriad of past systematic reviews that have demonstrated the growing adoption of AI in various clinical subspecialties from the context of medical education.

Meta-Analysis

Our meta-analysis demonstrates that the use of artificial intelligence significantly augments medical education in various domains of improvement, including improved learning accuracy,

WMD

WMD

Study	WMD	[95% Conf. Interval]	% Weight
Fernández-Alemán e	0.711	0.180 1.242	15.38
Cheng et al 2020	10.210	4.173 16.247	9.22
Cheng et al 2020	6.270	-4.129 16.669	5.14
Cheng et al 2020	4.800	-7.236 16.836	4.19
Cheng et al 2020	-0.130	-7.986 7.726	7.20
Cheng et al 2020	-5.070	-16.860 6.720	4.32
Cheng et al 2020	6.270	-4.129 16.669	5.14
Cheng et al 2020	10.930	-0.716 22.576	4.39
Cheng et al 2020	1.600	-8.527 11.727	5.32
Cheng et al 2020	6.400	0.540 12.260	9.44
Cheng et al 2020	6.200	5.086 7.314	15.11
Cheng et al 2020	6.700	5.632 7.768	15.14
D+L pooled WMD	4.789	1.904 7.674	100.00

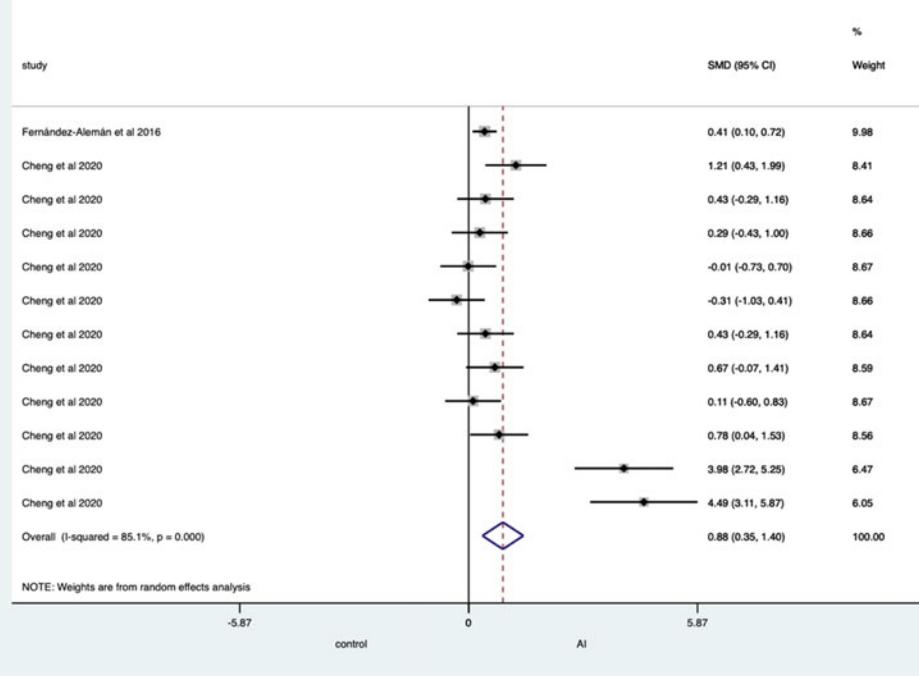

Heterogeneity chi-squared = **158.28** (d.f. = 11) p = **0.000**
 I-squared (variation in WMD attributable to heterogeneity) = **93.1%**
 Estimate of between-study variance Tau-squared = **14.0113**

Test of WMD=0 : z= **3.25** p = **0.001**

Fig. 2 The weighted mean difference using a random effects model supports a 4.789 times improvement of AI in various aspects of medical education over comparator. This would mean there appears to be a 479% improvement

in favor of AI in medical education compared with conventional methods alone suggesting promise in this area and worth exploring

SMD

SMD

Study	SMD	[95% Conf. Interval]	% Weight

D+L pooled SMD	0.878	0.352 1.404	100.00

Heterogeneity chi-squared = **73.75** (d.f. = 11) p = **0.000**
 I-squared (variation in SMD attributable to heterogeneity) = **85.1%**
 Estimate of between-study variance Tau-squared = **0.6964**

Test of SMD=0 : z= **3.27** p = **0.001**

Fig. 3 The standardized mean difference meta-analysis showing a significant benefit for improvement with AI applied to various aspects of medical education. Moderate

degree of heterogeneity is observed with an I^2 of 85% with an 88% improvement for using AI over conventional methods alone

ROM

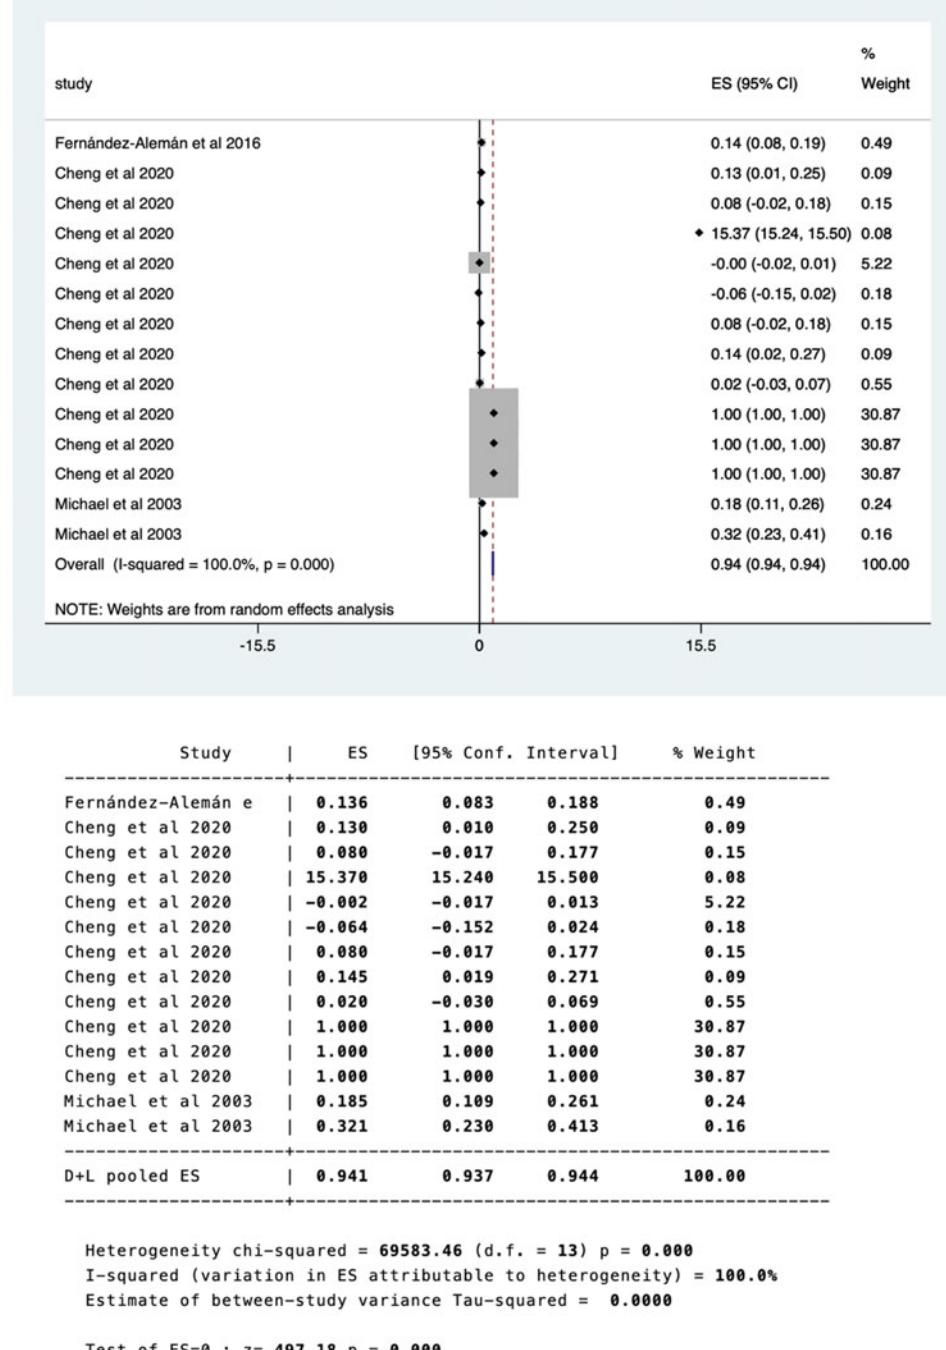

Fig. 4 Ratio of means meta-analysis suggesting significance, but with a high study heterogeneity between study I^2 , but a 94% improvement for using AI in medical education compared to conventional methods alone

sensitivity, and specificity. There is still a chasm that must be crossed between artificial intelligence model explainability and how this impacts model delivery. Skepticism still surrounds the black-box nature of these models. However, it is likely that as evidence continues to accumulate and newer more robust models/approaches to analyze their behavior are developed, the gap that exists between model selection and implementation in education will also close.

Currently, the global community remains open-minded about AI for education but continues to research opportunities to stay in touch with developments in various spaces. In our meta-analysis, study heterogeneity ranged from 85% to 100% commensurate with the model tested. We presented all models 1) for transparency; 2) to demonstrate that this approach may benefit from a standardized regimen as there is yet to be an established consensus on how to meta-analyze projects involving machine learning and artificial intelligence within the global community; and 3) to circumvent and reduce model selection bias as the ratio of means was also robust to missing values of non-reported standard deviations. Thus, selecting a single model may not be the best approach as it is also bias prone.

Proposing a New Method of Unbiased Reporting of Meta-Analysis of Improvement in AI Studies

In our study, the weighted mean difference approach demonstrated a highly significant effect size estimate using a random effects model of 479% improvement compared to not using artificial intelligence and presented the greatest effect size estimate among the three models. In contrast, the ratio of means and the standardized mean difference both showed near-comparable effect size estimates of 94.1% versus 87.8% improvement, respectively, using a random effects model.

Both SMD and WMD factor into their calculations of standard deviations and tend to eliminate absent values within a non-imputed and incomplete dataset. We propose to the community looking at improvement domains to report

all significant effect size estimates from models as either in a standardized or nonstandardized descending order ratio – call it “effect size index of improvement.” For instance, our study presents a ratio in descending order of ES as follows; $\text{WMD}_{\text{RE}}: \text{ROM}_{\text{RE}}: \text{SMD}_{\text{RE}}$ and could either be non-standardised [5.80] or standardised over the highest number of studies used by the models meta-analysed ($\text{WMD}_{\text{RE}}: \text{ROM}_{\text{RE}}: \text{SMD}_{\text{RE}})/14 = [0.414]$, here _{RE} stands for Random Effects, but could equally be the Fixed Effect _{FE} model used). This may eliminate the bias in reporting just the significant model, but also allows the research community to better assess the impact of improvement reported for that AI. Future evaluation of such a metric will help identify the degree of usefulness of a particular AI tool in a meta-analysis and eliminate reporting or model selection bias. There will also be a need to globally standardize protocols for conducting studies for AI in medical education to reduce the degree of study heterogeneity across borders as previously discussed in a recent study [90].

Nonetheless, the fact that early meta-analyses is revealing significant improvement suggests that some perceived benefit does exist for the medical education community to continue to explore the use of AI platforms over the years to come.

The State of Medical and Surgical Training and the Use of AI in Simulation

While surgical training paradigms have scarcely changed since their inception by Halsted at Johns Hopkins over a century ago, and have produced leading surgical personalities of eminence that have left their mark on the wider community [48, 49], this paradigm is now widely seen as in need of a radical overhaul. Trainees now work fewer hours than their predecessors and need to learn a wider variety of surgical techniques and keep up with advancements in surgical theory that are increasing at an ever-faster pace [50]. This has led to calls for change in surgical curricula from junior surgeons and their trainers [51–54], with a great emphasis placed on surgical skill acquisition outside the theatres [55–64]. Several studies have

shown the efficacy of simulation in enhancing the speed of skill acquisition in surgery [65, 66].

Simulation training paradigms vary. Simulation training in surgery can take myriad forms, ranging from training on anatomic replicas of the organs in question, actors, and in a more recent development, emerging novel technologies such as Virtual and Augmented Reality [48, 67–72]. While AI is finding increasing utilisation in many healthcare domains [73] as explained in this chapter, the use of AI in surgical skill acquisition is still in its infancy and there are very few wide-scale applications thereof in surgical training today. Research into AI in non-surgical and non-medical education dates back several decades [74, 75]. Examples thereof include AI-assisted tutors in computer science, mathematics, basic sciences such as physics, and various other domains [75–81]. An example of large-scale deployment of an AI-assisted tutoring program is the Pittsburgh Urban Mathematics Project (PUMP), which was used to help 470 middle school students improve their mathematics skills, and was shown to be effective in helping these students achieve higher grades than their counterparts [82]. Numerous other AI-assisted tutoring programs have shown their efficacy in real-world scenarios and find wide deployment in the classroom. Higher education institutions have recently begun to recognise the importance of educating their students in the field of AI; two examples hereof include the Massachusetts Institute of Technology, which aims to invest \$1 billion to build an AI-focused college, and the University of Oxford, which will institute its first new college in 30 years, Reuben College, with a focus on new technologies including AI [83, 84].

The market size for AI in education is estimated to have a value of about \$6 billion by 2024, with a growth rate that is projected to be 45% [85]. Supranational bodies such as the EU have also recognised the potential impact on Education. The European Commission Science for Policy recognises that “in the next years AI will change learning, teaching, and education,” and declaring it a “political priority” [86]. The increasing availability of AI-assisted education tools proving their utility in real-world classrooms [87], makes it imperative that surgical educators add

this valuable tool to their education arsenal. We need to evolve beyond the limited and few-and-far in between deployment of basic intelligent tutoring systems devised in the last decade of the past century [88], to make use of the astounding advancement in AI in order to better educate our surgical junior trainees, and look towards specialties that have begun to utilise AI in education such as radiology [89]. We hope that this chapter illustrates where the use of AI in surgical education currently stands, and will provide an impetus as to where AI deployment can improve surgical training.

AI in Medical Specialties for Education

In an era of holistic approaches to care, there is a shift toward more personalized healthcare. The ability of an AI to learn without explicit instruction has multiple applications in personalized education in medicine and specifically in the field of radiology. Much attention has been focused on teaching radiology trainees about AI with fear that radiologist roles will be usurped by an AI, but the reverse is beginning to gain traction with multiple institutions investing in using AI to aid teaching radiology trainees to augment their diagnostic capabilities. One study considered AI-augmented radiology education for precision medicine where specific needs-based instruction was tailored to individuals [89]. Currently, multiple successful AI radiological applications have ranged from (i) abnormality detection, (ii) anatomic segmentation, (iii) image quality assessment, (iv) natural language processing (NLP), (v) improvement of protocols and worklists, etc. [90]. The development of intelligent teaching files, which are case-based repositories for radiology, can also be integrated with adaptive learning platforms to facilitate personalized learning [89]. One tool that has been developed is the Adaptive Radiology Interpretation and Education System (ARIES). ARIES is a Bayesian network teaching platform tool that has been effective at distinguishing Neuro-Behcet’s disease from other diagnoses in the basal ganglia neuroradiology network. Table 1 summarizes some of these AI agents and how they have been used to implement medical education.

AI in Ophthalmology, Dermatology, Cardiology, Gastroenterology, and Rheumatology

Image and video analysis in ophthalmology and multisystem interface dermatology education have benefitted from the use of deep learning as a tool for quantitative assessment of pathology. Infectious diseases education has also leveraged intelligent tutoring systems like MYCIN and GUIDON to deliver education on diagnosis using a computer-based instruction platform. Cardiology and cardiovascular physiology have benefitted from using AI for educating learners on echocardiographic studies and electroencephalograms with page-turning architectures developed to achieve these objectives using platforms like CARDIOLOG and CIRCSIM tutor. In gastroenterology, artificial intelligence systems have been developed as e-Learning platforms using preprocessed clinical features and machine learning models such as support-vector machines, artificial neural networks, and decision trees. In general, medical case vignettes for rheumatology using AI-powered web-delivered multimedia-based training platforms have also been reported.

AI in Obstetrics and Gynecology, General Surgery, Orthopedic, and Neurosurgery Education

Obstetrics and gynecology as well as subspecialty general surgery have also benefited from these AI-augmented technologies such as laparoscopic trainers and intelligent tutoring platforms. In system-based learning, locomotor system education requiring descriptive anatomy has also benefited from artificial intelligence augmentation. AI has also been used in orthopedic surgical education and for fracture classification and didactic analysis such as the TELEOS project for screw fixation, AI system for hemilaminectomies, virtual operative assistance, and virtual reality systems for procedural teaching and performance assessments [91].

AI for Surgical Performance Assessment

Surgery is a discipline that carries inherent risk. For surgeons in training, accurate and reliable assessment of performance is therefore critical. However, while surgery has often been compared to other

disciplines with similar levels of risk, such as aviation or motor-racing, the assessment of surgeons is much less sophisticated than in these fields. Seminal work from the Michigan Bariatric Surgery Collaborative in 2013 demonstrated the importance of assessing surgical performance, finding a direct relationship between performance and patient outcomes [92]. Performance assessment should not be limited to surgeons in training only. While surgeons may complete training and are deemed capable of independent practice, the continuous introduction of novel techniques and technology demands the need for reliable and objective measures of performance. The development of reliable and efficient performance scoring systems could therefore have far-reaching consequences including the accurate determination of learning curves for novel techniques or technology, revalidation of surgeons, determining patient selection of surgeons, and selection of doctors for surgical training programs.

Surgical training is broadly based on an apprenticeship model, and as a result, performance assessment is still largely delivered by the expert mentor. However, means do exist for more objective measures of performance assessment. Observer rating tools such as the Objective Structured Assessment of Technical Skills (OSATS) [93, 94] require experts to rate performance of tasks on a procedure-based checklist as well as a global rating scale. Such techniques have also been adapted for minimally invasive techniques [95, 96] or to be procedure-specific [97]. However, these tools require expert assessment, are time-consuming, and are prone to rater bias.

The modern-day operating room now offers a wealth of data including sensor, kinematic, and video data. AI allows surgeons to capitalize on these heterogeneous datasets and move away from blunt indicators of performance such as operative time and postoperative outcomes. The use of AI has the promise of rapid, automated, objective, and reproducible surgical performance assessment which would allow continuous feedback limited only by hardware and without the need of an expert assessor.

Current surgical robotic platforms allow precise mapping of the movement of its instrument arms, and tools such as the dVLogger (Intuitive Surgical,

Sunnyvale, California) have allowed the recording of kinematics and video data. The use of these kinematic datasets can be leveraged to provide objective and constructive feedback to the surgeon. The simplest way to translate this kinematic data is its conversion into global movement features. These range from time to completion, speed and number of hand movements, path length, force, and torque. These metrics have been successfully processed via a variety of machine learning techniques such as k-nearest neighbors, logistic regression, and support-vector machine to achieve good accuracy in determining expertise level in robotic benchtop tasks [98]. While they are able to give a generic measure of technical ability, the clinical utility to a training surgeon is limited. It is more important for surgical trainees to understand why they have been classified as a novice than simply that they are one.

Deep learning allows models consisting of many processing layers to process and learn from the input data achieving state-of-the-art results in pattern recognition [99]. As a result, deep learning is an ideal candidate for feature extraction. Use of convolutional neural networks (CNN) can translate kinematic data into interpretable feedback for surgeons. The utilization of a class activation map can inform which part of the task plays a significant part of the model's decision when evaluating the skill level of the surgeon [100]. Therefore, surgeons are able to identify which behaviors are specific to a certain skill level and thus identify good or bad behaviors. Moreover, CNNs have also successfully predicted OSATS scores, and class activation maps have been similarly applied in order to identify key aspects of the task influencing the score [100].

Although assessment of surgical performance using kinematics has largely been in benchtop tasks, they have also been applied to real-life surgery. A study investigating automated performance metrics (APM), motion-tracking and events metrics, in 100 robot-assisted radical prostatectomies (RARP) has shown experts perform the four key steps of the procedure faster with less idle time and travelling less distance [101]. Further clinical significance of measuring APMs is in its applicability to patient outcomes. The use of APMs alongside machine learning algorithms

has been shown to be able to predict length of stay [101] and also long-term outcomes such as continence following RARP [102].

Data used for surgical performance assessment is not restricted to kinematics only. Surgical video datasets of laparoscopic cholecystectomies have been processed to allow spatial detection of surgical tools based on the region-based convolutional neural network, Faster R-CNN [103]. This output allowed qualitative and quantitative analysis of tool movements such as usage patterns and motion economy in order to predict surgical skill and performance that was consistent with expert ratings.

The application of artificial intelligence for surgical performance assessment shows significant promise. Surgeons of the future will be able to obtain automatic objective analysis of intraoperative performance, which will accelerate surgical education and allow surgeons to advance up learning curves, first as a trainee and then continually throughout their career.

The use of AI for surgical performance assessment, however, is still in its relative infancy. A large proportion of work has been undertaken on the JIGSAWS dataset [104], an annotated open-source dataset of kinematic data, video data, and manual annotations of eight surgeons performing various benchtop tasks. Future advances in AI-driven surgical performance assessment are dependent on the increasing availability of such datasets. The advent of surgical video datasets such as Cholec-80 and Lapsig-300 is promising and may provide the impetus for more units to develop their own datasets [105, 106]. The focus for future AI assessment tools, now, must not only be accuracy but also provision of targeted and constructive feedback for surgical trainees, which is clinically relevant.

AI for Precision Examination and Ethico-Legal Aspects of Medical Education and Autonomous Robotic Surgical Regulation

Another area is precision examination and exam practice, where artificial intelligence is being designed and implemented both to mimic human actors in understanding decision-making and to help to tailor questions for revision aids. The

United States Medical Licensing Examination is one such area that teams like Beam and Colleagues at the Department of Biomedical Informatics in the Blavatnik Institute at Harvard Medical School are developing AI models for trialing [107]. Other algorithms such as natural language processing have been considered to aid a scoring system for USMLE [108, 109]. Companies such as CloudMex AI's deep learning model were able to outperform doctors taking the USMLE exam by 10% improvement. Doctors working with CloudMex had a significant improvement in a simulated USMLE exam scores compared with average doctors taking the same exam. Group 1 were human doctors averaging 75% (range 68–81%) which was less than the CloudMedx AI score of 85%. Impressively, Group 3 human doctors along with CloudMedx AI scored 91% [110]. Undoubtedly, the combined medical intelligence of an AI with the human doctor can be beneficial to the patient and improve outcomes.

For completeness, we also briefly mention the need for legal, regulatory, and ethical frameworks for AI tools developed both for medical education and for standard development of protocols for autonomous robotic surgery. This is an area that is necessary to help identify accountability, culpability, and liability. If an autonomous agent is taught/trained to perform an independent robotic procedure and does it erroneously leading to harm, the question of who is responsible needs to be considered and a subject of considerable debate. So too is the question of who is responsible if an autonomous agent teaches a learner erroneously that then impacts negatively on medical practice, thus leading to a clinical error. Safety critical systems for AI and cybersecurity are also worth mentioning as the community becomes dependent on the digital infrastructure that an AI is built on where vulnerabilities could lead to autonomous agents being hijacked by attackers with devastating safety and economical consequences [111].

Conclusion

AI continues to be used in various medical subspecialties to augment education and has a growing impact across the board. Medically, various

subspecialties are seeing the need for artificial intelligence. This chapter's systematic review and meta-analysis show that there is a potential for AI to augment educational needs in medicine and support workforce training and performance needs. AI-powered surgical assessment also offers the potential to revolutionize surgical education by providing surgeons with continuous and reproducible feedback on their intraoperative performance. There have been several discussions about the challenges faced and the black-box nature of how some artificial intelligence models like neural networks work in their classification. For strong opponents of AI based on explainability for most applications including medical education, there is a counterargument that just because we do not completely understand how our brains work perhaps does not mean we should not use our brains to solve problems. To which the opposing view would be that just because we know how to and can use our brains but do not completely understand how does not mean we should stop trying to understand how it works. Both points of view are valid, and in the context of education where we seek knowledge by learning, understanding, and implementing what has been learned, we must appreciate how both sides of the coin work by staying open-minded. As we use machines to enhance education and its delivery, we must also start to learn from how these machines are behaving to help design better systems to benefit society. The interaction must be bidirectional allowing us to improve ourselves from an educational perspective while improving and discovering better AI to further augment education.

Abstract

Artificial intelligence (AI) applied to the genome sciences has the potential to revolutionize healthcare. Yet to fully harness the predictive power of AI, at least in the fields of oncology and infectious disease, evolutionary

theory must be brought to bear. In oncology, AI is uniquely suited to analyze the complex lattice-work of correlations among the many genomic and environmental influences that constitute cancer risk. It also makes possible the evolutionary theory-inspired concepts of next-generation cancer treatment, such as evolutionary traps, adaptive therapy, and treatment vaccination. In infectious disease, AI promises the rapid diagnosis of a pathogen's current drug resistance profile, as well as the prediction of its potential to develop resistance. Using anticipatory diagnostics, drug regimens can be tailored to probabilistically channel pathogens toward less resistance-prone genotypes to avoid the emergence of resistance. Advanced computational methods are also used in antimicrobial drug design and to anticipate

outbreaks of infectious disease and the evolution of epidemics, such as the SARS-CoV-2 pandemic. In detailing these advances, we discuss illustrative examples of the productive collaboration of data scientists, evolutionary theorists, epidemiologists, and clinicians. In addition, we briefly note the dangers of over-reliance on advanced computational tools that involve “black box” algorithms and question whether they undermine the synthesis of Mendelian genetics and Darwinian theory. Yet, insofar as evolutionary theory is used for hypothesis algorithm development and AI for data creation and analysis, this problem may be avoided, and the potential of both will be realized.

Introduction

Research during the COVID-19 pandemic highlights the technological progress driving improved understanding of the evolution and etiology of infectious disease. Numerous ongoing studies and collaborations continue to track changes in the SARS-CoV-2 genome and to evaluate the frequency of new variants as they spread in human populations. Notably, the discovery of the B.1.1.7 variant in late 2020, and the consequent association with higher transmissibility, led directly to new lockdown measures in the United Kingdom and to other public health policy changes in countries across the world.

The success of these projects depends entirely upon improvements in technological sophistication: even a decade ago, this level of variant tracking would not have been possible. Data are now rapidly analyzed on novel platforms that rely, in many cases, on algorithms developed using artificial intelligence. For the first time in history, we are able to use these enormous technological capabilities to model, monitor, and potentially

anticipate how disease changes in its new ecological environment.

Yet a problem may be emerging that has been seen in other areas of evolutionary science: the focus on genomic change, measured using tools generated by artificial intelligence, is not necessarily Darwinian. Rather than making evolutionarily informed predictions about phenotypic change, many, if not all, of the ongoing studies in evolutionary epidemiology rely entirely on observing genomic change.

Understanding the implications of this problem requires a cursory overview of some of the major changes in the evolutionary sciences since Darwin first published his *Origins*. Prior to the modern synthesis, Mendelian genetics and Darwinian theory were entirely separate; they were, however, essentially united in the first half of the twentieth century, largely because of the mathematical contributions of R.A. Fisher and colleagues.

The synthesis of Mendelian genetics and Darwinian theory laid the groundwork for population genetics and predictive modelling across the biological world, leading, in the past century or so, to an explosion in output in the evolutionary sciences. Over the past 40 years, furthermore, evolutionary theorists have started applying these tools to behavioral trends, genomic change, and even cultural phenomena. Evolutionary theory provides the foundation for making predictions about how phenotypic change will occur; genomics helps us to evaluate, and to better understand, these changes.

The next-generation computational tools that now enable us to track genomic changes in a pandemic also have the potential to help us to predict phenotypic change, given our understanding of the Darwinian forces operating both on us and the pathogens we share with one another. The potential for improvement in the medical world – from public health recommendations to individual care optimization – is boundless, and for the first time, it seems that technology is outpacing our ability to use it.

A consequence of these rapid technological advancements may, however, be overreliance on outputs from algorithms used in the medical sciences. As much of the machine learning is done

“under the hood,” we depend on the data generated so much that we can only react to them, rather than predict them. Artificial intelligence needs an explicit evolutionary framework in order to capitalize on the power of predictive analytics; observing genomic change is not enough. COVID-19 is the perfect illustration of this issue: the new variants now raising alarm are doing so because they appear to be more transmissible than those with which they are competing. Yet from a Darwinian point of view, more transmissible variants are a natural product of circulation within human populations: the virus is fitter insofar as it spreads more effectively. Vaccine escape is also expected when vaccines are employed. Crowding millions of living animals together in market conditions gives viruses ample opportunity to adapt to new hosts, which increases the risk of zoonotic jumps.

And yet, on review of the vast literature developed between late 2019 and early 2021, very little focuses on Darwinian predictions, but rather on genomic observations. Researchers react with surprise to variants like B.1.1.7, which should, rather, have been uniformly expected. The virus’s ecology – namely, human populations – drives its evolutionary change, and the genomics should aid in our tracking these phenotypic changes. Instead, we find new variants that appear fitter and scramble to find out why.

It is difficult not to view this reactivity as a symptom of a “desynthesis” of Darwinian theory and genetics, in a way unraveling the efforts of the modern synthesis of a century ago. Yet, as we aim to show in this chapter, there is a great deal of research in the medical sciences that relies on the tenets of evolutionary selection – with the critical understanding that humans can and do drive the evolution of infectious and non-communicable diseases. What follows is an overview of this work – conceptual, modelling, and empirical – in the studies of cancer and infectious disease.

Mathematical Oncology

Evolutionary selection has a direct impact on the effectiveness of cancer therapy. Dhawan et al. note, for example, that in modern lung cancer

treatment, “...after failure of first line ALK-TKI [tyrosine kinase inhibitor] therapy, another ALK-TKI is administered, though collateral sensitivity is not considered” [1]. The authors challenged this practice by inducing resistance in non-small cell lung cancer cells with an *ALK* rearrangement. Cross-resistance was found for each of the four ALK-TKIs tested, and the authors noted that, despite these findings, oncologists have yet to consider cross-resistance before administering a second ALK-TKI after resistance to a first evolves.

Intuition suggests that if a therapy is likely to fail because of cross-resistance, it should be standard practice to attempt a second-line therapy that works on a different pathway or by a different mechanism than any treatment in the first line. This is not, however, yet common practice, and two factors – namely, underappreciation of the importance of selective pressures created by anti-cancer therapies and, relatedly, a lack of use of artificial intelligence to determine issues, created by evolutionary selection, such as collateral sensitivity – have, thus far, hindered an integrated approach to personalized medicine.

The purpose of this section is to highlight the importance of the distinction between natural, artificial, and unconscious selection in the evolution of drug resistance to cancer treatments and suggest that cross-disciplinary integration of evolutionary theory and data science is essential for future breakthroughs in personalized oncology [2]. To treat cancer drug resistance as a natural phenomenon is to imply it is a result of evolutionary selection, understood as evolution through differential reproduction. Yet once oncologists and researchers are made aware of the influence of their actions on the evolution of drug resistance, the process shifts from unconscious to unintentional anthropogenic selection, a subset of artificial selection. While this is becoming the dominant view in particular research groups, it is not widely appreciated, and awareness of this paradigm may drive its uptake [3].

If this is true, oncologists and researchers may recognize that each aspect of cancer treatment, including type and order of intervention, dosage, and timing, is of evolutionary and therefore

practical significance in oncology – each of which can be adjusted in line with evolutionarily informed predictions generated by artificial intelligence. Work in both modelling and the clinical setting are revealing the enormous potential of this field, sometimes called mathematical oncology [4, 5], which, as with other areas of medicine, is being revolutionized by improvements in evolutionary understanding and technological sophistication. We discuss the evidence thus far in prediction of cancer risk and precision medicine and note future avenues of interest.

Prediction of Cancer Risk

Diagnosing cancer at as an early a stage as possible has significant effects on patient prognosis [6]. A decade ago, Li et al. noted that traditionally used cancer risk models, which rely on a distinction between people without cancer, people with asymptomatic cancer, and people with symptomatic cancer, rely solely on morphology, which, in view of improvements in other areas relevant to oncology, is no longer sufficient for diagnostic purposes [7]. This, according to Li et al., makes distinguishing between people with cancer and people without cancer an important and challenging task [7].

Technological developments and improvements in understanding of genomics have enabled researchers to pinpoint particular heritable genomic mutations linked with cancer risk, including *BRCA1* and *BRCA2* in breast and ovarian cancer [8], *RB1* in retinoblastoma [9], *TP53* in multiple cancer subtypes [10], and *BCR-ABL* in chronic myeloid leukemia [11], though these, and other known heritable syndromes, are not linked with a wide range of cancers, leaving the majority of cancer subtypes without direct genomic links.

The issue of diagnosis is further complicated by the relatively recent realization that many cancers are probably a product of many genomic and environmental factors, which include the still poorly understood human microbiome, lifestyle, and persistent infection. Some viruses, notably human papillomavirus [12], have direct links with cancer, while others, such as cytomegalovirus [13], have

established but indeterminate links with disease. Even strongly correlated lifestyle variables like smoking do not have perfect correlation with any type of cancer, including lung cancer. Zur Hausen [14] notes, for example, that while smoking is common in India, lung cancer is not; lack of consumption of beef may, instead, explain this – and the identification of widespread bovine milk and meat factor infection in Western countries may be playing an underappreciated role.

Together, aside from some standout cases, the majority of cancers cannot be explained by individual factors, whether genomic, lifestyle, viral, or bacterial. Li et al. suggest, instead, that a dynamic system's approach, which accounts for these factors together, as well as tumor clonal evolution, be developed [7]. Improvements in artificial intelligence are, unlike a decade ago, making this possible: the apparently infinite number of connections among the factors described above can now be evaluated in predictive models, which will, over the coming years, allow researchers to stratify patients by a more realistic set of risks of cancer.

Precision Medicine

In *The Origin of Species*, Darwin distinguishes between artificial and natural selection by describing how a farmer selects for qualities in livestock. Animals that display the qualities and traits desirable to the farmer are allowed to reproduce; the others are not. The result, generations later, may be a group of animals with the characteristics the farmer intended. While all the biological changes are still consequences of differential reproduction, the farmer was the immediate agent of selection.

Darwin later introduced the concept of unconscious selection, distinguishing it from “methodical” (or artificial/anthropogenic) selection and from natural selection. Heiser argued that features distinguishing domesticated plants from their undomesticated ancestors may result from this unconscious process: artificial selection may produce some unsought results in addition to the traits the farmer seeks [15]. These unintended traits are products of Darwinian unconscious selection.

An example of unconscious selection is that of competitive release in oncology, where a clinician treats a cancer patient in a way that encourages the development of drug resistance. If resistance is secondary, it should be seen, rather than as unconscious, as a product of artificial selection: the oncologist induces resistance by inadvertently selecting for the clones likely to resist the targeted therapy, immunotherapy, chemotherapy, and so forth. Once sensitive cells are eliminated, the resistant cells are able to propagate without the inherent restraint of intratumoral competition.

Like the farmer's artificial selection, the oncologist's unconscious selection works via the same mechanism as ordinary natural selection but should be understood in this context as the unintended result of the regimes the oncologist chooses to treat her patients. Artificial and unconscious selection should therefore be seen as two distinct subsets of evolutionary selection that depend on the knowledge state of the agent, and once the distinction is integrated into clinical oncology, drug resistance will necessarily be viewed as a product of artificial interventions.

In the clinical setting, however, having only understanding of this set of distinctions in evolutionary theory is insufficient for personalizing medicine for cancer patients. Artificial intelligence makes implementation of evolutionary theory in oncology possible: not only can we predict how tumors will respond to targeted therapies that eliminate one part of a cellular population, but we can adjust treatment to reflect expected biological changes. Noted examples in the clinical setting that have reached at least phase 1 study are evolutionary traps, where the biological makeup resulting from artificial selection is specifically targeted by a second-line therapy [16], and adaptive therapy, where competitive release is intentionally unreached to maintain intratumoral competition [17, 18]. In the latter case, which is growing in popularity in mathematical oncology, cure is not the intention; instead, patients can live with a slowly growing tumor for an extended period. Other methods, including treatment vaccination of established infectious risks [19], are of increasing interest – and as the broad field of evolutionary oncology grows and our ability to

pinpoint specific cancer causes and adaptive changes improves, the number of evolutionarily informed treatment options in oncology will expand dramatically.

Future Directions

Dujon et al. recently published a paper highlighting issues raised by leading experts in evolutionary medicine and mathematical oncology in an effort to determine which questions in the ecology and evolution of cancer are the most pressing [20]. Overall, the authors determined 84 questions that must be answered as mathematical oncology moves forward, ranging from how to obtain insights from cancers in wild species to how best to evaluate conceptual and mathematical models of cancer progression. The future, the authors note, will necessarily require interdisciplinary collaboration among evolutionary theorists, research oncologists, statisticians, and engineers for the next major transition in the clinical treatment of cancer. While novel therapeutic strategies, such as adaptive therapy, confirm that evolutionary considerations are integral to improving clinical outcomes, widespread embrace of this new paradigm, grounded in the relationship between artificial intelligence and evolutionary reasoning, is essential for reaching the next adaptive peak on the scientific landscape in cancer treatment.

Infectious Disease

Infectious disease is another field at the crossroads of evolutionary theory and artificial intelligence. The dynamic interplay between pathogen and host environment is a paradigmatic case study for evolutionary theory. Selection pressures, for instance, drive the ominous rise in the prevalence of multidrug-resistant (MDR) organisms. With the massive population sizes and short generation times of bacterial colonies, resistant strains readily emerge when subjected to strong selection pressures from the immune system and antimicrobial drugs, as Darwinian theory accurately predicts.

The European Centre for Disease Prevention and Control (ECDC) maintains the antimicrobial resistance interactive database, EARS-Net, which documents the strong correlation over time between increasing antibiotic use and increasing prevalence of antimicrobial resistance. The evolution of drug resistance is also studied at the individual level, where resistance can arise in the course of individual therapy, such as during treatment for tuberculosis [21] or for chronic diseases such as cystic fibrosis, where recurrent infections are common [22].

Evolutionary theory is also implicated in the emergence of novel human pathogens. These pathogens cross from nonhuman reservoirs to human populations due to ecological and evolutionary factors, and genetic changes, such as neutral drift or adaptive evolution of the pathogen during chains of transmission in humans, lead to the possibility of epidemic disease [23].

Artificial intelligence is indispensable to analyzing and interpreting the explosion of data accumulating in the genome sciences, and it is revolutionizing the field of infectious disease in the process. For instance, Abudahab et al. describe a machine learning model to go beyond the typical phylogenetic modelling of mutations in the core genome to incorporate non-core elements, such as movement of phage, plasmids, and other mobile elements, enriching our understanding of bacterial evolution [24]. As more genomic, proteomic, and transcriptomic data are combined with clinical phenotypes, and with historical information regarding treatment history and healthcare outcomes, machine learning techniques will rapidly improve our ability to monitor and treat infectious diseases.

The purpose of this section is to demonstrate the importance of evolutionary theory to infectious disease and to show how anticipatory, machine learning diagnostics will be essential for further advances in the field, leading the way to next-generation interventions. We discuss the research specifically in regard to drug resistance, drug design, and emerging pathogens and epidemic disease.

Drug Resistance

Starting in the 1940s, the increasingly widespread use of antibiotics in medicine and agriculture has driven the rise in MDR pathogens. The scope of the problem is vast, and the consequences are dire, with the World Health Organization warning that resistance to antimicrobial drugs has reached alarming levels that threaten the achievements of modern medicine [25]. To counter the rise of MDR organisms, machine learning techniques are poised to help provide novel solutions to urgent problems at the patient and population levels.

At the patient level, genomic diagnostics can decrease the time to diagnosis, rapidly identify a pathogen's current resistance profile, and predict its future potential for evolution of drug resistance by shedding light on intrahost resistance evolution [26, 27]. Studies have shown that machine learning methods can accurately and rapidly predict resistance phenotypes from genotype data for HIV protease and reverse transcriptase [28] and for mycobacterial infections [29]. A machine learning-driven analysis of drug resistance in HIV protease, combining protein structure and sequence, demonstrated that resistance tends to be conserved and that there is a secondary selective pressure to become highly resistant over time, while isolates that do not become highly resistant tend to lose resistance [30]. These insights into drug resistance – inspired by evolutionary theory and made possible by artificial intelligence – are crucial to the development of next-generation therapies.

Computational strategies to quantify the genetic potential to develop drug resistance are also being developed, which have the potential to decrease the likelihood of resistant strains emerging [31]. Evolutionary models can inform these methods in order to design and test multi-drug regimens that utilize different strategies to select against specific resistance mechanisms, for instance, using resistance mechanism inhibitors (e.g., beta-lactamases) and selection inversion using suppressive drug interactions, synergy-inducing drug pairs, and collateral sensitivity [27]. Ideally, these strategies can be used to design drug regimens specifically tailored to channel pathogens toward less resistance-prone genotypes. For instance, using an *E. coli* model, Nichol

et al. show how an optimal drug regimen can probabilistically channel the bacterial population through “genotype space” to avoid the emergence of resistance [32]. By rapidly establishing a genotypic diagnosis complete with a current and potential resistance profile, machine learning techniques have the potential to devise a drug regimen specific to an individual case that minimizes the probability of developing resistance at the individual case level, which would be a revolutionary achievement in the field.

At the population level, artificial intelligence has the potential to inform surveillance of resistance trends on both a local and global scale and predict the emergence of resistant mechanisms, allowing for the preemptive implementation of targeted preventative measures. Since bacteria are exposed to antibiotics not only in the human body during therapy but also in veterinary medicine, agriculture, and aquaculture, an inclusive, multidisciplinary approach to infectious disease and drug resistance is necessary to effectively address the problem. Metagenomic and functional metagenomic studies show that bacteria harboring resistance genes are present in all ecosystems, for example, in the soil, the human gut microbiome, and extreme environments, such as permafrost [33]. Therefore, environmental monitoring for drug resistance genes will be an important component of an ideal model for anticipatory diagnostics. Beyond surveillance, advanced computational methods have the potential to determine optimal strategies for combating infection and epidemic disease. Factors such as the timing of antimicrobial therapy, choice of drug regimen, drug cycling, and ecology can be manipulated to optimize patient outcomes and minimize the degree of drug resistance [32, 34]. Continued cross-disciplinary collaboration involving ecoimmunology, disease ecology, and data science is crucial to realizing the potential of artificial intelligence at the epidemiological level.

Drug Design

Antimicrobial drug design and vaccine development are being revolutionized by artificial intelligence. The process by which such computational methods can be utilized is explained well by Park

et al.: “A novel method for *de novo* compound design combines deep learning with reinforcement learning, which estimates the statistical relationship between possible actions and outcomes. Neural networks are trained to generate chemically feasible compounds and predict their chemical properties. Then, using reinforcement learning, the program becomes biased towards compounds with desired physical and biological properties” [35]. Such computational methods will integrate multiomics data to elucidate and anticipate target specificity, molecular effects, and pharmacodynamic, pharmacokinetic, and toxicological characteristics of pharmaceutical compounds. In addition, genotype-phenotype correlations on a large scale will have the power to reveal novel resistance genotypes as potential targets for intervention. Studies in the intrahost evolution of Lassa virus, for instance, found that mutations accumulate in epitopes of viral surface proteins, suggesting selection for immune escape and also potential targets for targeted prevention and intervention [36]. This detailed knowledge of viral genomics could be used to develop antiviral drugs to anticipate and interfere with the known pattern of mutations that result from antimicrobial-induced selection pressure. To wit, machine learning and reverse vaccinology were successfully used to identify six potential vaccine target proteins in the SARS-CoV-2 proteome during the pandemic [37].

Emerging Pathogens

Emerging pathogens are of keen interest today due to the SARS-CoV-2 pandemic. Evolutionary models are crucial to understanding how and when pathogens cross barriers from their natural reservoir to human populations. Machine learning methods can identify common risk factors for emergence and highlight the relative roles of ecology and evolution [23, 38]. For example, a comprehensive study of all known RNA viruses employed machine learning techniques to show that viral virulence can be predicted by ecological traits, including human-to-human transmissibility, transmission routes, tissue tropisms, and host geographic range [39]. Machine learning methods

also increase the efficiency of biosurveillance and outbreak detection, accurately predict the spread of novel pathogens [40, 41], and enable early case detection and tracking, such as for COVID-19 [42]. Researchers have combined machine learning methods with remote sensing data (i.e., data collected by satellite or aircraft sensors), local sensing data (i.e., data measured on site such as rainfall), and data from online social media networks and search engines to track and predict outbreaks of dengue virus, malaria, Zika virus, and influenza with impressive accuracy [43]. Researchers are also predicting viral mutations even before a new strain has emerged. Salama et al. utilized rough set theory and neural networks to develop a model to predict new nucleotide substitutions in the Newcastle virus with an accuracy of about 70% [44]. As the prediction accuracy of artificial intelligence continues to improve, evolutionary theory-informed data science will yield increasingly powerful and innovative tools to combat problems in medicine.

Avoiding the Desynthesis

Anticipating and reacting to phenotypic changes in disease, across oncology and infectious pathogen studies, is essential both for designing individual treatment regimens and for public health planning. The works cited above highlight the enormous potential of combining Darwinian theory with predictive modelling, and research in the health sciences is the most useful when both are used: instead of reacting to change, we can predict it and use such changes to our advantage.

Avoiding an evolutionary desynthesis, where genomic studies become separated from the predictive power of Darwinian theory, will require continued collaboration between and among researchers in evolutionary biology, engineering, genetics, and public health. Continued collaboration – the fruits of which are obvious in the work noted above – will allow healthcare systems and policymakers to adequately prepare, and, hopefully, prevent, the next virus with pandemic potential from disrupting the world as we know it.

Abstract

It is still early days for the use of AI in medicine, and so the public discourse centers around perceptions of the technology rather than actual experiences. The public have major concerns about data sharing and privacy and the ability or otherwise of the technology to act independently of doctors and human oversight. Regulations are complex and poorly

understood by the public, and media attention focused on recent breaches of trust and security threats has heightened public concerns around sharing sensitive healthcare data, especially with technology companies. However, when given the opportunity to evaluate specific AI use cases, patients become more accepting of data sharing but still expect to be asked for consent or otherwise made aware of their data being used. Companies using public data need to be transparent about its use. Public bodies providing data need to do so transparently and ensure that a greater public good is achieved and distributed fairly across society. Furthermore, developers need to ensure data privacy by design and to make use of innovative technologies being specifically developed for this

purpose. AI technologists need to enter a meaningful and open dialogue with the public and to maintain this throughout their development and adoption pathways. Only by forming true partnerships with the public, putting patients back where they belong, at the center of the discussion, will the field develop to reach its true potential.

Introduction

As illustrated by this chapter, there are myriad applications of artificial intelligence and machine learning to medicine, often involving the manipulation of patient-derived data to power research, provide early diagnosis, or achieve operational efficiencies. While much of this data processing will be invisible to the public, the impact on all our lives will be enormous and depends, to a significant extent, on the provision of access to sensitive data by patients, through consent or other mechanisms.

Future healthcare systems will run on prolific, multisource, patient-derived data. By being able to access and use this data, medical professionals, researchers, managers, and AI software agents will be empowered to provide services more efficiently, safely, and accurately than today. In an ideal world, patients would choose to allow their latest smart device to stream data into their health records or to grant access to companies and researchers developing new diagnostics or treatments. Entrepreneurs with promising ideas would be able to harness data with patient permission, without the need for cumbersome regulatory blocks and administrative overhead, to help create a thriving ecosystem of software and hardware to guide and monitor therapy.

Currently patients have only limited awareness of the applications of machine learning and of AI

in general to medicine or of the importance of, and need for, data sharing in research and development. Patient attitudes to data sharing are shaped by the public debate, and there is much concern around the sharing or leakage of health information and over who profits from their data.

Public trust in the industry is essential, so to fully realize the AI-enabled health data economy, we need to raise awareness of the benefits and provide the means to deliver and distribute the resulting public goods fairly across society. This will require the full awareness, understanding, and cooperation of the data subjects – the patients.

The current regulations are complex and obscure to the public. Governments can play a role in helping to stimulate public debate and by providing further clarity as the technology develops. But it is incumbent on the industry to operate transparently and collaboratively, with patient safety, privacy, and security always in mind.

AIM and the Patient's Perspective

The Need for Transparency

The development and testing of AI for medical applications such as clinical decision-making or diagnosis requires public health or personal health data. Data needs to be of high quality and of known and well-understood provenance. Sometimes several linked datasets may be needed, holding further personal or sensitive information. To ensure a thriving medical AI ecosystem, data needs to be readily available to both public and private organizations. For this to happen, governments and citizens need adequate regulatory regimes that help to create public understanding and trust. Regional statistical data produced for public health purposes are usually not controversial and in many jurisdictions are now made freely available under open-source directives [1–3]. However, data garnered from individuals, even when aggregated or anonymized, usually require consent or another legal rationale governing their use, and for this, the utmost openness and transparency are needed. *N.B. Data are anonymized in different*

ways, and sometimes they are pseudonymized, with the possibility of linking datasets that refer to the same person with a separate key even though all the identifying fields have been removed.

Regulations and Data Sharing

In many jurisdictions, there are specific provisions that determine the permitted processing of personal data. For example, under the UK General Data Protection Regulation (GDPR), organizations will need both a lawful basis (from a specified list) to process personal health data and an additional condition (from another specified list) because health data is sensitive. The lawful basis could, for example, arise from explicit patient consent, or be permitted for the public good, or in order to fulfil a contractual obligation with the individual concerned (such as the provision of treatment). The extra conditions for sensitive data include explicit patient consent, the provision of healthcare or social care, and use by not-for-profit bodies or for public health purposes. Furthermore, each of these conditions has specific detailed provisions that must be met. Where consent is needed, it must be freely given, informed (with stated and understood purposes), explicit, and limited in time and scope to the stated purposes. The UK's Information Commissioner's Office (ICO) [4] states that "*Consent means offering individuals real choice and control. Genuine consent should put individuals in charge, build trust and engagement, and enhance your reputation.*" Also, that service organizations should "*Avoid making consent to processing a precondition of a service.*"

GDPR applies to organizations across Europe and outside of Europe too. It covers the processing of personal information by any entity that offers goods or services or that monitors individuals who are physically located in the European Union (EU).

In the USA, the Health Insurance Portability and Accountability Act of 1996 (or HIPAA rule) requires appropriate safeguards to protect the privacy of personal health information and sets limits and conditions on the uses and disclosures that

may be made of such information without patient consent. However, currently, HIPAA only applies to traditional entities, such as health insurance plans and healthcare providers, but does not apply to software development and other technology companies that may wish to collect sensitive patient-generated data. In these cases, patient consent is obtained under various complex "terms of service" agreements, which hardly anyone reads before accepting.

Under HIPAA, there are no restrictions on the use or disclosure of anonymized health information. Data can be anonymized either by removing specific personal identifiers listed under HIPAA or after sufficient processing for an expert to certify that the risk level for re-identification is "very small." Echoing the UK ICO's call for further guidance in this complex field, the Center for Open Data Enterprise and the Office of the Chief Technology Officer at the US Department of Health and Human Services (HHS), after roundtable discussions with government, industry, and academia, highlighted the need for further clarification and guidance, including specifically updating HIPAA's rules around anonymization to meet modern demands. They also called for further clarification for software developers on the appropriate use of patient-generated data [5].

UK public bodies such as hospital trusts or GP surgeries are regarded by patients as authoritative and therefore in a position of power over them, but under GDPR, they would need to show that consent to access a patient's sensitive information has been freely given. For this reason, there is a different basis altogether to enable healthcare organizations to provide treatment and to share electronic health records for treatment purposes: patient data is held under a duty of confidence (a provision in common law) that allows healthcare providers to operate on the basis of implied consent to use patient data for the purposes of direct care, without breaching confidentiality. This form of implied consent, however, does not allow further uses of the data, such as in machine learning, so AI organizations need to consider GDPR as well, and this applies even for pseudonymized data.

The interplay between common law and the duties of privacy under GDPR is complex, and the ICO admits that greater clarity is needed. In their ruling on the case of DeepMind and the Royal Free Hospital, the ICO stated [6] “*Greater clarity is needed and we are committed to working with other bodies including the National Data Guardian and Health Research Authority, to improve guidance and support to the sector so that healthcare organisations like NHS Trusts can implement data-driven technology solutions safely and legally.*” Under GDPR, the hospital’s role is that of *data controller*, and a technology company like Google Health (formerly DeepMind) would become a *data processor*, able to operate on the data only to the extent specified contractually. The ICO investigation had been triggered by media reports that the Royal Free Hospital had given DeepMind access to unnecessarily large numbers of personal health records, but the ICO later accepted that this was in fact required during the software’s clinical testing phase to ensure patient safety. At the time that the ICO investigated, they found that the Trust had not fully complied with data protection laws, and this was later rectified contractually. The Royal Free [7] later stated “*The data used to provide the app has always been strictly controlled by the Royal Free and has never been used for commercial purposes or combined with other Google products, services or ads – and never will be.*”

In the USA, a patient brought a claim against Google and the University of Chicago, alleging that the University Medical Center had released confidential medical information to Google without proper de-identification. Over 100,000 records had been shared without removing attendance timestamps. A judge dismissed the case on the grounds that the patient had not suffered losses as a result, but the case highlighted the possibility that tech companies could use unrelated datasets (in this case, timestamps from searches or location data from phones) to re-identify otherwise anonymized records [8, 9].

Despite the official findings, these cases have raised media attention and public fears around personal health record sharing with technology companies, and these perceptions were

heightened by the case of Facebook and Cambridge Analytica [10].

The ICO in the Royal Free case commented that “*Organisations must assure themselves and document how they have taken appropriate steps to mitigate data protection risks beyond contractual obligations and the obligation on Google Health under data protection law, such as audits, reports, and other appropriate measures.*” In other words, openness, transparency, and candor are vitally important for public trust.

The Public’s Understanding of AI

Artificial intelligence is a blanket term that is often misused or misunderstood by the media and in popular culture. Compounded by social media’s potential to spread falsehoods and exaggerations, it is no wonder that public understanding of AI and of its role in society is poor. However, there is little doubt that most people have heard of AI and are likely to have views on its uses and dangers.

In a recent US survey on attitudes toward AI, the median respondent predicted a 54% chance that by 2028 AIs would be able to perform most tasks of economic relevance better than humans, with more people believing this to be harmful to humanity rather than beneficial [11].

There are benefits to effective communication by the media. Stories in the popular press can help the public to fathom the real benefits and risks associated with the technology, its actual pace of development, and its current prevalence, but they can also sensationalize aspects of the technology, so we need to probe deeper to discover what patients and the public think about these topics.

According to surveys in the USA and UK [11, 12], most respondents claimed familiarity with AI, but fewer than 15% believed they had encountered it, and only 2% believed it had any current impact on society. Furthermore, there was confusion over those everyday technologies that were in fact powered by AI. Most respondents correctly identified personal assistants and smart speakers as using AI, but only 35% knew that Google Search did so, and fewer than 30%

realized that Google Translate or Amazon's recommendation engines did so.

The Public's View on Data Sharing

Data, of course, is key to the use of AI in medicine, and personal healthcare records are sensitive, being considered by most to be both personal and private. Naively, patients often believe that healthcare records are owned and should be controlled by the patient, and it is possible to imagine a future in which this becomes true through suitable regulation and the technologies described later in this chapter. But, as we have seen, the current situation is a lot more complex and nuanced. It is revealing that in the UK survey, most people did not realize that personal data could or would be used by AI to perform tasks, and around half of respondents were not comfortable with the thought of their personal information being used by AI to perform tasks for them. Personal and operational data are as vital to medical research as they are to AI product development. But a mixed-method study [13] found that almost two thirds of people were unaware that the UK National Health Service (NHS) granted access to such data for research and development purposes. Participants were engaged in a broad and deep discussion on the value of healthcare data to various stakeholders such as patients, the NHS, industry, charities, and academia. This confirmed a high level of interest in how researchers and corporations would use healthcare data. Most people (almost 75%) believed that the public should be involved in decisions about providing specific organizations access to NHS data, and their main consideration was of course the benefits that would accrue to patients. Over 80% of participants were also concerned to ensure that those benefits would be fairly distributed across the country.

This sensitivity to data sharing for secondary purposes, and in particular for AI research, has been seen in many other studies. In the UK, the NHS is the organization that the public most trusts with their personal data if it leads to an improved service or capabilities [14]. Fifty-five percent of

the public trusted the NHS against 22% trusting government, with even fewer trusting pharmaceutical companies (15%) or Internet companies (8%), and surprisingly only 11% trusted charities (academic institutions were left out of the survey). Over half of those surveyed were positive toward AI, but almost the same number were especially worried about their data privacy when AI was involved. An EU consultation found that 73% of EU citizens want to share health data for research and innovation provided the data is secure and only accessible by authorized parties [15]. This high level of acceptability of data sharing for research has been borne out in other studies covering the UK and Ireland. However, citizens still expected to be asked for consent when their identifiable data was used, and enthusiasm was much lower concerning de-identified data to be used without consent [16]. Reasons for concern around de-identification also emerged in several qualitative studies where participants questioned what would qualify as identifying information, whether de-identification could be achieved effectively, whether it was sufficient for the elimination of consent, and whether there were risks of re-identifying individuals. Those surveyed wanted the security of records to be ensured and called for private profit to be capped and for access to third parties to be vetted. In several studies, participants also indicated their preference to retain control over the data in their own electronic health record with explicit opt-in consent and the right to withdraw at any time, coupled with an ability to tailor their sharing preferences for different purposes.

The situation is more complex than surveys can reveal. Citizens' juries enable the public to make considered, informed judgments about complex matters by providing adequate time and a framework for deliberation in a group discussion. Citizens' juries in England [17] were more accepting of data sharing to both private and public sectors after the discussion process. Many participants accepted commercial gain if public benefit was achieved. Data sharing for efficiency gains was acceptable too, provided that the overall aim was public good rather than profit. And, in practical terms, as of October 2020, fewer than

3% of England's NHS patients had used the national opt-out mechanism to prevent their confidential healthcare records being made available for research or planning purposes.

There is widespread belief among patients that they own their healthcare data, even though there is no substance in law for this. No doubt this contributes to the public's data sharing hesitancy. However, when properly informed, patients and the public accept the need for data to be shared with researchers and commercial organizations. They accept that this is necessary and desirable in order to develop AI products and services for public good, provided that there is full transparency and that the benefits are shared across society.

Weighing the Benefits and Risks

Patient experience is what the process of receiving care feels like for the patient and is one of the most important aspects of healthcare provision, strongly influencing patient recall and quality and safety outcomes. For example, in patients undergoing elective surgery, the aspect of experience most strongly associated with a better health outcome was the level of communication with and trust in their doctor [18]. As AI in medicine matures, we should expect that its impact (if any) on patient experience is what will matter most to patients, while healthcare professionals will tend to concentrate more on outcome measures. For further reading, see [19].

It is indeed early days for the use of AI in medicine, and so the public discourse centers around perceptions of the technology rather than actual experiences. However, we can expect patient concerns to center around data sharing and privacy and the ability or otherwise of AI-enhanced technologies to act independently of human control.

A UK study [20] concentrated solely on machine learning (ML) and found healthcare to be the area accepted to have the greatest potential for this technology and where its social benefits most outweighed the potential risks. Despite a low level of understanding of the term ML or of how it

works, the public nevertheless appreciated that computers could improve diagnostic accuracy and medical decision-making by being able to consider more data than doctors. However, participants stressed the need for human doctors to remain involved, to ensure personal contact for genuine engagement and empathy. There was also concern that machines might make broad generalizations about groups of people, rather than producing a tailored or individual response, and that this could lead to an inaccurate diagnosis, which could have far-reaching repercussions for a patient's treatment options and well-being. Despite this, people readily appreciated that machine decision-making could be more accurate and less error-prone or subject to bias than that of a human. They also understood the benefits of ML for resource allocation and public health and its potential to reduce pressure on public services.

In the UK, media attention has focused on negatives of increasing automation such as cybersecurity breaches (e.g., the WannaCry ransomware attack) and some notorious deals between specific hospital trusts and technology companies (e.g., Royal Free Hospital and DeepMind) and on government mishandling of data sharing practice (e.g., Care.data [21] and the sharing of patient data for immigration control [22]). The WannaCry attack in May 2017 did not specifically target the NHS but nevertheless had widespread impact, causing significant disruption and public attention [23].

In the USA, cybersecurity attention has been focused on the targeted theft by hackers of medical records from health insurance and technology companies. The largest to date was Anthem Insurance Company who suffered an attack by a foreign government in 2014, resulting in the loss of 80 million personal data records [24]. In fact, according to Accenture, one in eight consumers in England and one in four consumers in the USA had their health data stolen from healthcare service providers [25].

The Facebook/Cambridge Analytica scandal broke in 2018 on both sides of the Atlantic. The affair brought to the public's attention the possibility of their personal data being used for unspecified purposes and that it may even have been used to influence their political judgment in

the 2016 US election [26]. This contributed to the Federal Trade Commission's decision to fine Facebook \$5 billion and to impose a structure of accountability, transparency, and oversight.

For AI technology to be effective and universally applicable, there is a need for developers to have increasing access to volumes of high-quality health and lifestyle data, and, as we have seen, this generates a tension between personal privacy and consent. Regulation can go some way to address this tension, but there are specific issues of intellectual property ownership and commercial interests and ethical issues such as ensuring equality of access and lack of bias that, for AI, demand even more transparency, candor, and trust than for other digital technologies.

In written evidence to the UK House of Lords AI Committee, the ICO stressed the need to prepare the public for the more widespread use of AI especially in terms of transparency and effective regulatory oversight [27]. With the possibility of AI-enabled technologies making significant decisions about people, with perhaps little or no human oversight, it becomes clear that data protection rules have become more relevant than ever and if applied effectively can help to protect individuals, mitigate risk, and allow society to reap the benefits of AI technology.

As we know, the use of AI in medicine is growing at pace, and there is clearly a lot of scope for further dialogue with the public, so that society can understand and weigh AI's real benefits and risks when applied to medicine. Only then will patients become empowered to exercise their rights and be able to hold practitioners to their obligations. In this respect, governments can help to build public trust and confidence in the technology as well as explain the risks.

There are further issues that could be explored in AI ethics, bias, explainability, and real-world behaviors that are discussed in the research literature and are beginning to enter public discourse. These issues will no doubt become more prominent and relevant to patients as the field matures.

In the UK, regulators have begun to discuss how they should approach regulatory issues in AI, and in both the UK and Canada, regulatory sandboxes have been set up where patients, providers,

clinicians, suppliers, and regulators can experiment with pilot projects in a "safe space" [28, 29]. In the UK, the principal digital transformation body, NHSX, is attempting an integrated approach across the different regulatory bodies [30]. In the USA, the FDA concentrating on AI in medical devices has spelled out some of their key issues including regulation across the lifecycle, transparency and labelling, algorithmic bias, and change control for devices that are able to learn once deployed and in the field [31].

Levelling the Playing Field

We should be mindful of the need to maximize the value created from data generated using public funds and of the social benefits and efficiencies that can be gained from its more liberal use. This is particularly important where healthcare is provided for free at the point of care, as it is in the UK.

Some data is publicly owned (as it has been paid for by public bodies), while other data is commercial (funded and held privately). The distinction is often blurred (especially in the public mind) as it is often necessary for public data to be labelled with metadata and appropriately enhanced by technology companies in order to render it useful for AI development. Indeed, there is a need for companies to maximize their returns from the significant investment that may be required to extract value from that data.

In the past, a workable commercial strategy has been to achieve lock-in for customers, for example, using a specific platform product such as an electronic health record. Other forms of vendor lock-in can result from overly restrictive or exclusive contracts between healthcare providers and an AI vendor. There is of course a need to ensure a level playing field whenever data is shared with a commercial enterprise. The NHS has now banned local healthcare organizations from entering into exclusive arrangements involving their data, and a new National Centre of Expertise was tasked with ensuring that commercial arrangements provide benefits for patients and the NHS. This new policy ensures that commercial arrangements should not include "conditions limiting any benefits from

being applied at a national level,” and the contractual terms should be “transparent and clearly communicated in order to support public trust and confidence” [32]. Furthermore, it is worth noting that antitrust legislation (e.g., in EU and UK competition law) would ensure that healthcare providers entering into a data sharing arrangement with a commercial AI developer should also be prepared to make the same data available to competing companies on the same or similar terms.

To maximize the utility of healthcare data, healthcare providers (such as NHS Trusts in the UK) need to think about the need to quantify and enhance the quality of the data in their custody. This would entail ensuring its provenance, providing suitable metadata, and taking steps to increase the percentage of completed fields in each record of the database.

Gaining the Public’s Trust

We have seen how important it is to retain the public’s trust, in order to be able to maximize the volume and utility of the data that can be made available for AI development, and for the public to have confidence in the resulting devices and services.

So how can a healthcare provider or AI developer go about gaining public trust in their products and services? DeepMind Health set a good example by holding a series of Patient and Public Involvement and Engagement (PPIE) meetings starting in 2016 [33]. They formed a user group/discussion forum that was active throughout 2017/2018 [34], and this culminated in a Patient User Group event in 2019 after their merger with Google Health, at which time the group was, unfortunately, dissolved. This group went beyond the contribution of patients to individual projects to reflect on what effective patient participation should be and what it could achieve. The discussions engaged a diverse group of enthusiastic citizens from around the UK and aspired to debate issues or concerns about the work of the organization and even for patients to initiate and participate in research themes. Other aspirations were for the company to be open and transparent

about its projects and to foster two-way discussion between the group and the company. This set a minimum standard that healthcare providers and the commissioners of AI should adopt in their own patient collaboration endeavors. It is incumbent on the whole value chain including researchers, developers, providers, regulators, and other public bodies to adopt this approach in order to fully gain public trust in AI. Companies using public data need to be transparent about its use. Public bodies providing data need to do so transparently and ensure that a greater public good is achieved and distributed fairly across society.

So, there are benefits for organizations involved in the development and adoption of AI technologies to set up diverse patient collaboration groups and conduct detailed conversations transparently with them. Patient representatives should be consulted from the outset of research and development, and this should continue through deployment and beyond. No questions raised by the group ought to be out of bounds, not even sensitive commercial arrangements.

Technologies for Trust

Beyond meaningful consultation, collaboration, and discussion, there are some specific new technologies that AI developers should consider. Their use can help to provide patients and the public with the assurances and transparency they demand.

Privacy by Design

It is possible to ensure that personal information is never transmitted beyond the healthcare provider’s firewall, so that it always remains subject to their information governance. Organizations can ensure that personal data is aggregated and that it is then transmitted externally in encrypted and summarized form. This approach to supporting privacy has been used successfully to help researchers conduct population-wide studies, requiring, for example, only patient counts to be transmitted externally, and this can speed the process of designing and recruiting patients to a clinical trial (e.g., the European

project *Electronic Health Records Systems for Clinical Research* [35]).

Of course, many projects still require individual healthcare records in which case it is necessary to remove further information to prevent re-identification. However, even best practice methods for de-identifying records have been called into question as potentially unsafe, and so the practice of simply releasing anonymized datasets to third parties is increasingly questionable [36].

In view of these risks and the possible need for ongoing and informed patient consent, innovative technologies are being trialed to help researchers to securely make use of sensitive healthcare data. For example, several universities and other organizations have developed verifiably secure computing environments [37].

Increasingly AI needs to be trained with large datasets, beyond the confines of an individual organization. Such large, nationwide, or international datasets pose even greater security risks and privacy concerns and present added regulatory complications where national boundaries are crossed. For example, it is technically straightforward for medical equipment manufacturers to collect performance data from devices scattered across the globe, but this presents them with regulatory hurdles. Similarly, regulatory hurdles are faced by pharmaceutical companies engaged in clinical trials for new drugs. They simply are not allowed to directly contact patients who have been involved in the trials, for follow-on research or for longer-term follow-up. Blockchain or distributed ledger technologies are becoming recognized for use as platforms for regulatory compliance. They can establish a trusted verifiable audit trail, to track compliance and streamline access to data.

Another promising field is that of *differential privacy*, which enables data to be processed while guaranteeing that no individual patient's data can be discovered from the dataset. This enables AI models to be trained without effectively sharing anyone's sensitive information [38]. Together with federated computing, which can link disparate organizations in a collaborative learning network where each retains its own data, or with techniques for machine learning from data that always remains encrypted, these technologies can

help ensure privacy by design [39]. Blockchain can also be used to protect patient identities while still allowing companies and researchers to obtain consent and access their data [40]. And *dynamic consent* mechanisms can ensure that this consent is informed and current, giving patients the degree of control that they tell us they want.

Blockchain

Blockchain is a form of distributed ledger technology, popularized by cryptocurrencies such as Bitcoin. This is a secure method of collective bookkeeping via the Internet whereby multiple parties can achieve consensus while each maintains an identical copy of a single database. Instead of feeding data from multiple systems into a centralized information exchange for processing, the multiple systems together maintain a single record of truth using irreversible cryptographic hashes [41].

Patient-controlled healthcare records are extremely suited to this kind of treatment. Imagine that it were possible to compile an up-to-date verifiable real-time ledger comprising a record of every encounter a patient has ever had with a healthcare professional. These encounters would be a series of sequential events which over time involve multiple organizations. Later events often depend on earlier ones. Each transaction would describe the addition of a resource to the official patient record by an authorized person, with the resource itself (the substance of the health record) stored externally with a pointer to its location. Similarly, it would be possible to track and audit lookup events as transactions in the ledger and incorporate the patient's own personal, lifestyle, or physiological records from their wearables. This very much resembles a financial ledger, where blockchain has already proven itself.

One of the other benefits of blockchain technology is that it helps with establishing data provenance and value discovery, both essential to a thriving data economy (e.g., Ocean Protocol [42]). Machine-generated data could be stored with information about the type of equipment used, its calibration status, and a precise timestamp. Patients' own devices would record information into the transaction log and would

be clearly identifiable as such. Algorithms used to process the data would also leave their imprint in the record. As these algorithms become more critical to healthcare delivery, with black box machine learning increasingly a feature of diagnosis and care, the ability to review and manage the entire supply chain of data across the population becomes important. If an error is later found in an algorithm used to make a diagnosis, it then becomes a simple matter to backtrack in order to identify and update everyone whose diagnosis or treatment could be affected.

Federated Computing

Federated computing enables healthcare organizations to pool data for machine learning while protecting both their own intellectual property and their patients' personal data. Sensitive data remain in protected zones within each site, unaltered and uncompromised, where they are transformed to a common data model and further processed for machine learning. Each organization in the network can only interrogate or analyze its own data, and only the results of data analysis are shared externally, hence protecting all parties. The technique can be used for formal clinical trials or for real-world data including observational trials, registry data, population, and operational data. In Europe, this approach has been used to build a federated data network capable of allowing access to the data of more than 100 million EU citizens standardized to a common data model and has been used successfully to provide a rapid response to Covid-19 [43].

Dynamic Consent

Since it is often necessary to process individual personal health records whose de-identification is not a reliable process, explicit patient consent may be the best basis for acquiring data for AI research and development. In addition, the public when given the opportunity have expressed a preference to be able to control their own data, to be able to withdraw consent at any time, and to tailor their sharing preferences for different purposes. Dynamic consent is a mechanism for accomplishing this at a detailed level of granularity. Recently there has been much interest in using blockchain to provide this mechanism without

centralized control, even enabling communication among patient stakeholders to aid with recruitment [44]. This would also help to make the documentation of consent transparent and traceable and foster increased trust and greater patient engagement than current (often paper-based) methods of obtaining consent.

When mature, these privacy-preserving and data-enhancing technologies would shift the balance of power back to society, as patients would ultimately be in control of sharing a comprehensive personal healthcare record or aspects of it with researchers in a transparent, trusted framework, with clinical governance principles verifiably followed. And this would help to shift the balance, from large technology companies and data aggregators toward small businesses and researchers with a great idea who could easily read from, or write to, a patient's record with straightforward authorization or consent. When scaled to entire populations, artificial agents could browse the data and make inferences that would aid in clinical decision-making or to help patients to take pro-active measures to maintain their good health. And this would be accomplished while maintaining the individual's ultimate right to privacy and consent.

Conclusion

AI technology is advancing on a broad front, and the public level of understanding currently misses the richness and diversity of the technology. Public perception is shaped by the media, and discussions tend to focus on specific topics such as data ownership and sharing, cybersecurity, privacy, and whether the technology can make decisions independently of the healthcare practitioner. Governments can help to foster discussion, but in order to establish the level of trust necessary for public support, AI technologists and researchers need to enter into a meaningful and open dialogue with the public and to maintain this throughout the technology development and adoption pathways. Only by forming true partnerships with the public, putting patients back where they belong, right at the center of business, will the field develop to reach its true potential.

Abstract

Hackathons are leveraged to crowdsource innovation. Hackathons have become an accepted approach to problem-solving and product development in the technology and healthcare sectors. Hackathons are used by companies, organizations, and research teams either internally or in open formats for different purposes. For AIM, hackathons could serve different purposes for different entities which can range from the discovery/development of new products, identification of innovative approaches, innovative application of existing resources or tools by an organization, and collaborative and inclusive design. Measuring the

success will vary and be relative to the set goals of the hackathon, but it is important that organizers come up with open practical questions that can enable them to gauge the effectiveness and usefulness of AIM hackathons. AIM hackathons can be better organized if organizers leverage on existing resources and knowledge, involve more experienced professionals as participants to benefit from their experience and insight, and plan strategically for follow-up to the event for winning teams or solutions.

Introduction

Hackathon is an intense, short, collaborative event focused on creating innovative solutions for pressing problems. It essentially combines the words “hack” and “marathon” to imply a sense of an intense and continuous event targeted at solving a specific problem [1].

Silver et al. have gone further to specifically coin a definition for healthcare hackathon which they define as

A competitive event (live or virtual) that has three specific goals—accelerating the innovation of medical solutions, improving the design in the beginning stages, and supporting educational training for all participants—and aims to accomplish them by focusing on a specific problem (pain point), bringing together in an open innovation format (internal and external resources) an interdisciplinary group of individuals (hackers) that include, but are not limited to, physicians and other healthcare professionals, data scientists, engineers, user interface designers, business professionals, students and other stakeholders who work in teams and follow a process to develop initial prototypes, pitch them to a panel of judges experienced in innovation and quickly alter them according to the feedback (pivoting). [2]

According to Ramadi and Nguyen [3], hackathons usually try to achieve several goals which are:

- To contextualize an impactful problem to a specific real-life scenario
- To convene cognitively, geographically, and socially diverse teams to tackle the problem
- To assemble an equally diverse set of domain and process expert mentors to provide accelerated customer discovery and subject matter expertise
- To optimize the design for accelerated development and implementation

Hackathons have become an accepted approach to problem-solving and product development in the technology and healthcare sectors. Hackathons are used by companies, organizations, and research teams either internally or in open formats for different purposes [4]. Different companies organize hackathons either internally

or externally to find innovative ways to solve the extant problems the companies face, while others organize them to create a platform for the involvement of multidisciplinary and diverse individuals to collaborate on finding the required solutions.

Hackathons could serve different purposes for different entities which can range from the discovery/development of new products, identification of innovative approaches, innovative application of existing resources or tools by an organization, collaborative and inclusive design, etc. These usually depend on the problem being targeted or the entity organizing the event. Hackathons create an avenue for interdisciplinary and interprofessional collaboration to solve health problems. This is more pronounced in cases that involve the development, iteration, and application of technology which domain experts might not be easily familiar with or understand the underlying principles.

Another often-overlooked goal and likely impact of hackathons is their role as educational avenues for students and professionals alike. They are potentially significant learning experiences that can help promote technical skills, thinking skills, and mastery of specific issues. They also help introduce and create professional and social networks that can be useful to these students and professionals in the long term [5].

Google, Facebook, and Microsoft usually organize internal hackathons for their employees to create new products or features [6]. The Massachusetts Institute of Technology (MIT) has an MIT Hacking Medicine community that has facilitated over 80 hackathons and healthcare design thinking events over the past 5 years. Its model is built on the concept of integrating collaboration and interdisciplinary gathering around innovation techniques. It has successfully launched about 20 active companies that have raised over \$120 million dollars [7].

Hackathons are also gaining grounds in developing countries. For example, there is a dedicated platform designed for competitions and hackathons, Zindi, established in 2018 and based in Cape Town, South Africa. Zindi describes itself as the first data science competition platform in Africa. Zindi hosts an entire data science ecosystem of scientists, engineers, academics,

companies, NGOs, governments, and institutions focused on solving Africa's most pressing problems; this includes health-related problems that can be solved by data and AI. Zindi works with companies, nonprofit organizations, and government institutions to develop, curate, and prepare data-driven challenges [8].

In July 2020, AI Commons collaborated with Data Science Nigeria for the AI Commons Health & Wellbeing Hackathon which was an online competition to develop groundbreaking and innovative working prototypes, models, or solutions driven by Artificial Intelligence that can solve identified local health problems or improve identified existing health technology solutions in Nigeria. The project aimed to increase/improve the accessibility, reproducibility, contextualization, and enhancement of Artificial Intelligence solutions globally and especially in emerging markets. The core participants were AI experts, health workers, academic researchers, health-tech organizations, students, and any other interested party [9].

The relevance of hackathon to solving problems and innovations in medicine became more prominent when COVID-19 became a pandemic, and there was a high demand for accelerated solutions that could be used in solving the public health emergency created by the pandemic. The medical community rose to the occasion and collaborated through different global hackathons which produced different solutions that were applied to varying degrees of success in managing the pandemic [3].

According to DePasse et al. [10], the significance of hackathons revolves around three core principles:

- A problem-based approach which harnesses the perspective and experiences of clinicians, patients, and other likely users in approaching the possible solution.
- Harnessing of diversity of thought, background, and perspective across different disciplines, professions, and experiences creating a platform that can help to shrink the innovation timeline with opportunities for rapid feedback and better productivity.

- Challenge of existing paradigms and easy pivoting. This is based on the possibility of rapid feedback that ensures that developed concepts or products are meeting the actual needs and problems.

These principles are very relevant when it comes to the application or implementation of AI/ML as tools in healthcare because of extant limitations in accessing the required data and resources for developing these tools due to privacy reasons and access to required expertise for both data scientists and domain experts. Also, medical professionals and data scientists and engineers rarely interact, and hackathons can help bridge this gap and create an atmosphere for collaboration and sharing of ideas and perspective. Hackathons also help ensure that use cases are best developed from the perspective of the end users.

Organizing AIM Hackathons

According to Nolte et al. [4], there are 12 key decisions that must be considered to ensure a successful hackathon, but for the purpose of this text, we will categorize these decisions under 10 contexts which are most relevant to AIM hackathons:

Goal and theme: There should be a clear setting of the goals of the event. The feasibility and attainability of these goals should be well considered to prevent disappointing outcomes from the event. These goals can range from the illustration of a concept to production of something useful, learning experience for participants, or connection of professionals. It is also important that these goals are clearly communicated to prospective participants to avoid possible mismatch of expectations. The theme of the hackathon is usually developed in conjunction with the goals of the event. This theme is best arrived at after discussions with relevant stakeholders and experts in that aspect by the organizers. Themes can be general or specific. It is usually much better for hackathons if the

selected themes are specific as they ensure that the work serves a specific outcome; however, specific themes can be limiting for participants especially when it comes to their personal interests or how much they can explore. Organizers will have to consider these tradeoffs based on their set goals.

Format: Organizers need to decide in the designing phase if they want a collaborative or competitive hackathon; this will involve the likely introduction of incentives to stiffen the competition if necessary. Hackathons are usually organized around a commonality, which might involve the development of specific aspects of an existing project, expansion of its capability, introduction of new features to it, or networking for the participants involved. Competitive ones focus on creation of innovations. For competitive events, winners can be decided by a jury or through popular votes. The use of a jury of varied experts might be more appropriate for AIM events.

Stakeholder involvement: The implementation of AIM is a multidisciplinary endeavor, and it is important that stakeholders from all the involved disciplines are involved in the planning processes for the hackathon. It is important that these groups of stakeholders are involved in the organization, execution, and follow-up of the hackathon. Their involvement will be very integral to the real-world deployment and sustainability of the outcomes of the event. These stakeholders could act as sponsors, speakers, coaches, resource persons, mentors, or judges for the event.

Participants: The targeted participant and mode of recruitment for the hackathon will vary based on the goal, theme, and format being planned. The recruitment could also be open or restricted to a closed community. These will affect the period of recruitment and the characteristics of the target participants. Some events might be open to anyone who might be interested; some would want people with a specific skill, technical expertise, and experience in specific domains.

Ideation: The structure of this aspect of the event has a bearing on how interesting and attainable

the ideas that will be worked on will be. Some events usually organize an ideation session before the event to come up with a cluster of ideas that will be eventually worked on at the main event, while others just allow the participants to ideate freely based on the theme. There are trade-offs for both approaches; allowing participants to develop their own ideas and work on them might be more motivating than limiting what can be worked on. There is also the trade-off of hacking time and ideation time, as hackathons are usually of short duration; it might not be helpful in some cases to have ideation during the main event.

Team formation: The strategy for team formation is another important decision that organizers must make in their plans. Teams can be formed by either open selection in which participants select the groups and roles they want to play themselves or assignment where participants are assigned to projects and roles by a mediator or a hybrid model that allows the participants to prioritize projects based on interest and expertise, after which they are assigned by a mediator based on the stated preferences. These teams can either be formed before or at the hackathon; the preference will depend on the goal and theme of the event. A learning and networking event may be best served by a model that allows people to cluster at the event itself. The multidisciplinary nature of hackathons should be leveraged for data interpretation, e.g., participants with medical background interpret and bring context into medical data, and those with other skills such as machine learning algorithms, data wrangling, etc. solve from their areas of expertise.

Resources: One of the most important resources at AIM hackathons is data. One of the barriers to leveraging AI for medicine is data confidentiality and understanding. Questions and concerns around data privacy are valid, and the nature of medical-related data increases these concerns. Data de-identification can go a long way in solving this for hackathons when possible; also the use of synthetic but similar datasets can reduce real data exposure. Organizers can also explore federated learning

systems; federated learning allows the sensitive patient data to stay either in local institutions or with individual consumers without going out during the federated model learning process, which effectively protects the patient privacy [11].

Participants in AIM hackathons should also be required to sign nondisclosure agreements; and role-based access should be activated as appropriate, such that participants only have access to what they need. Organizers of AIM hackathons who can explore the use of virtual machines should also consider this, so participants only have access to data for a limited time. A peculiarity of AI in medicine that planners should prepare well for is the length of training time for machine learning/deep learning models and other needs like Graphics Processing Units that hasten model training.

Agenda: It is important that organizers have a clear agenda for the event as this will also help to manage expectations and allow participants to adequately plan for the event. It is important to make this agenda available to everyone involved a few days prior to the event. It is advisable that extra-hacking activities are limited so that participants can have more time to work on their projects. A significant activity that might be helpful is “checkpoint.” This involves teams reporting their progress, discussing challenges they are facing, and outlining the plans for the time ahead. Checkpoints will be an opportunity for teams to get additional support and insights on what they are working on.

Mentoring: A common strategy is to provide mentors on demand for the teams; this is usually employed when teams are working on their own projects and have the necessary skills required to develop their ideas. Some events use dedicated mentors who are specifically assigned to individual teams or give teams the opportunities to source their own mentors. The most important thing is the accessibility of the mentors for the participants. These mentors can be recruited through an open call which usually happens long before the main event, or they can be handpicked by the organizers from

data science, engineering, medicine, public health, or the specialties and disciplines that are relevant to the theme of the event. In some cases, a team of mentors might be important, e.g., a team made up of mentors with technical skills and domain expertise as this might be more helpful to the teams depending on the level of expertise of recruited participants.

Continuity framework: Depending on the goals of the hackathon, it is important that adequate plans are made for what will happen after the event. This should be planned for before the event and well communicated to the participants when the publicity for the event is being shared. These continuity plans could involve the creation of a community, transformation of projects to startups, connection of solution with support and funding to take it to market, etc. This plan will also help in informing which stakeholders might be relevant to involve in the plan and execution of the hackathon. It is possible that participants might have different plans for continuity but adequately conveying that prior to the event will help manage expectations and planning for prospective participants.

Proposed Metrics for Measuring the Success of an AIM Hackathon

Measuring success of a hackathon will vary and be relative to the set goals of the hackathon, but it is important that organizers come up with open practical questions that can enable them to gauge the effectiveness and usefulness of an AIM hackathon. These could include:

- Were the predefined goals met?
- Did the event run as planned? (Assessments using pre- and post-surveys for all participants)
- Was the judgment of the winning solution fair and in alignment with previously outlined criteria?
- Is the winning solution practical in context? Does it work for the end user (patients, health professionals)?
- What progress did the winning team(s) and solution(s) make thereafter?

Limitations of the Hackathon Approach

Many problems require continuous and long-term iterations in design, implementation, and testing; therefore, hackathons would not suffice in proposing the most appropriate solution to such problems. Hackathons are not intended to be a standalone innovation event or process but rather as a part of an innovation continuum that can help accelerate and improve future solutions [2].

Organizers of AIM hackathons or any hackathons at all attempt to bring together an interdisciplinary team, but the perfect mix is not guaranteed; sometimes important professionals are missing, e.g., an AIM hackathon without medical doctors or AI engineers applying to be part of the team. A way to mitigate this is to include instructions on professionals that should be in a team at the call for participation if the team is self-coordinating; if the decision on team formation is made by the organizers, then they may need to involve important professionals that may be missing in certain groups.

There is also the question of who owns the intellectual property (IP) of innovation during the hackathon. If the participants (who probably do not have an existing relationship) own the IP, how do they share the benefit? Many hackathon organizers solve this by making the innovation open source or taking up the IP. It is suggested that these terms are clear in the call for participation.

Recommendations for Organizing Better Hackathons

Leverage Existing Resources: It is tempting to assume a concept is new, but hackathons have been well explored and documented. It is suggested that organizers do not reinvent the wheel, research, and adapt to what works in your system. This also includes using existing competition platform's infrastructure rather than setting up new ones from scratch.

Involvement: Most hackathon participants are usually drawn from pools of young and early career individuals, while experienced professionals

are mostly used as mentors or coaches. It will be more helpful for the quality of outputs of these events to have these groups of experienced professionals take part as participants. AIM hackathons would benefit from the experience and insight that these professionals offer and involve them in the development of technology solutions.

Continuity: AIM hackathons are meant to be catalytic processes. The follow-up to the event for winning teams or solutions should be well planned during the design process to ensure the outcomes of the event can translate more meaningfully for the targeted problems.

Abstract

This chapter explores AI through a philosophical and ethical lens. This includes an examination of how AI impacts on medicine in terms

of uses and promises, limitations, and risks, as well as key questions to consider. While AI offers scope for complex and large-scale data processing, with the promise of an increase in efficiency and precision, some central limitations need to be highlighted. The use of AI also brings some pertinent and predictable, as well as unpredictable risks, such as those due to biases. Also considered is what may be lost where AI replaces established processes, not least those relational and interpersonal aspects that are central to healthcare. By covering these and related issues, this chapter offers ways to evaluate, and also balance, key benefits and

Introduction

This chapter examines AI through a philosophical and ethical lens; it explores some fundamental impacts on medicine in terms of promises, limitations, risks and key questions. On the one hand, AI has the capacity to process huge amounts of data on medical issues. This may increase efficiency and precision for diagnosis and treatment and offer progress in medical research. On the other hand, the possibility emerges of a drift toward over optimistic techno-solutionism in medicine and healthcare. This includes the application of problem-solving approaches which are apt for data-centered practice, but which are not obviously improvements when it comes to other dimensions of medicine, especially its relational aspect. Whereas medicine in general has a clear anchoring in scientific accounting for the biological body, it also has responsibilities in recognizing subjective, interpersonal, sociopolitical, and historical realities about health and illness. The inclusion of AI in medical practice raises interesting and challenging philosophical, ethical, as well as practical questions. In exploring these topics related questions about asymmetric interpersonal relations in medicine, and on topics of personal identity as they relate to AI and medicine will be considered.

This chapter begins by considering the promises of AI (section “[Promises of AI in Medicine](#)”), but gives only limited time to this endeavor since many of the chapters in this volume offer more detailed examples of how AI can fruitfully be used in medicine. The primary aims in this chapter therefore concern on the one hand, AI in relation to philosophy, and more specifically in terms of medical epistemology (section “[AI and Medical Epistemology: A Changing Paradigm](#)”), and on

the other, in relation to medical ethics (section “[AI and Medical Ethics](#)”). The argument is that the epistemological issues are at the core of many of the ethical issues that follow, and so this earlier section is necessarily longer and more detailed. The suggestion is that understanding the limitations of AI in terms of issues arising from data and from bias will enable the reader to more easily anticipate and assess the other ethical issues that are outlined in section “[AI and Medical Ethics](#)”. Many of these also overlap with, or build on, those earlier issues and so can be explained more concisely by that stage.

Before beginning, it is important to note that AI and ethics is a vast area, and there is plenty of literature already written on this topic generally [1], as well as in terms of AI as it pertains to medicine, healthcare and clinical settings. See for instance recent work on whether AI and medical principles can align [2], on the application of AI to specific areas of medicine, including intensive care [3] and on the use of AI in surgery [4]. Meanwhile there are also texts that offer high level mapping, thereby outlining general ethical issues as they relate to AI in healthcare [5]. Mapping offers a useful general picture, while detailed accounts on single applications offer scope for focused analysis of specific issues. However, the aim in this chapter is to offer a practical, middle ground that introduces the reader to a few central topics that are core to thinking philosophically and ethically about AI in medicine. By restricting the focus in this way there can be some detailed discussion of each, while not precluding the importance of other ethical issues relevant to these topics. The reader can therefore use this chapter as an introduction to some foundational issues, and a way to begin the important work of ethical and philosophical analysis of AI as it pertains to medicine. It should thereby be considered a stepping stone to further reading and analysis.

Promises of AI in Medicine

AI applications in medicine may be claimed to be more objective than standard, human-based approaches. Some of the methods employing AI might appear able, to some extent, to bypass

clinician bias. Where, for instance, a human may see a person and make snap judgements or harbor implicit biases about them, AI “sees” only data (this apparent potentiality is explored more critically later in this chapter). This hope for objectivity would be a boost for justice in healthcare. Certainly, it may be true in cases whereby AI is employed to assist in the managing or assessment of data and/or in ensuring that approaches to clinical procedures and processes are consistent and rigorous. While there may be these improvements brought by AI in medicine in terms of justice – through more equitable access or distribution of resources – they may alternatively be seen simply as efficiency boosts for the practical implementation of medical decision-making. Where AI can take over more laborious tasks that otherwise tie up clinicians’ time, this can free those clinicians to do more valuable work.

A large amount of what AI can do in medicine centers on imaging, given the aptitude for pattern recognition in AI applications. This can be seen in radiology, pathology, ophthalmology, and dermatology [6]. In these areas, AI can be used to detect fractures from scanning x-ray images, or potential eye or skin problems from processing photographs of retinas and skin. In this way, the system can assist clinicians to prioritize their work. Besides imaging, an emerging and potentially very powerful application comes from classifying text. Clinicians make detailed notes as they work, including their observations and practices. AI can be set loose on amassed clinical note data, and spot common findings, approaches, mistakes, and inefficiencies [6]. This processing can then lead to recommendations that would allow protocols to be fine-tuned based on analysis of many instances of clinical notes. AI could do this classification in an unsupervised way, freeing up time for clinicians.

Even where the promises of objectivity and efficiency are assumed, a further query arises. *How sure can we be that AI can deliver on those promises?* It isn’t automatically clear that more and more data applied to individual cases is necessarily better than careful attention to the individual specifics. Imaging and clinical note consolidation are valuable applications, but as

explored below it would be prudent not to expect an AI replacement for clinical expertise in general, given much can be lost as well as gained. One risk to be avoided is that of imbuing AI with an “enchanted” status [7], which would serve to close down scrutiny of those applications. Advances in AI technology don’t inevitably lead to improvements in applications. They may represent changes to applications that require evaluation on their own terms.

AI and Medical Epistemology: A Changing Paradigm

Data

Doctors have always collected data (observations, case notes, research findings) in order to come to diagnosis. Typically, these data have been handled so as to inform medical theories, bolstering clinical insights through broad observational regularities. One hope for the future of medicine includes the idea that AI can be used on data in a much more directly instrumental way in order to boost the efficiency, predictive power, and ultimately the effectiveness of medicine. Such a data-centric approach – where research, diagnosis, and treatment primarily derive from the processing of digitized health data, rather than patient observation – is thought by some to permit a computational approach to medicine. This would diminish the role of medical theories, and expertise, replaced by exploratory data science [8].

The promise of data in general, and big health data specifically, is that it can represent vast arrays of knowledge based on samples, processed in various ways, without guiding theoretical knowledge required. The data-centric approach surpasses limitations present in case study or cohort analyses by aggregating wide ranges of quantitative and qualitative observations. This provides scales not available by other means. These mass aggregates of data can be transformed into new knowledge, through applying statistical transformations and pattern analyses. At its simplest, the idea is that where there are patterns in data, there can be reasons to explain those patterns [9]. These

patterns would be taken to signify relationships among arrays of observations. Doubtless, owing to the way in which humans are primed to spot patterns anyway – like pareidolia and seeing faces in clouds – such things will be seen frequently. But there will be a set of patterns among datasets that are not mere coincidence. By exploring data closely, these can be shifted from the burgeoning whole.

Patterns found within data that aren't mere coincidence will have some other causal explanation. This means that the patterns in the data, representing structures implicit among the observations of some phenomena, will reveal causal structures among those phenomena. The relationships among data such that a pattern emerges are thought to reveal fundamental information about whatever the researcher is investigating in this way. And in finding new causal structures among phenomena by examining patterns in data, the formulation of new insights into those phenomena are enabled by examining the data. This in turn can be used as a basis for new practical approaches to the field. This has application in medicine where medical and other data can be combined and from the whole predictions made to explain patterns. The patterns in data are then expected to relate to causal factors in diagnosis, prognosis, health outcomes, treatment, and so on.

For example, demographic information might be aggregated into a large dataset, along with clinical data, genetic information, observations from specimen biological samples, and other meta-data [10]. By turning to data analysis, relationships among this trove of heterogeneous material might serve to yield patterns that suggest underlying structures among lifestyle, medical history, illness, and health outcomes [11]. This in turn can offer novel prevention, diagnostic, and treatment strategies for an illness, or even suggestions for public health policy. The insights would be gained from predictions based on patterns among data. This means whole populations needn't be interviewed, nor even specifically sampled for a purpose. The data processing appears to do it alone. Nevertheless, in order to curate, populate, maintain, and operationalize such datasets

with sufficient quality, expert knowledge is required across a number of disciplines.

Data scientists, software and hardware engineers, and developers are needed to ensure quality systems and structures. Medical expertise is also required, able to identify health-relevant data and connections between that and other data. Likewise, to point out what is irrelevant, meaningless, obviously wrong, etc. Clinical expertise aside, there are also technical decisions that must be made about data which can bear upon their medical relevance. Indeed, how and in what respects data are accurate to the medical phenomena they represent is a question in need of careful scrutiny. As other contexts have shown, data isn't neutral with respect to its collection, storage, or mediation [12, 13].

Data-Utopianism

In an idealized data-utopian scenario, the AI approach to medicine would constitute what has been in another context termed a “screen and intervene” paradigm [14]. This is not “diagnosis” as it is known today, where interview, examination, and observation are essential elements. Biomarkers are of central importance in a more datafied approach. AI will look for these as patterns in data, on the basis that over time they have been established as indicators of illness. But biomarkers are not without problems in themselves, owing at least in part to questions over consistency and standardization [15]. The reduction to biomarkers represented as patterns in data, apt for automated detection, bypasses pertinent questions including some concerning what is being detected, and why that is being looked for in the first place (see section “Data Curation and Use” below).

It might be that the promises of AI prompt the datafication of medical investigation too quickly. If the data is approached in a spirit of exploration, and so too is the diagnostic field, then there appear to be overlapping explorations without specific guiding strategies. In human behavior generally, Tversky and Kahneman provide examples of decision-making under uncertainty wherein it is not necessarily helpful to gain more and more

information [16]. That is, when the future is uncertain, those facing a decision can be hampered in making optimal choices if they are presented with more to think about. Yet in this context of multiple uncertainties and explorations, the solution is taken to include amassing data. This is not without risk, especially in medicine where human health and wellbeing is at stake.

Unlike examples of human reasoning examined by Tversky and Kahneman, the AI approach doesn't proceed by gathering information and then coming up with decisions. In certain respects, AI centering on data turns traditional medical-scientific investigation on its head. Scientific research is often thought of in terms of heavily disciplined normal human reasoning: hypothesis-formation, investigation, then confirmation or refutation in the light of evidence gathered specifically for a carefully defined purpose. A typical way to characterize a clinical encounter might be along these lines: a patient presents with a complaint. The clinician carries out an examination, and makes observations. Based on these, and expert knowledge, a clinical diagnosis is made, following which, treatment or further examination is recommended. This stresses interpersonal skills, like empathy and including patients in the process overall [17]. The data-centered paradigm emphasizes a more thoroughly empirical drive, in which facts, in the shape of digitized data, are prioritized over testimony.

This approach instead amasses data from a variety of sources, and seeks hypotheses based on what emerges from the data. This is an exploratory approach that claims to need no guiding theory, instead seeking correlative information among data to prompt explanatory work. The models to explain patterns are "born from the data" [18]. Such approaches have seen some success in areas like predictive data analytics to forecast likely Parkinson's Disease development [19]. The data can also be harnessed to make narrow predictions about disease development for specific patients. Again, using Parkinson's as an example, whether a patient is likely to suffer falls or not can be taken from analysis of swathes of data far beyond the scale of comprehension of an individual clinician [20]. This kind of

predictive power concerning likely disease course is made available by data, and seems a dimension not open to the interpersonal clinical encounter. How to conceptualize the potential pros and any emerging cons of this approach, and how to weigh them against one another, remains a difficult endeavor. The following sections explore this difficulty in order to throw some light on what otherwise remains obscure.

Data Curation and Use

The aggregation of heterogeneous, large datasets, taken from myriad sources, makes the data in these applications complicated to deal with. This raises ethical questions about data ownership, privacy, consent, purpose, re-use, anonymity, and others, as well as the nature of dataset-making as a scientific, sociopolitical, and technological endeavor [21]. Once created, the analysis of these huge and varied datasets cannot be carried out by humans. Owing to the scale and complexity of data, algorithms and machine processing techniques more widely are required. Using techniques like Compressive Big Data Analytics (CBDA), algorithmic processing of data sets aims to be "model free" or "model agnostic" [22]. This kind of analysis can be taken to imply the objective nature of the data being collected, and of its subsequent analysis. But this objectivity is anything but secure.

One of the largest medical AI datasets at the moment is known as "ChestX-ray14." As Kulkarni et al. discuss [6] this is an interesting case that illustrates some of the issues raised here. This dataset was used in a study to train an AI-detection model called "CheXNet." In order to know what CheXNet should look for, a "ground truth" had to be established such that positive cases might be defined. This would represent what CheXNet was looking for. Ground truthing was carried out by text mining clinicians' radiology reports. This is the inclusion of medical expert opinion in the course of training the AI, mentioned above as necessary. But, "Intriguingly, CheXNet's performance mirrored human weaknesses in many respects; the algorithm had much

greater accuracy in detecting hiatal hernias, a radiographically distinctive diagnosis, compared to pulmonary infiltration, which is frequently ill-defined” [6].

This is taken to be the case because the notes from which the dataset is comprised, and on which the AI diagnostic model was trained, themselves are replete with uncertainty. Diagnoses aren’t always binary cases. One can speculate that the kinds of uncertainty present throughout clinical notes are exactly the sort of thing expertise is well honed to draw conclusions from, or otherwise use in informed medical decision-making. If the data is all there in the dataset, and machine learning techniques discover patterns in that set, then there is a ring of objectivity to it. The pattern is really there, somehow. But there are uncertainties in the data that are themselves hallmarks of medical expertise. Radiologists rightly record their uncertainties in their notes. What’s more, besides these kinds of responsible uncertainties, there are other potentially unconscious or historically derived biases in data. This is especially so where women and people of color are poorly represented in health data. Successful, data-driven skin cancer lesion detection algorithms, for instance, are effective mainly for light-skinned people [23]. The dataset here is incomplete following specific sociopolitical non-inclusivity. Issues such as these may be compounded if they become hidden behind the supposed objectivity of data processing.

Just as there are questions about dataset creation and its completeness, illustrated here with ChestX-ray14, others arise around algorithmic processing (see next section). How these questions and how the requirements of data in general relate to medical reasoning is in need of careful scrutiny. It is not clear that by deploying data in their investigations, clinicians will necessarily get closer to better answers simply owing to datafication.

There remain those who emphasize that the use of data ought to be handled judiciously, and used in tandem with expert clinical decision making [24]. Here, tools are deployed as decision support rather than considered as silver bullets. As with the scope for predicting falls in Parkinson’s

patients, data here can provide value. A clinician, faced with specific observations about their patient can draw upon arrays of information relating to similar observations. The singular case can thereby be related to a population-level sample. This could aid clinicians and patients alike in providing a rich backdrop to the otherwise one-to-one clinical encounter. It could further serve to minimize healthcare disparities by boosting clinician confidence and performance, not least through eliminating more burdensome dimensions of clinical work [25].

This would ideally translate into better patient outcomes, with world-class healthcare data available in even the most under resourced locations. While this promise sounds worthwhile, it does entail some changes to expected medical practice. The biostatistical reduction of the patient to correlations among data points not only methodologically detaches the person from their body and his/her sociopolitical context, but also the functioning of that specific body from clinical observation. This is replaced by an aggregating view of bodily function and deficit. The clinical encounter then takes on the function of harmonizing the deficient with the aggregate, mediated in depersonalized data processes. This represents a challenge to the traditionally interpersonal doctor-patient relationship. Whether and how this represents a problem, or a medical advance is an open question, though one addressed below.

AI and Medical Epistemology: Limits, Risks, and Biases

There are certain inevitabilities with regard to the limitations of a technology, including that it will serve more or less narrow purposes, and that it will be defined by those who imagine, determine, fund, and build it. In those senses then, “limits” and “biases” can be understood in terms of the parameters within which a technology is designed and developed. This includes the aims, ambitions, and outcomes, as well as the structure within which it comes to be, e.g., financial and political. A preference to develop one method and not another would count as a nontrivial bias on that

account, and the development of a technology that can do one thing but not another would count as one of its not unreasonable limitations (cf. [26]). Such limits and biases need not be either inherently negative or positive, nor are they necessarily problematic. Whether a limit or a bias matters would likely be linked to whether the technology “works” in fulfilling its aims and objectives, considered in context, and whether its benefits outweigh any harms.

This section turns to those limitations and biases that are necessarily negative, and in those respects the concern is with problematic limitations and biases that need not occur. These weaken the overall quality of the technology and its impact, and may cause a variety of harms, including physical, psychological, social, and environmental. The argument is that these kinds of limitations and biases are tied to a number of predictable, sometimes inevitable, negative consequences and therefore also risks. There are many negative biases that impact on AI, some of which are discussed here under two categories. The first concerns human biases and prejudices, which includes the kinds of biases contained and expressed in language as well as in interpretative endeavors including perception. The second concerns computational biases, and these are biases that are contained in programming and algorithms. This latter variety emerges to some extent from human biases, whether implicit or explicit, such as in the selection or categorization of data.

Human Biases and Prejudices: Language and Interpretation

Biases are unavoidable to some extent, and they can be either implicit, e.g., unacknowledged or even to some extent unknown, or explicit, e.g., stated, acknowledged, and to some extent known. Whether a bias is implicit or explicit, it can be demonstrated in both language and interpretation, i.e., words that are chosen, used, and understood, as well as in judgement and action, i.e., in decisions made and resulting behaviors. These biases may be intentional or unintentional, and they can result in a variety of consequences. For instance,

they can be seen in a tendency to connect certain illnesses to gender or culture, ethnicity, or socio-economic context. There are many examples of these biases, especially negative, in medical practice.

For instance, it has been suggested that there is a link between diagnosis of borderline personality disorder (BPD) and gender, including the possibility that it is overdiagnosed in young women [27], and elsewhere there is evidence to suggest that schizophrenia is overdiagnosed in young black men [28]. Meanwhile the expectation that someone who is overweight will necessarily suffer as a result of their weight has led to non-weight-related illnesses and diseases being misdiagnosed, missed, and even ignored [29]. Bias can also be tied to judgements made about a person based on their perceived class and socio-economic circumstances, including as these intersect with ethnicity [30]. Such problematic judgements are sometimes equated with understanding and knowledge. For instance, biases tied to perceptions of ability and disability intersect with gender with the outcome that disabled people describe being ignored or dismissed [31]. For example, people with visible disabilities report a lack of recognition regarding their complex situations. This includes where the focus centres only the disability, to the neglect of other topics, such as basic checks for blood pressure and cholesterol, and tests related specifically to prevention of disease. Patients report a lack of effective communication, particularly acute for those patients with severe disabilities, which sometimes results in excessive communication between physicians and caregivers to the neglect of the patient’s own perspectives [32].

How much credibility is given to a speaker, and how much credence to their testimony, has clear, direct, and serious consequences in medical contexts. A lack of care to the specificity of a patient’s concrete situation can lead to epistemic injustice, whereby negative biases and prejudices impact on the scope within which the speaker’s credibility is assessed and what then follows in terms of time given to their account, as well as outcomes and decisions (cf. [33, 34]). The kinds of biases in the examples noted above might be explicitly or

verbally expressed as prejudices, or they can be seen in the terminology that is used and the actions that follow. For instance, where the term “hysterical” subsumes and thereby also neglects a whole set of (typically women’s) physical and psychological health conditions [35]. Biases can also be enacted without being expressed, for instance, in the framing of a physician’s expectations and actions, which may nevertheless be recognized by patients, and which can frame their experience of the medical experience, as per the examples described above.

Recognition of some key principles can help to avoid such problematic biases in medical contexts. First, that empirical observation is never neutral, and as such empirical positions need to be viewed as at least partly normative [29]. Second, that the clinical gaze of individual physicians is itself normatively structured. As Foucault [36] argues, “The clinical gaze is not that of an intellectual eye that is able to perceive the unalterable purity of essences beneath phenomena. It is a gaze of the concrete sensibility, a gaze that travels from body to body, and whose trajectory is situated in the space of sensible manifestation.” This concrete sensibility is tied to contexts with specificity, cultural meaning, and, inevitably, more or less prejudice. Third, embodied humans have tacit bodily knowledge, which can be considered in terms of intercorporeal ways of knowing, i.e., as beings-in-the-world ([29] *ibid.*). It will suffice for now to highlight that the necessarily concrete nature of subjective experience both feeds into and is informed by biases. Even if are ways in which to recognize and mitigate these. The suggestion here is that these principles can also inform how AI is developed and used in medical contexts.

Computational Biases: Programming and Algorithms

Without careful attention, biases and prejudices can feed into both the data (see previous section) and the production of the algorithms on which AI relies. In such instances, a negative bias captured or reified in a technology like AI is always morally

problematic regardless of whether the technology is otherwise “successful” in its practical aims. An ethical approach to AI requires that people and ethics should not be sacrificed on the altar of “faster” or more efficient technologies, for instance benefiting some while harming others. It is worth recognizing that negative biases can, and often do, affect the overall success of a technology, but that conflating practical solutions with ethical solutions is not sufficient, and the ethical ought not to be subsumed within the practical. For instance, Google’s immediate response to the racism caused by their facial recognition algorithms – that identified some black people as gorillas – was to amend the recognition categories, i.e., by removing the identification of gorillas [37]. This technical workaround might solve a short-term practical problem, but it is very far from an ethical solution. The latter requires instead a broader recognition of the problems and their causes, as well as a wider range of solutions, some of which include greater representation both in terms of data and in the teams developing the AI [38].

To consider ethics first includes the recognition that human biases impact on computational biases, and that to some extent this may be unavoidable. It has been suggested that linguistic biases inevitably find their way into programming, and thereby into AI [39]. The argument suggests that biases are inherent to language, and since language is the framework within which an AI is developed and structured, it is also inevitable that bias will find its way into the programming. If this is accepted to be the case, then it becomes clear that vigilance for bias may not be enough. In medicine, this is especially problematic, and there are already many examples of where harm can occur if medical practitioners bring prejudices and biases to their practice, as discussed above. It is therefore essential to take this into account when planning, designing or using AI, if the risk of simply replicating and reifying those same biases is to be avoided in the development and use of these new tools. Where AI is used for automated decision-making and judgement, rather than as a tool for data management, the risk is even greater given the possibility that such systems will become embedded in medical

structures and future changes may be difficult or even impossible.

Once it is accepted that bias may be unavoidable, mitigation of negative biases in particular needs to be considered. For instance, it is clear that data scientists and engineers will not necessarily have expertise about the medical fields for which an AI is being developed. Evidence for this can be found in the language about medical conditions in papers that primarily describe the development of AI systems for use in those fields, e.g., the development of AI systems for the assessment of autism (cf. [40]). AI developers working on technologies for medical applications may demonstrate cursory understanding at best, and limited or flawed interpretations at worst. It's clear that the task of developing AI for fields outside of computing and engineering ought to be an interdisciplinary endeavor. Yet when expert knowledge is sought, this can lead to a replication of the biases of those whose theories are then privileged. As with the biases noted above, this may be inevitable to some extent. An expertly-informed AI system can serve to amplify the practice of the experts chosen to inform it. The views and preferences in theory and practice that are evident in an expert's perspective are implicit or explicit choices, judgements, and decisions. In selecting an expert to provide input to an AI system's development, elements of that specific perspective are being tacitly endorsed. Selecting expert advice is thereby, to some extent, omitting the theories and ideas that might animate the practice of an equally expert, but contrasting practitioner.

The above situation is not itself unusual, in so far as any clinician would also bring their preferences and biases to their individual practice. A key difference, however, concerns the scope and the reach that can be achieved by an embedded AI. In other words, what happens once a technology becomes ubiquitous? In the case of the individual physician, their prioritizing of certain theories, to the neglect of others, in their individual practice may only impact on the number of people who are patients in that practice, as well as whatever influence they may have on those they train or mentor. An AI that is developed with their

input would extend the reach of those biases and preferences, while also lending credence and authority to the selected theories. Autism is again a useful example here, especially as dominant theories about traits and characteristics have already led to exclusionary diagnostic practices [41]. Yet many of those problematically exclusionary practices are already being replicated in AI [40].

Mitigation requires a number of factors. First, that expertise is sought in the development of an AI, but also that such expertise is handled critically by an interdisciplinary team with a breadth of knowledge. This range ought to be sufficient for both the identification of problems of negative bias early in the design and implementation stages, as well as to ensure that sufficient attention is given to whether theories on which AI programming rely avoid exclusionary practices. Transparency in such processes is also essential so that medical professionals who will be end users of an AI enabled technology can themselves identify biases in the programming. Without these elements, the quality of an AI will remain vulnerable to the replication of unchecked biases, including those that are dominant but not unproblematic and those that have form for historical inequalities, whether in terms of overrepresentation or exclusion, among others. Opportunities to change the programming of potentially expensive AI may be few once it has already been embedded, so understanding of these necessary limitations and risks are essential if the tools are to be used critically and applied cautiously.

AI and Medical Ethics

The previous two sections explored how AI is transforming medical epistemology and bringing particular value to the field but also challenges and risks. This changing epistemological foundation with potential threats is also having a significant impact on medical ethics. The last section of this chapter is therefore dedicated to exploring how AI is affecting medical ethics.

Medicine is fundamentally a relational practice founded on the relationship between a patient and

a doctor. A key aspect of this relation is its constitutive asymmetry – the vulnerability of a patient who asks for the help of a health professional equipped with the competence to respond to the identified vulnerability. However, this asymmetry of abilities, or power, may lead to abuses on either side: (a) the patient might abuse the professional's service or (b) the professional might abuse his or her power over the patient. As the philosopher Worms puts it: "Care cannot exist without a relationship in which the weakness of one person requires assistance, which can turn into submission, and the capability of another allows for devotion, which can turn into power, or even abuse of power" ([42] ii). Because of this constitutive asymmetry between the patient and the doctor, medical practice has been, from very early on, regulated by ethical codes and guidelines. The earliest of these is the Hippocratic Oath and many others have followed, notably the principles of biomedical ethics by Beauchamp and Childress [43].

How is the deployment of AI in medicine modifying this fundamental aspect of this practice as a relation, given that it is one that is essentially asymmetric? This is a key question for medical ethics in the era of AI, one that philosophers, ethicists, healthcare professionals, patients, and society at large need to explore to identify potential challenges and risks and propose mitigating strategies. This section explores this question through two different aspects: (a) the patient-doctor relationship and (b) the medical profession in the era of digital capitalism.

The Patient-Doctor Relationship

The fundamental relationship between the patient and the doctor is affected in various ways by the introduction of AI to medicine. There is the risk that the clinical encounter – this fundamental moment of the therapeutic relationship – is set aside, replaced by a mass amount of data automatically collected and analyzed. The claimed "superhuman" accuracy and insight" [7] produced by AI risks replacing the value of this encounter. This is a potential threat for clinical

diagnosis as an outcome from a doctor-patient encounter. Indeed, what causes a person to seek medical help may not be the primary issue for which they need most help. In other words, the narrow approaches to diagnostic processes as conducted by AI systems may lead to missing potential for incidental findings. For instance, referred pain, physical manifestations of mental health issues, hoarding and other self-harm behaviors can be indicators of a brain disorder, a mental health condition, or of abuse, such as domestic violence. These kinds of potentialities could be straightforwardly considered in an interpersonal clinical encounter, but missed by an AI.

Additionally, with the entrance of new, highly complex technical tools in medical practice, the doctor might not fully understand the results of the analysis produced by the AI, and therefore be unable to properly explain to the patient and their family the full rationale behind the diagnosis and prescription. As Campolo and Crawford put it, "claims about 'superhuman' accuracy and insight" are "paired with the inability to fully explain how these results are produced" ([7] ibid). This is a key challenge of explainability brought about by AI, also presented as the issue of an AI system as a black box [44]. This issue is particularly critical in the context of medicine since human life and wellbeing are at stake.

The clinical encounter between the patient and doctor is also affected by the introduction of new actors, i.e., data scientists and engineers, and their technical systems, especially where these gain a central role. This inclusion affects the intimate relationship that characterizes the clinical encounter and brings challenges in terms of confidentiality and privacy [45, 46]. For instance, a study has shown that "a well-trained deep learning system is able to recover the patient identity from chest X-ray data" [47]. Even if CheXNet, discussed above, were to become an effective prediction model, such revelations could undermine its usefulness in terms of patient willingness to undergo scanning. This also leads to challenges related to trust and informed consent: two essential aspects of the medical relationship. In turn, this threat to the patient-doctor dialogue and relation of trust might make it difficult for the patient to make

sense of their own illness or issue. Indeed, the interpersonal dialogue with the doctor plays a major role in this self-understanding.

The Medical Profession in the Era of Digital Capitalism

The entrance of AI in medicine is also impacting the medical profession in various ways. Data science is increasingly gaining a central role in the field, at the expense of more traditional medical expertise, including its intuitive dimensions. As Matuchansky puts it: “One quickly learns from clinical practice that medicine is as much an art as a science or a technique” [48]. With the entrance of AI in medicine, this should not be forgotten or obscured behind claims of precision, scientism, and objectivity of AI systems.

Connected to this challenge to the profession, there is also the risk of deskilling of medical professionals [49]. If AI systems are seen as better placed to conduct various activities that were initially conducted by a doctor, chances are high that they will progressively replace humans (hence, also redirecting money from clinician’s wages to technology companies). For instance, use of deep learning techniques for chest radiography shows “the potential to exceed human performance” [47]. In turn, this leads to the risk of increased dependency on technology for key aspects of human existence (cf [49, 50]). Against this, many experts have called to ensure that AI remains an assistant to the healthcare professional, acting as a “support tool,” and not as a replacement to the human [51].

Additionally, this trend further pushes medicine in the direction of a technical discipline, taking attention away from the relational aspects of this practice. As the ethics of care has shown, the relational aspects of care already tends to be undervalued in the medical sector. These non-technical tasks are primarily undertaken by people from marginalized groups, primarily women and migrants, and those who are poorly paid. This can be contrasted with those highly specialized and technical areas of medicine such as surgery, which are highly respected and valued,

and rewarded accordingly [52]. The introduction of AI to the world of medical care further contributes to this over-valorization of the technical at the expense of relational aspects.

Exploring relations in medicine is not only restricted to interpersonal relationships (between patients, doctors, and other professionals). It also requires looking at relations within the broader sociopolitical landscape and the power asymmetries at this level. Here as well, the growing dependency on technology, and in particular on big technology companies needs to be investigated. The use of AI in the medical sector has brought about new actors, including Google, Apple, Facebook, and Amazon [53]. Because these companies are in possession of massive amounts of data and the ability to process them, they have found themselves well placed to enter the medical sector. For instance, Tamar Sharon talks about the “googlisation of healthcare” and its promises to “advance health research by providing the technological means for collecting, managing, and analysing the vast and heterogeneous types of data required for data-intensive personalised and precision medicine” [53]. This entrance of healthcare in “digital capitalism” is posing key questions in terms of privacy and confidentiality. Indeed, these big tech companies have a rather poor track record when it comes to the protection of personal data [50]. Medical data is enormously valuable and a particularly sensitive type of data that requires special protection. Access to such data only further increases the power of technology companies. Meanwhile, there is a general consensus that already powerful actors from insurance to recruitment companies should not have access to this data as it could lead to significant discrimination on the basis of health.

As the above has shown, the introduction of AI in medicine changes the power dynamics in the sector. With the digitalization of the field, data scientists, as well as big technology companies are gaining a central role in medicine. It is also pushing the sector toward “technicization” at the expense of relational aspects that are nonetheless central. Although AI in medicine brings great promises for the field in terms of efficiency and precision, it is nonetheless essential to pay

attention to these changing power dynamics as well as the technicization of the field to ensure that the interests and wellbeing of the patient remain the central consideration of medical practice. Additionally, it is essential to ensure that healthcare professionals, whether doctors or nurses, are well equipped for the digital transformation of their field and protected against abuses by industry actors. Finally, policy makers also have a role to play to ensure digital capitalism does not interfere with the interests of patients.

Conclusion and Recommendations

This chapter has investigated some of the promises for medicine in the algorithmic age and what these claims mean philosophically and ethically. After briefly exploring what AI promises to achieve in terms of medical advances, this chapter looked at how the introduction of AI in medicine deeply impacts medical epistemology. In particular, it explored the implications of a technology that claims to generate knowledge and diagnosis from data alone. Numerous questions raised by this epistemology, based on a form of “data-utopianism,” and how this interrogates the nature of objectivity in the medical field have been pointed out. This chapter has then highlighted the limitations, risks, and biases of AI and how these impact medicine. Finally, it looked into the ethical implications of the introduction of AI to medicine, especially in relation to the patient-doctor relationship and how the medical profession is evolving as it enters the era of digital capitalism.

This chapter has highlighted some key challenges and risks brought about by AI in medicine, but also some ways to mitigate these. To begin with, it is essential to refer to relevant ethical guidelines and frameworks. A number of these have been developed for AI over the last few years, such as the 2019 “Ethics guidelines for trustworthy AI” of the High-Level Expert Group on Artificial Intelligence set up by the European Commission [54]. The SIENNA project has also developed a set of ethical instruments to promote an ethical development, deployment and use of AI, including an ethics by design framework and an approach for research ethics [55]. It is also

important to carefully assess where AI can truly add value and where it does not (and might even be harmful). To these ends, ethical impact assessments as well as social science studies on the use of AI in medicine can help to better understand the impacts and consequences of AI for the medical sector, including in the short, medium, and long term [56].

Finally, it is essential for the healthcare community to develop their understanding of AI in technical terms. This would help to ensure appropriate and proportionate levels of trust, which is not too little, such that the AI system would become useless or poorly applied and adopted, nor too much, such that it is trusted and allowed to function independently of oversight and appropriate human intervention. It is also essential to raise awareness of the kinds of unique challenges that are brought by AI, including for doctors, for the healthcare community, and for society at large. Effective AI in medical contexts requires transparency so that people are aware of these tools in their work and their everyday lives, and so as to ensure a certain degree of oversight in these contexts. Finally, and as already mentioned above, AI should remain a tool that human beings can use if they deem it useful to achieve specific and identifiable objectives, but not as a replacement for human expertise and intervention, especially in medical domains where a person’s needs and their vulnerabilities may be greatest.

The practice of incomplete study reporting is rife within scientific literature. It hinders the adoption of technologies, introduces considerable “research waste,” and represents a significant moral hazard. In order to combat this issue, there has been a shift towards the use of reporting standards and quality assessment tools, a move that has been endorsed by major biomedical journals as well as other key stakeholders. These instruments help [1] to improve the quality and completeness of study reporting as well as [2] to aid researchers in their assessment of a study’s risk of bias and applicability. These instruments are carefully created through a multistep evidence generation process and are specific to individual study

designs or specialties. Recently, it has been noted that many of the existing instruments are poorly suited to aid the reporting and assessment of artificial intelligence (AI)-based studies on account of their niche study considerations. As such, there has been a concerted effort to produce AI-specific extensions to preexisting instruments, such as CONSORT, SPIRIT, STARD, TRIPOD, QUADAS, and PROBAST. This chapter expands upon why AI-specific amendments to these instruments are required in addition to highlighting their contents and proposed scope.

Artificial intelligence · Reporting standards · Quality assessment tools · CONSORT-AI · SPIRIT-AI · STARD-AI · TRIPOD-AI · QUADAS-AI · PROBAST-AI

Introduction

Ensuring that treatment strategies are founded upon well-reported and unbiased scientific research is one of the cornerstones of good patient care. While completeness of reporting constitutes sound and ethical conduct among all scientific endeavors, it is of particular importance within health sciences, a field in which indiscretions may manifest in avoidable harm to patients. There are many notable examples of poor reporting, even within high profile randomized controlled trials, which have hindered the clinical translation of potentially useful research outcomes [1]. Such practice constitutes “research waste” [2] and poses a significant moral hazard.

As greater awareness regarding this issue has developed, experts have highlighted a number of key phases within a research study during which poor reporting may occur, as illustrated in Table 1.

While many hold the assumption that the responsibility of ensuring comprehensive research reporting falls primarily upon the editorial boards of journals, this, in fact, is a fallacy. Poor reporting is best viewed as a system failure across researchers, research funders, peer

Table 1 A table detailing examples of poor reporting across different study phases

Study phase	Examples of poor reporting
Study protocol	1) Ambiguous sample size calculation [3] 2) sparse administrative information regarding study conduct [4]
Main study abstract	1) Selective presentation of study results [5] 2) incongruity with message from the main study manuscript [6]
Main study methods	1) Ambiguous inclusion and exclusion criteria [4] 2) Inappropriate statistical analyses [7] 3) Inconsistencies in comparison to the associated study protocol [8]
Main study results	1) Incomplete reporting of study results [9] 2) Statistical errors [10] 3) Post hoc subgroup analyses [3] 4) Omission of harm reporting [11] 5) Misleading visual representation of data [12]
Main study discussion	1) Selective or inappropriate citation of other studies [13]

reviewers, and journal editorial boards, an issue, at least in part, analogous to the “Swiss cheese model” used in risk analysis across multiple industries [14]. As evidenced by the many thousands of dubious studies that have been published following peer review process [15], it is inappropriate and unrealistic to assume that a single layer of defense against poor reporting will suffice.

While the issue of poor reporting is a multi-faceted problem, one of the principal means in which the scientific community may mitigate the risk of this is through adherence to consensus-achieved reporting standards and quality assessment tools. Since their introduction in the mid-1990s [16], these instruments have garnered considerable traction in the scientific community and are now mandated by the majority of major biomedical journals [17]. Reporting standards and quality assessment tools may be differentiated as follows:

- Reporting standards provide structure and advice upon the information required in a primary health research manuscript. They typically consist of a checklist of minimally

essential items, which are often completed alongside accompanying explanatory documents and flow diagrams in order to facilitate its appropriate usage. Typically, reporting standards are specific to either the proposed study design or the clinical specialty under investigation. Moreover, each set of standards is created through a multistep evidence generation process. The aim of these processes, which often take years to complete, is to produce an internationally accepted set of reporting standards which aids the interpretation of the study's methodology, internal validity, external validity, and the overall "real world" utility. Given the needs across specific clinical specialties and study designs, there are now over 250 reporting standards available for consultation. In order to aid researchers in the appropriate identification, use, and creation of reporting standards, the Enhancing the QUAlity and Transparency Of health Research (EQUATOR) network [18] was established in 2008.

- (b) Quality assessment tools are instruments that are designed to specifically appraise one or more dimensions of quality within a research study. These tools are typically employed when conducting secondary research projects, such as systematic reviews and meta-analyses; study designs that are widely trusted to be the most reliable form of evidence within most taxonomies of empirical strength [19]. Systematic reviews should involve "a systematic approach to minimizing biases and random errors which is documented in a materials and methods section" [20]. In keeping with the aforementioned statement, a key component in conducting such secondary research studies is the appraisal of the risk of bias and applicability within shortlisted studies. Foregoing this crucial step can lead to the improper inclusion of studies which may, in turn, lead to unreliable and inaccurate estimates of treatment effects. Much like reporting standards, quality assessment tools are study design specific and are created following a multistep evidence generation process, typically led by experts within the field.

The Case for AI-Specific Instruments

As noted in other chapters in this book, AI-based technologies dominate medical headlines and are often touted as the panacea for a number of longstanding deficiencies across health systems globally [21]. Stakeholders from healthcare, government, computer science, and industry backgrounds are confident that AI can be positioned to tackle (1) the high rate of avoidable medical errors [22], (2) clinical workflow inefficiencies [23], and (3) the current level of unsustainable resource utilization associated with contemporary healthcare provision [24]. Despite these lofty ambitions, the integration of AI into everyday clinical practice within the health sector has been limited thus far. Issues that preclude its meaningful clinical translation across health systems include sparse regulatory guidance [25], wavering patient acceptability [26], and, pertinent to this chapter, the paucity of AI-specific instruments to assess the emerging scientific evidence.

As highlighted previously, reporting standards and quality assessment tools serve as critical tools which allow stakeholders from varying backgrounds to uniformly appraise the validity of research findings. While there are a wide number of specific tools available, none are specific to AI methodologies. As such, their ability to interrogate key reporting and quality considerations in this genre of studies is limited.

This is highlighted in the largest systematic review to be undertaken assessing the performance of AI models in healthcare, led by Liu et al. (2019) [27]. The review highlights that AI models have a high degree of diagnostic accuracy across a range of specialties, imaging modalities and clinical workflows. However, they also highlight the large degree of methodological and reporting variation that exists in the literature currently. Examples of this variance include:

1. Terminology: The term "validation" is used inconsistently in the literature. In some instances, the term "validation," when used in isolation, was used to describe the process of testing the final model, whereas other research groups used the term to describe the process of fine-tuning models as part of its development.

2. Dataset: The majority of AI studies are reliant upon retrospectively collected data, which are often labeled for purposes other than AI model development (e.g., more commonly for clinical radiology or histology reports). As such, the criteria for either the presence or absence of a pathology are poorly defined. In addition, there is often minimal rationale as to how images are chosen for inclusion within the dataset. There is often no justification for the size of datasets. Moreover, pertinent details regarding multi-vendor image sources are commonly missing. Lastly, there was often a lack of transparency regarding the split of data amongst the training and test sets, particularly when stating whether test sets were out of sample.
3. AI model: Very few studies provided enough detail that would allow for meaningful replication and independent validation of the models. Moreover, details which impact “real world” translation, such as availability of the model as well as whether the model is static or dynamic, are also poorly reported.
4. Study Methods: Studies often undertook their assessment of their models in isolation, which is poorly reflective of clinical practice. Moreover, even as part of the “*in silico*” assessment, many studies typically did not undertake validation of their model in an external test set, a poor practice that has been shown to lead to inflated measures of model performance. In addition, very few studies compared the performance of AI models against expert human clinicians.

Adding to this growing body of evidence is a meta-research assessment conducted by this authorship group. Through our own work, we have examined the use of existing quality assessment tools in secondary research papers reporting upon the diagnostic performance of AI systems. We note that formal quality appraisal and risk of bias assessment was not uniformly applied in AI-based diagnostic accuracy systematic reviews. Despite being considered a prerequisite among many journals, only 74% of studies shortlisted performed any form of quality assessment, with 56% of reviews opting for the QUADAS-2 tool, the most widely used tool within its class. Further to this, we are able to demonstrate that there is

either high or an unclear risk of bias in all of the quality domains assessed. We note the following issues, as framed by the QUADAS-2 domains of assessment:

1. Patient selection: The principal factors leading to a high risk of bias within the patient selection domain include poor patient sampling technique as well as the inappropriate exclusion of data at either a patient or feature level. AI-based diagnostics require rigorous datasets representative of real-world characteristics to produce reliable and generalizable diagnostic results. Therefore, inappropriate exclusion of participants and/or features can affect the interpretation of AI results in a more significant way compared to conventional analysis and contribute considerably to bias in patient selection. Excluding pathologies that may be similar in characteristics or have overlapping features to the diagnoses of interest (e.g., exclusion of patients with inflammatory bowel disease when determining diagnostic accuracy of endoscopic detection of polyps) may lead to overestimation of the algorithm’s diagnostic accuracy as well as low generalizability and clinical utility of the algorithm.
2. Index test: The term “index test” relates to the AI model that is being evaluated against the reference standard. AI models developed using overlapping datasets can overestimate diagnostic accuracy in comparison to using external validation data. Conversely, a lack of exposure to multiple manifestations of a pathology can result in “The Frame Problem” [29] whereby seemingly obvious diagnoses may be missed by the model simply due to inexperience.
3. Reference standard: Determination of an appropriate reference standard, which serves as the “ground truth” in model development, requires consideration of the best available evidence. This process may involve amalgamating clinical, radiological, and laboratory data. There are multiple instances in which AI models are compared to a human reference standard as the gold standard while alternative tests providing higher sensitivity and specificity are feasible. This is illustrated by Harris et al. (2019) [30] who deemed that 32 out of

33 shortlisted studies reporting upon the diagnostic accuracy of AI models to analyze chest x-rays for pulmonary tuberculosis were of high risk of bias due to the reference standard relying upon human interpretation of the chest x-ray as opposed to the use of sputum culture confirmation.

4. Flow and timing: The flow and timing domain considers the interval between the index test and reference standard, similarities in the reference standard evaluation among all patients and the inclusion of all patients in the final analysis. We highlight that the use of different reference standards between positive and negative cases can pose challenges in AI-based studies. This is illustrated in the case of cancer studies in which histological confirmation is often utilized as part of the reference standard for confirming malignancy; however, obtaining biopsies from clearly benign lesions poses ethical and practical challenges, thereby necessitating the use of alternative confirmatory tests [31]. Moreover, utilizing different reference standards, such as follow-up alone in comparison to histology, may also result in verification bias.

Given these aforementioned issues, there is a concerted global effort to address these flaws, promote more complete reporting, and produce quality assessment tools that are better placed to appraise emerging literature. A number of research teams are undertaking AI-specific extensions to existing reporting standards and quality assessment tools. In the following section, this chapter will highlight these AI-specific reporting standards and quality assessment tools that have either been developed or are in the process of development currently.

Specific AI Reporting Standards

SPIRIT-AI and CONSORT-AI

The SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) 2013 [32] document serves as guidance for authors who wish to undertake either randomized or nonrandomized trials. It is an essential document that enables readers

to undertake three key tasks: (1) understand the background, methods, target population, statistical analyses, and ethico-legal considerations associated with the proposed study, (2) replicate aspects of the trial methodology, if desired, and (3) appraise the study's scientific rigor.

It is essential for study protocols to be complete in their reporting as they often serve as critical pieces of evidence when used by external reviewers, such as funding bodies, regulatory authorities, research ethics committees, and peer-reviewers on behalf of scientific journals. However, despite its comprehensiveness, SPIRIT 2013 does concede that certain methodologies and specialties would require a specific extension.

The CONSORT (Consolidated Standards of Reporting Trials) statement provides guidance for authors who are reporting the findings of a randomized controlled trial (RCT). It is well accepted that RCT designs are considered to be the gold standard in providing evidence upon the safety and efficacy of an intervention. Stakeholders often rely upon the results of RCTs in order to inform clinical standards and health policy.

CONSORT was first introduced in 1996 [16] and was last updated in 2010 [33]. Like the other statements in this section, the CONSORT study authors have conceded that certain methodologies and specialties would require a specific extension.

Both SPIRIT-AI [34] and CONSORT-AI [35] initiatives were conducted by the same multi-stakeholder research group in order to ensure harmonization between statements. The AI-specific extensions and elaborations to both statements are listed in Table 2.

STARD-AI

The STARD (Standards for Reporting of Diagnostic Accuracy Studies) 2015 statement [36] remains the most widely accepted set of reporting standards for diagnostic accuracy studies. However, STARD was not designed to address the issues and challenges raised by AI-driven modalities. This is an increasingly pressing issue due to the fact that the majority of AI interventions that are close to translation are predominantly in the field of medical diagnostics. Recent market

Table 2 A table detailing the corresponding AI-specific additions to SPIRIT-AI and CONSORT-AI

SPIRIT-AI Item	CONSORT-AI Item	Explanation
Item 1 (i) elaboration: Indicate that the intervention involves artificial intelligence/machine learning and specify the type of model	CONSORT-AI 1a,b (i) elaboration: Indicate that the intervention involves artificial intelligence/machine learning in the title and/or abstract and specify the type of model	<i>This facilitates indexing and searching. The use of the broader terms of “artificial intelligence” and “machine learning” within the title allow for easy interpretability by a wide audience</i>
Item 1 (ii) elaboration: State the intended use of the AI intervention	CONSORT-AI 1a,b (ii) elaboration: State the intended use of the AI intervention within the trial in the title and/or abstract	<i>This allows readers to understand the intended use of the AI intervention in an unambiguous manner</i>
Item 6a (i) extension: Explain the intended use of the AI intervention in the context of the clinical pathway, including its purpose and its intended users (such as healthcare professionals, patients, public)	CONSORT-AI 2a (i) extension: Explain the intended use for the AI intervention in the context of the clinical pathway, including its purpose and its intended users (e.g., healthcare professionals, patients, public)	<i>A detailed description of the clinical workflow and the role of the AI intervention within this system aids readers in understanding the importance of the study</i>
Item 6a (ii) extension: Describe any preexisting evidence for the AI intervention	N/A	<i>Details regarding the development and subsequent validation of the intervention provide useful background and should be provided</i>
Item 9 extension: Describe the onsite and offsite requirements needed to integrate the AI intervention into the trial setting	CONSORT-AI 4b extension: Describe how the AI intervention was integrated into the trial setting, including any onsite or offsite requirements	<i>AI interventions are heavily dependent upon specific operational environments. As such, it is imperative that these are explicitly specified. This includes the presence of vendor-specific devices, hardware requirements, and software requirements</i>
Item 10 (i) elaboration: State the inclusion and exclusion criteria at the level of participants	CONSORT-AI 4a (i) elaboration: State the inclusion and exclusion criteria at the level of participants	<i>It is important to differentiate between the inclusion/exclusion criteria at both a participant level and a data input level</i>
Item 10 (ii) extension: State the inclusion and exclusion criteria at the level of the input data	CONSORT-AI 4a (ii) extension: State the inclusion and exclusion criteria at the level of the input data	<i>There should be clearly stated minimum input data entry requirements, which can be related to image resolution or data format</i>
Item 11a (i) extension: State which version of the AI algorithm will be used	CONSORT-AI 5 (i) extension: State which version of the AI algorithm was used	<i>AI interventions should state the version number associated with the study. If there are alterations with respect to the agreed upon version number, this should be justified. When available, regulatory marking references should be provided</i>
Item 11a (ii) extension: Specify the procedure for acquiring and selecting the input data for the AI intervention	CONSORT-AI 5 (ii) extension: Describe how the input data were acquired and selected for the AI intervention	<i>The quality of the AI intervention output is heavily dependent upon the quality and nature of the input data that is selected for the study. As such, clear procedures regarding acquisition, selection, and preprocessing should be provided in order to allow input standardization across study site.</i>

(continued)

Table 2 (continued)

SPIRIT-AI Item	CONSORT-AI Item	Explanation
Item 11a (iii) extension: Specify the procedure for assessing and handling poor quality or unavailable input data	CONSORT-AI 5 (iii) extension: Describe how poor-quality or unavailable input data were assessed and handled	<i>As previously noted, poor quality data can severely impact upon the performance of the AI intervention. As such, minimum standards for input data are required. There should be transparency regarding how poor data is handled</i>
Item 11a (iv) extension: Specify whether there is human-AI interaction in the handling of the input data, and what level of expertise is required for users	CONSORT-AI 5 (iv) extension: Specify whether there was human-AI interaction in the handling of the input data, and what level of expertise was required of users	<i>This relates to how end users interact with the AI intervention and whether specific user training is required in order to attain maximal benefit from the intervention</i>
Item 11a (v) extension: Specify the output of the AI intervention	CONSORT-AI 5 (v) extension: Specify the output of the AI intervention	<i>The output, which can vary between a diagnostic classification, a recommended action, and a prognostic probability, needs to be clearly specified</i>
Item 11a (vi) extension: Explain the procedure for how the AI intervention's outputs will contribute to decision-making or other elements of clinical practice	CONSORT-AI 5 (vi) extension: Explain how the AI intervention's outputs contributed to decision-making or other elements of clinical practice	<i>This extends from the premise set forth in item 11a (iv) whereby there needs to be a clear process in place for the human-AI interaction when interpreting the intervention's outputs. There needs to be clear criteria as to who (experience and skill level) interprets the output as well as what the output is permitted to safely suggest (e.g., diagnostic probability expressed as a percentage vs. binary outcome values)</i>
Item 22 extension: Specify any plans to identify and analyze performance errors. If there are no plans for this, explain why not	CONSORT-AI 19 extension: Describe results of any analysis of performance errors and how errors were identified, where applicable. If no such analysis was planned or done, explain why not	<i>Failure case analysis is of vital performance as these nascent technologies become increasingly incorporated into clinical practice. This is a vital step in minimizing potential harm to patients. When appropriate, risk mitigation strategies should also be provided</i>
Item 29 extension: State whether and how the AI intervention and/or its code can be accessed, including any restrictions to access or re-use	CONSORT-AI 25 extension: State whether and how the AI intervention and/or its code can be accessed, including any restrictions to access or re-use	<i>This is an important part of maintaining transparency in study conduct</i>

analysis performed by Benjamins et al. (2020) [37] has demonstrated that over 90% of AI products that have been approved by the United States Food & Drug Administration are related to the field of diagnostics. In the current paradigm, diagnostic investigations require timely interpretation from an expert clinician in order to generate a diagnosis and to direct subsequent episodes of

care. The recurring issue with this system is that diagnostic services are inundated with large volumes of work, which can often supersede workforce capacity. In order to address this, diagnostic AI algorithms, with notable examples targeted toward breast cancer [38] and lung cancer [39], have positioned themselves as medical devices that may achieve diagnostic accuracy comparable

to that of an expert clinician while concurrently alleviating health-resource use. However, although this paradigm shift may seem imminent, it is crucial to note that much of the evidence supporting diagnostic algorithms has been disseminated in the absence of AI-specific reporting standards.

In order to tackle these problems, the STARD-AI Project Team and Steering Committee are preparing an AI-specific extension to the STARD statement (STARD-AI) [40] that aims to focus upon the specific reporting of AI diagnostic accuracy studies. This work is complementary to the other novel AI extensions noted in this section. This process is being developed in close collaboration with key stakeholders consisting of clinicians, computer scientists, journal editors, researchers, trialists, industry leaders, regulators, funders, policy makers, and patient groups. STARD-AI is anticipated in Q1 of 2022.

TRIPOD-AI

The TRIPOD (Transparent Reporting of a Multi-variable Prediction Model for Individual Prognosis or Diagnosis) statement was published in 2015 [41] and provides guidance on the key items to report when describing studies developing, evaluating, or updating clinical prediction models.

Although TRIPOD has been well adopted in the reporting of regression centered prediction model studies, its uptake within AI studies has been comparatively stunted thus far. This is a concerning feature given that one of the most prominent areas of AI healthcare research centers around the use of prognostic models. These models offer the potential of analyzing large and complex patient datasets in order to create precise and personalized outputs pertaining to patient prognosis [42]. This, in turn, can be leveraged in preventative clinical strategies which can lead to improved patient outcomes as well as more efficient resource utilization at a health system level.

In order to address these issues, TRIPOD-AI [43] is being developed in order to focus on the reporting of machine learning prediction algorithms. Like STARD-AI, TRIPOD-AI is being

developed in close collaboration with key stakeholders consisting of clinicians, computer scientists, journal editors, researchers, trialists, industry leaders, regulators, funders, policy makers, and patient groups.

Specific AI Quality Assessment Tools

QUADAS-AI

The most commonly used tool for the methodological assessment of diagnostic accuracy centered secondary research studies remains the Quality Assessment of Diagnostic Accuracy Studies 2 (QUADAS-2) tool [44]. QUADAS was developed in 2003 [45] and updated, as QUADAS-2, in 2011. The original tool comprised of 14 items on patient selection and spectrum, reference standard, presence of various biases, test execution, study withdrawals, and indeterminate results. The updated version was streamlined to categorize the questions into four key domains: (1) patient selection, (2) index test, (3) reference standard, and (4) flow and timing, with each domain assessed for the risk of bias as well as potential external validity. Although systematic reviews serve an important role in summarizing evidence in a precise fashion that aims to minimize bias, 96% of those related to AI diagnostic accuracy have been conducted in the absence of an AI-specific methodological quality assessment tool. The absence of a robust quality assessment tool for AI in this field not only hinders efficient quality appraisal at an evidence synthesis phase but has considerable downstream effects as key stakeholders; such policy makers, regulatory officials, technologists, and healthcare professionals are unable to effectively evaluate the translational potential of these nascent technologies.

In order to tackle this issue, an AI-specific extension to QUADAS-2 (QUADAS-AI [46]) is in production, which aims to provide researchers and policy makers with a framework to appraise methodological quality in systematic reviews evaluating the diagnostic accuracy of AI models. This work will be complementary to the ongoing STARD-AI initiative [40], PRISMA-DTA [47],

and QUADAS-3 and QUAPAS [48]. QUADAS-AI is being coordinated by a global Project Team and Steering Committee consisting of clinician scientists, computer scientists, epidemiologists, statisticians, journal editors, EQUATOR Network representatives, regulatory leaders, epidemiologists, statisticians, industry leaders, funders, health policy makers, legal experts, and bioethicists.

PROBAST-AI

PROBAST (Prediction model Risk Of Bias Assessment Tool) was published in 2019 [49] in order to help stakeholders critically appraise the study design, conduct and analysis associated with prediction model studies. PROBAST consists of four domains (participants, predictors, outcome, and analysis) and 20 signaling questions to facilitate risk of bias assessment. PROBAST-AI is being developed in parallel to the ongoing TRIPOD-AI initiative and will serve as a tool to assess risk of bias in machine learning-based prediction model studies.

Conclusion

There is increasing recognition that AI studies require bespoke reporting standards and quality assessment tools in order to aid completeness of reporting and minimization of bias. CONSORT-AI, SPIRIT-AI, and the forthcoming STARD-AI, TRIPOD-AI, QUADAS-AI, and PROBAST-AI will all serve first as consensus-derived iteration of global standards in this space.

Abstract

As the use of machine learning (ML), a sub-field of artificial intelligence (AI), is becoming popular in healthcare, understanding the role of demographic traits such as sex, gender, age,

race, and socioeconomic status on model performance becomes crucial. In this chapter, we first give an introduction into the concepts of gender and sex and show how medical research has been biased toward these concepts. Since ML models are mostly based on historical medical datasets, existing bias might be picked up and distort ML results in favor of one group over another. After explaining the methods for finding bias in ML models, we present possible solutions for debiasing ML models including the collection of more balanced datasets, better documentation regarding underlying data as well as better documentation of the ML model itself, and the use of fairness metrics during model training. Finally, we discuss the current challenges and highlight the potential of deep neural networks for helping in mitigating bias.

Introduction

Currently, ML models are expected to become a transformative tool in healthcare, bringing individualized medicine for everyone. As these ML models are used more and more extensively in everyday life, it becomes vital to evaluate the outcome performance disaggregated on various demographic traits and make sure that the ML models are fair and not discriminative across those traits. These demographic traits include but are not limited to sex, gender, age and race, as well as socioeconomic status. Here, we will focus on gender and sex traits in ML models used in medicine.

According to the World Health Organisation (WHO), sex can be defined as different biological characteristics of females and males, whereas gender can be defined as societal characteristics of those as well as individuals across nonbinary gender scales [1]. In addition to sex differences, gender also affects access to healthcare, and especially gender minorities have been discriminated against based on societal judgments [2, 3].

Although there are clear sex differences between males and females, for long years, sex differences were mostly ignored in medicine. Male physiology was accepted as the default, and most medical research was done using the male body as standard [4]. In the last decades, sex- and gender-specific approaches to medicine are gaining popularity, and more research is being done to understand sex- and gender-related differences in metabolism, physiology, and illnesses. Additionally, clinical trials are planned in a way such that they include both males and females [5]. Yet, sex and gender bias in medicine persists and is still a big problem. While some diseases are sex specific, such as various types of cancers affecting reproductive systems, others have different prevalence among males and females. For

instance, most autoimmune disorders such as multiple sclerosis (MS) are more common in females than males, whereas type 1 diabetes affects more males than females [6]. Additionally, some diseases such as cardiovascular diseases that affect both males and females manifest differently for each sex [7, 8]. However, as many clinical trials have been predominantly performed on male participants until recently, different symptoms in females could be overlooked and might result in females being underdiagnosed.

The gender and sex bias in medicine is currently present in the datasets that are used to train ML models for healthcare. The historical bias is not only reflected in the ML models but can even be amplified [9]. Recently, various methods for detecting and mitigating bias in ML models have been developed [10], and while they might not be specific to ML models used in healthcare, some of them have successfully been applied to medical data.

In the following parts, sex and gender differences in medicine, sex and gender bias in ML systems, and their interaction will be reviewed. Finally, current challenges and possible solutions will be discussed.

Sex and Gender Differences in Medicine

Bias, such as sex, gender, or racial bias, is a recurring issue in healthcare. For long years, the majority of clinical trials were carried out only in male patients, for reasons such as complex physiology of women due to menstrual cycle [11] or due to concerns regarding the development of the fetus [12]. Furthermore, even when women are included in the clinical trials, sex- or gender-based data are not analyzed separately [12]. As a result, the differences in the manifestation of a given disease in females were not well known. For instance, women are less likely to get correctly diagnosed for having a heart attack because their symptoms can differ from those of male patients [13]. Another example is chronic pain, which affects women more frequently [14, 15]. Yet, it was shown that they receive less painkillers when

they visit the ER and wait longer to receive them compared to men [16]. Even when a disease is more common in women, the research data does not always follow the gender ratios. Although thyroid disorders are more common in women [17], one study investigating effects of high thyroid levels on brain functions recruited only male participants [18]. Additionally, perceived gender identity might have a role in bias in clinical practitioners, and this could affect many areas of clinical process such as delay in diagnosis. One study regarding Parkinson's disease showed that although there was no difference in the time from symptom onset to first physician visit between male and female patients, there was a difference in the duration from first symptom to movement disorder specialist visit (61% greater for women), meaning that gender differences affected the referrals to the correct specialists [19]. So, sex and gender bias exists in various areas of medicine in different forms. A particular point of attention are sex differences in the human brain. Previous studies showed differences in pre-frontal areas, the superior temporal sulcus, the posterior insula, and orbitofrontal cortex, as well as in subcortical temporal structures, such as the amygdala, hippocampus, visual primary cortex, and motor areas [20]. Even after matching for gray matter volume, as the head size differs between males and females, studies showed that sex can still be successfully classified using resting-state brain connectivity measures [21, 22]. Studying sex- and gender-related differences is also important for developing strategies regarding prevention and therapy. For instance, research investigating the effect of physical activity in relation to brain health showed physical activity resulted in greater improvement of cognitive functions in females compared to males [23].

Bias in healthcare is not limited to sex and gender. A meta-analysis covering 2511 studies found that 81% of participants in genome-wide association studies has European ancestry [24]. In a neuroimaging study, differences were found across various brain regions between African-American and white participants [25]. Moreover, although African-American patients are affected by Alzheimer's disease (AD) more often, they are

still underrepresented in studies [26, 27]. Sometimes the data is not disaggregated according to different sex, age, and racial and social groups, and as a result, it is not possible to study the problems of underrepresentation. For example, the frequently used brain atlas, MNI152 template, does not specify the female/male ratio in the population sample used to construct the template [28]. The effects of bias in models used in healthcare are not well understood or well documented. Understanding and documenting the effects of bias is crucial with the recent efforts to collect big data in medicine and recent advances in clinical use of ML models.

Sex and Gender Bias in Machine Learning Models

Algorithms are traditionally defined as a procedure for computers that defines step by step what they should do with a set of input to create an output. By this definition, algorithms are bound to work within the limits of what has been programmed. The need to explicitly program every output quickly becomes a limitation with the growing number of inputs and outputs. To overcome this limitation, ML was born as a field within computer science. ML can be defined as the ability of the algorithm to adaptively learn the outputs from the inputs and to generalize this knowledge on unseen inputs.

Today, ML models play an important role in automating the decision-making process, and society increasingly relies on ML models for supporting decision-making with potentially severe consequences in many areas of human life: from credit scoring and CV screening for job applications to deciding whether defendants awaiting trial should be detained or released [29, 30]. As the algorithms used in automated decision-making are trained using historical data, the learning depends particularly on the so-called labels of training data, which is influenced by the human decision-making process. Human decision-making is and has been affected by various forms of cognitive bias [31], and the data collected regarding those decisions are also prone to bias. As a result,

with the increasing use of big data and ML algorithms for decision-making, algorithmic bias is a growing concern [32]. There are many different underlying reasons of algorithmic bias. One reason is underrepresentation of minorities and lack of diversity in the data and labels collected for training the algorithms. For instance, a recent study has shown that various commercial facial recognition software platforms have significantly reduced performance when applied to women, and the performance difference was even stronger in the case of black women compared to white men [33]. Another example showed that when used for translating job titles from gender-neutral languages to languages with gendered job titles, machine translation uses male defaults for STEM (science, technology, engineering, and mathematics) job titles [34]. Even word embeddings, which have a range of applications from web search results to parsing resumes, show gender bias [35]. Furthermore, the existing biases in the dataset are amplified through the algorithms used. A recent study investigating captioning of the gender in the context of activities seen in an image (for instance, cooking) found that not only the datasets used for training such tasks contained bias, but also the models trained on these data amplified the existing bias [9]. Most importantly, as most of those algorithms are perceived as a black box, the people affected by the algorithmic bias might not be aware of it.

Recently there has been an increasing awareness in the ML community about algorithmic bias. Recent research developed methods about understanding and mitigating algorithmic bias as well as pointing out the importance of algorithmic fairness. The open source Python toolkit AI Fairness 360 (AIF360) is one of the recent tools that provides methods to investigate and mitigate bias in algorithms [10]. Gebru and colleagues proposed datasheets for datasets, where every dataset is accompanied by a datasheet explaining characteristics and recommended use of the dataset [36]. A similar approach, model cards for model reporting, was proposed for documenting dataset characteristics, benchmarking results across different demographic groups and explaining intended use of ML models [37].

Role of Sex and Gender in Machine Learning Models for Medicine

Use of ML models in medicine is gaining popularity especially with increased availability of big datasets and novel algorithms. Thus, understanding the role of sex and gender traits in these models and datasets is becoming more prominent. Medical imaging is one of the cornerstones of diagnostic methods, and with the currently available big datasets, it is perfect for so-called supervised learning methods of traditional ML algorithms as well as convolutional neural networks (CNN), a type of deep learning model [38]. Traditional ML algorithms and statistical methods require domain expertise and manually picking features used as input data. However, deep learning algorithms are data driven, meaning the feature selection can also be automated [39]. Deep learning algorithms can also help finding subtle and complex differences in the data. As a result, deep learning methods are used in various applications in medical imaging, from disease classification for diagnosis to prediction of disease development and treatment outcome [39]. But nevertheless, the need for tuning of hyperparameters and the fact that the deep learning algorithms are perceived as a black box are raising concerns about the fairness of the models across different traits such as sex, gender, and race.

Since the historical data are now being used for training ML algorithms to aid medical decision-making, the lack of diversity and underrepresentation issues are transferred to the models, thus causing algorithmic bias across demographic traits. For instance, a recent study found that a commonly used commercial healthcare risk score prediction algorithm in the United States has racial bias; at a given score, it is showing black patients sicker than white patients [40]. Many neuroimaging studies exclude left-handed participants, thus resulting in a representation bias [41]. When the diversity in the datasets is ignored, the sample distribution would not be similar to the general population, which can influence results [42].

There are still no standardized methods for evaluating models for fairness and bias, and

many models in healthcare are still not reporting results stratified by sex or gender. In a recent review, it was shown that research articles about medical imaging-based diagnosis models rarely report the demographic traits of the dataset used or include the demographic traits as variables in the model [43]. However, one study has indeed demonstrated that sex imbalance in medical imaging (X-ray) datasets used for computer-aided diagnosis (CAD) based on state-of-the-art CNNs produced biased classification results [44]. When they investigated different proportions of sex in the training data, they found that a model trained with balanced and diverse dataset performed best for both male and female patients. Moreover, the balanced dataset resulted not only in an improved performance for the underrepresented group but did also not change the performance for the overrepresented group, so the balanced dataset resulted in an overall better performance [44].

Current Issues

Today, ML is used increasingly in healthcare, and investigation of algorithmic bias is important in order to advance health equity [45]. Gianfrancesco and colleagues investigated the types of bias in ML models trained on electronic health records and suggested paying extra attention to data being used to train the algorithms and making the intended use case of the algorithms clear [46]. Some reasons of bias in healthcare include underrepresentation of female patients [13], lack of diversity [24], and implicit bias by medical professionals [16]. While new tools are developed for the assessment of bias in clinical data and clinical accuracy recently [47, 48], these tools are not specific for machine learning applications, and some of the metrics rely on judgment instead of quantitative measures. More recently, Rajkomar and colleagues categorized key biases in the design, data, and deployment of ML models used in healthcare [45]. For instance, systematical misdiagnosis of a subgroup, differences in the distribution of data across subgroups, features missing not at random in a subgroup as well as clinicians trusting the model even when it is wrong or otherwise ignoring

the outcome of the model, and unavailability of the models to a certain subgroup will all result in unfair outcomes of a ML model [45].

Although deep neural networks are great at modeling the underlying complex and nonlinear characteristics of the data, they are still prone to modeling the confounders that do not have a causal relationship with the outcome but nevertheless can be used to make outcome prediction. The bias in the dataset caused by these confounders will not only be captured but will also be amplified within deep neural networks [42, 49]. Even though this concept is well understood for linear models, it is not so straightforward when it comes to deep neural networks. One example is a skin lesion classification model recognizing the presence of ruler in the skin images as malignant, as the dermatologists would use the ruler when the lesion is more concerning [50].

Dataset bias includes any bias happening in the dataset, possibly due to data collection issues. Lack of diversity, missing data not at random, underrepresentation of certain groups, and transfer of current societal biases via data are some examples of dataset biases [51]. A recent study on prediction of acute kidney injury reported that only 6.38% of the patients were female; thus, the model performance was lower in females [52]. Another type of bias, namely, task bias, can be defined as the intrinsic dependency between a demographic trait and the outcome [53]. For instance, difference in age range between healthy control group and disease group during disease classification task can be given as an example to task bias [53].

Outlook and Potential Solutions

To understand and mitigate bias in ML models in healthcare, the following approaches based on the location of interference in the ML model lifecycle exist (see Table 1):

Collecting Balanced Datasets

Collecting representative and balanced datasets is the most straightforward solution for mitigating bias in ML models. Including both male and

Table 1 Bias detection and mitigation methods grouped based on their respective location in the ML model lifecycle stage

What	When
Collecting balanced datasets	Before model development
Using fairness aware models	During model development
Incorporating fairness metrics	
Measuring bias in model	After model development
Reporting dataset characteristics	
Describing model characteristics	
External auditing of models	
Continuous monitoring of the model performance	

female patients in a balanced way as well as other gender-diverse individuals in any healthcare-related dataset collection process would ultimately mean that the model will learn variability of individuals across sex and gender traits. However, as the data collection is neither easy nor cheap, current use of historical data is still very valuable. Moreover, another issue is that the true distribution of sex- or gender-based disease characteristics on the population level is not always well known. Still, understanding the dataset characteristics based on the demographic traits and reporting those are good practices. Lastly, current initiatives for collecting big data in medicine usually have goals around certain diseases, such as Alzheimer's disease, and those datasets might not be representative of the general population. Benchmark datasets such as ImageNet in computer vision [54] are necessary to compare the performance of machine learning models and are mostly missing in healthcare domain. This is also bringing reliability issues (such as having a significant effect of scanning location in MRI datasets) and bias into ML models in healthcare. Finally, it is important to design data collection with bias awareness in the first place.

Disaggregating Data

As current practices on reporting model performance metrics are not standardized, not reporting on disaggregated data is one of the issues resulting

in not knowing how much bias is included in the machine learning models used for healthcare. In some cases, providing sex-disaggregated data would show opposite effects of a medication across sexes [2]. For instance, levels of hemoglobin A1c (HbA1c) is used for monitoring diabetes, although it was shown to have ethnicity- and gender-specific differences [55, 56]. Here, investigating model performance per subgroups would provide insight about such complex relationships between the bias parameter and model outcome. Standardized reporting on disaggregated data according to demographic traits would help understanding fairness of the ML models developed and increase transparency and trust in the systems designed.

Data and Model Documentation

Good documentation practices help understanding datasets and models and in particular their limitations. The first step would be understanding the limitations of the training dataset and specifics of the model. For the purpose of understanding datasets, Gebru and colleagues developed datasheets for datasets, a documentation model for explaining the data used for training the ML model [36]. A similar documentation method was also developed for the ML models; "model cards for models" was developed as a one-page outline to report standardized results regarding the model performance [37]. For ML models used in medicine, model documentations should help collaboration between clinicians and machine learning researchers [57].

Fairness Aware Models

There is a growing concern regarding fairness in ML models developed and used in everyday life. Various definitions of fairness are introduced based on the final goal. The choice of loss metric of a model is influenced by the fairness metric chosen. Fairness can be on individual level or group level. Individual-level fairness is concerned by having similar treatment for similar individuals, whereas group-level fairness is interested in treatment of different subgroups based on protected parameters such as sex, gender, or race

and obtaining similar model performance across those subgroups. As an example, the performance of a disease prediction model can be evaluated separately on male and female patients using true positive rate for both groups separately. It is important to note that individual fairness metrics might not always be the best fit for using in ML models in medicine. For instance, sex could be affecting the probability of getting an illness; thus, aiming for similar outcome for similar individuals might hinder the model performance. In contrast, the group fairness in this case would aim for equally minimizing misdiagnosis rate across sexes. A study investigating model constraints to match reimbursement for different demographic groups in American healthcare insurance scoring models successfully improved undercompensation for groups without big effects on overall model performance [58].

Especially deep learning networks offer new ways of dealing with bias in the data. One promising approach is adversarial optimization for removing the effects of bias such as sex, gender, or racial bias. Here, while training the deep neural network for the classification task, the model simultaneously disentangles the bias variables by minimizing their classification accuracy on an adversarial network [53, 59].

Although removing bias and correlated features is investigated as a solution for unwanted bias, if the bias is inherently correlated with the disease outcome, such as sex differences in prevalence, removing it could cause unfair outcomes for the minority group [2]. Thus, it is important to understand the relationship between bias and the predicted outcome.

External Auditing Framework for Machine Learning Models

Auditing and regulating models by external bodies is not a standard approach in healthcare ML models as in some other fields such as aviation [51]. Model auditing would inspect the model performance on groups and outcomes post-deployment [51]. Audit studies could document disparities of the models developed [40]. Although the topic of external auditing is still not well

studied in the context of ML models in healthcare, a recent study proposed a framework called FairLens to investigate bias in the decisions of commercial black-box models used in clinical settings [60]. As the ML model use increases in medicine, there will be more need for external auditing and regulation bodies especially when deciding which model benefits which subgroups best. Such comparisons are only reasonable through objective auditing processes.

Continuous Monitoring of the Models

In addition to training ML models, the question of how the trained models perform on new data samples after training and how they generalize to unseen data samples remains another challenge. It is possible that the new data is collected using a new threshold, a different lab instrument, or a different model of MRI scanner. Additionally, if the diversity of the population is not captured in the training data, it is possible that the model will encounter unseen samples belonging to certain racial or gender minorities or different age groups of patients with unseen comorbidities. Continuous monitoring and maintenance of the models as well as taking dataset shift into consideration is vital to keep the model performance from deteriorating. Dataset shift can happen due to many factors such as change in data collection tools and methods, adding data from other sites, policy change, and shift in population [57]. Different approaches to handle dataset shift have been developed recently [61]. However, those approaches usually require predetermination of likely shifts [61]. Alternatively, continuous monitoring of the models and retraining when the performance worsens are recommended [51]. Having the continuous monitoring as part of the ML model development cycle and embedding it into the practices of model development as well as automating the monitoring itself will help to guarantee high quality of ML models in healthcare.

As the use of ML models is still in its infancy in medicine, there are still many obstacles to overcome. ML methods in medicine have a huge potential to provide new personalized diagnostic methods and novel insights into various illnesses.

Standardizing fairness practices will help minimizing gender and sex bias in these methods and help equalize the benefits brought to all gender groups in the society.

Abstract

The huge torrent in data collection and the advent of deep learning have been transformative in artificial intelligence research, where deep learning models have achieved enormous success in divergent complex tasks ranging from computer vision to robotic control. However, the success of these models necessitates large quantities of data and exhaustive computational resources. Meta learning on the contrary aims to improve the AI learning process by imitating the human learning process, thereby enabling the AI to learn new concepts and generalize even from few samples of data. In this chapter, we highlight the most prominent approaches in meta learning and its applicability in medicine.

Introduction

Artificial intelligence (AI) is transforming almost every industry due to its versatile nature of computation. It is endowed with the ability to extend and adapt to any data it is presented with and thereby optimize itself to achieve any given task. This feature in particular can be achieved through deep learning. If you imagine AI as a set of Russian nesting dolls, AI is the largest doll encasing the others, followed by machine learning, with deep learning nestled inside. Each of these aforementioned subdivisions is a component of the prior term. Deep learning is the most successful class of machine learning algorithms, and it is comprised of artificial neural networks. These neural networks loosely simulate the human brain, whereby adjusting neural connections enables the algorithm to learn and perform complex tasks with increasing accuracy independently (without any human intervention). Similar to the networks in the brain, deep learning models are multilayered, which allows them to learn multiple levels of abstractions of the underlying data.

Deep learning-based approaches have achieved great success in a variety of fields ranging from computer vision, natural language processing, to autonomous control in robotics and much more. Specifically, in medicine, it has dominated in the realm of disease detection and suggesting treatments. However, there are limitations to where AI can be applied. Thus far, successful algorithms have been largely dependent on vast quantities of data and where exhaustive computational resources are available, for the training to be conducted over a long duration. This poses a huge problem for further development of AI models, since it may not always be possible to collect large quantities of data for a

specific task nor have the resources to train large models for an extensive amount of time, such as GPT-3 [1]. These settings break the current AI paradigm, as it is not feasible for an AI model to learn every single new task from the outset (which would also require large amounts of data for support). This is exactly the problem **meta learning** (also known as “learning to learn”) aims to solve. It is an exciting research direction that aims to strengthen the approach of training AI models, similar to how learning in the human brain occurs. To understand this further, one can draw parallels between machine learning and human learning.

Humans do not just learn new concepts; they also learn associated biases so that they can learn to generalize. This enables humans to use the lessons gained from past experiences or different tasks as a foundation to learn new ones. As a result, humans are able to generalize correctly from very few data samples. Sometimes it only takes a single sample/experience to learn a new skill [2]. Human learning is selective; it is able to re-utilize approaches that worked well in previous experiences and focus on enhancing them in new challenges. This makes acquiring new skills easier and less dependent on multiple attempts to learn. The research question that meta learning aims to answer is: *Is it possible to design machine learning models capable of adapting and generalizing to new tasks that have not been encountered before, with relatively low training data, similar to how humans adapt?* Understanding the behavior of machine learning techniques in such challenging and extremely difficult tasks can enable the design of processes to help the model make the correct choices.

Therefore, meta learning is also known as *learning to learn*, as it defines a set of methods that can be used to rethink the AI training process. A deeper understanding of computer programs that focuses on the improvement of their ability to learn new concepts faster and more effectively can have enormous practical impact in the field of medicine. Examples include working with electronic health records (EHRs) [3]. These EHRs contain the necessary data to conduct health data analytics such as prediction of in-hospital mortality, re-admission, disease classification, and many more. However, the data contained in an EHR

poses its own challenges like irregularity (e.g., irregular time series signals), sparsity (missing data), imbalance in labels, and many more. Hence the authors used meta learning for risk prediction and disease classification, where a “meta learner” model was trained entitled “Meta-Pred” that learns the domain knowledge for deep feature learning, which is later fine-tuned via transfer learning for specific tasks like disease classification, etc.

Meta learning has also extended to:

- Medical image segmentation [4], where the authors utilized meta learning to evaluate and select models for segmentation efficiently by predicting their performance for new tasks
- Multi-modality medical image segmentation, achieved using a single convolutional neural network via multi-task learning in [5]
- Skin disease identification, addressed by meta learning (few-shot learning in particular) in [6]
- Dermatological disease identification, a huge problem where deep networks must be capable of adapting to novel diseases while being robust to changes in images such as lighting, brightness, color tones, etc.

Meta learning generally enables deep learning models to adapt to the ever-changing new environments, thus making them ideal for exploration in medical applications.

This chapter highlights a survey of the frontiers of the most prominent and exciting approaches in meta learning, with the objective being to investigate the feasibility of such methods applied in medical AI research to enhance the development of AI solutions. In particular, the general foundation of meta learning will be reviewed and compared with regular machine learning paradigms. Furthermore, specific methods for improving data representation in meta learning will be discussed by exploring the following sections: “[Transfer Learning](#),” “[Few-Shot Learning](#),” and “[Continual Learning](#).” Next, methods specific to making deep learning models efficient at meta learning will be discussed via neural architecture search. Finally, an outlook into where the general direction of future research is heading to will be discussed.

General Considerations

Prior to delving into the specifics of meta learning research, it is vital to have a solid foundation for investigating this notion further. In this section, the general areas of machine learning will be discussed, followed by its contrast with meta learning and how the two are related. Consider in particular two different paradigms of machine learning: supervised learning and reinforcement learning. In **supervised learning** the machine learning model learns from a set of ground truth values captured in the data. For example, a dataset comprising of a set of images with and without skin lesions is provided, including a set of labels associated with these images defining their class. The task of the model is to recognize and correctly classify the respective image. The model optimizes for predicting the correct labels, but any task beyond what is represented in this dataset will result in poor performance. The model would require to be trained once again from the beginning. With meta learning the aim would be to use the knowledge gained from this training and apply it to other tasks and datasets, instead of having to train again from the outset. To achieve this, a meta-training dataset is defined, which is a set of multiple datasets. These multiple datasets are for different tasks, though they must have structural similarity (i.e., still visual recognition, but not identical to the original). The aim is for the model to learn meta-knowledge, so that it can learn a variety of different tasks well; hence it is “learning to learn.” However, retaining this meta-training dataset forever in memory is inefficient, as it requires storing large amounts of distinct datasets. Instead, in addition to training the base AI model (referred to as the “base-learner”), a “meta learner” model is learned. This “meta learner” model learns all the information required for solving new tasks from the “meta-training” data. The objective of meta learning is thereby solving or estimating the best possible “meta learner” model (usually another deep learning model). The “base-learner” then uses the “meta learner” to hone its predictions to get high performance, known as the adaptation process, illustrated in Fig. 1. Hence, meta learning is broken down into two phases: (1) meta-training phase and (2) adaptation phase.

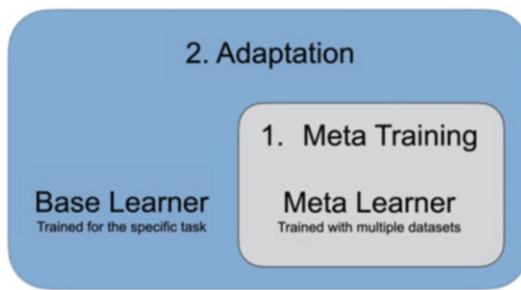

Fig. 1 Displaying the supervised meta learning process. Comprising of two training steps: 1. meta-training and 2. adaptation

In **reinforcement learning** the “base-learner” model learns from experience. Unlike supervised learning where ground truth labels are available, reinforcement learning enables the model to learn from trial-and-error. Consider an example of playing a game. This problem comprises of an environment within the game and the character the AI model has to control. This character is referred to as the agent. The aim of the agent is to traverse through the game such that it always wins. Hence the model must select the best actions conducted by the agent to always win the game. The definition of winning is defined by how much reward is earned by the agent (dictated by a mathematical reward function). The higher the reward, the better the selected action and therefore the higher the likelihood of winning. *The reinforcement learning goal is where the agent learns how to act in order to maximize its expected reward.* However, training reinforcement learning algorithms, despite being powerful, have major challenges, such as long training times [7, 8], lack of multi-tasking, and algorithmic training instability.

Given that meta learning aims to solve generalizability to different tasks, this paradigm can be re-factored into a meta learning process, i.e., **meta-reinforcement learning** to enable generating more efficient reinforcement learning algorithms. The ability to learn from multiple data distributions to solve unseen tasks grows extremely broad, enabling AI to be en route toward general-purpose methods. Using the analogy of meta-supervised learning defined above, meta-reinforcement learning can be introduced also as a two-step process. Reinforcement learning does not comprise of data as in supervised;

instead it comprises of a Markov decision process (MDP), a set of state, actions, rewards, and next state pairs. Where state is an instance of an environment at a given time, action is the predicted action the agent performs, and reward is the respective reward attained for that action, and finally next state is an instance of an environment at the next time step. Hence, instead of the “meta learner” training on meta-training data (multiple datasets), it trains on multiple MDPs, i.e., meta-training MDPs, where each MDP is associated with some different task.

Transfer Learning

Transfer learning is the simplest form of meta learning, often conducted in deep learning. The aim of transfer learning is to transfer the knowledge of previous tasks with larger data, learned by some “base-learner,” to new unseen tasks via further training or commonly known as “fine-tuning.” The focus here is only on the adaptation phase, as the assumption is that the meta-training phase already occurred by training on large datasets like in [9]. When the dataset lacks sample diversity or quantity, the deep learning model is unable to extract strong features. Thus, re-training a “base-learner” that has imbibed the meta-knowledge it gained from the original task can enable learning a new one, faster. This is achieved by selecting a state-of-the-art model for a given task together with their corresponding learned parameters, commonly known as “weights.” For example, in a visual recognition task, such models are in [10, 11]. This pre-trained model would be initiated with its weights (i.e., the meta-knowledge) and retrained on the new dataset/task. Since the original parameters are reused to initialize the training process, the knowledge of the previous task is carried forward to learn the new one. This results in both shorter training times due to higher likelihood of convergence and strong features being learned, despite the presence of a small number of data samples. This outcome would not be possible, if the model would have started the training from square one.

This has profound impact in the medical machine learning community due to data scarcity for many problems. Consider the following

example, where skin disease detection was performed using the aforementioned state-of-the-art vision models in [12]. In another study, a similar method was utilized for detection of diabetic retinopathy [13]. Similar cases are applied in different domains of machine learning, like in medical natural language understanding where state-of-the-art natural language processing (NLP) models like [14] were fine-tuned on medical text data to attain cross-domain high performance [15]. However, the biggest limitation of transfer learning is that the benefit of a pre-trained model decreases substantially if the desired target task diverges from the original, as shown in [16]. The key here is to initiate the training process with some prior meta-knowledge. Hence, it is imperative that we define a method to attain a generalizable and a valuable initialization of model weights that serves as a good foundation to initiate further fine-tuning for other datasets/tasks.

Few-Shot Learning

Humans can usually learn to generalize from very small amounts of data; sometimes it just takes a single sample. Consider face recognition: for humans only one image of the face is required to recognize it again, despite variations in environment which may change the way a face appears such as different angles, lighting, brightness, size, orientation, race, etc., yet humans do not need to see the original image sample again. Few-shot learning aims to achieve this similar characteristic, unlike transfer learning which still requires additional data for training. Few-shot learning is also referred to as N-shot learning, where N is the number of samples, i.e., 1-shot learning denotes learning from a single sample, likewise 5-shot learning denotes learning from five samples. There are three approaches to this meta learning paradigm: metric-based, model-based, and optimization-based. Obviously using traditional methods of training on such a handful of (N) samples will result in over-fitting and the model performing poorly. The three approaches aim at alleviating this problem.

Metric-based methods involve learning a distance function over the data samples, similar

to nearest neighbor algorithms like K-NN classifiers [17] or K-means clustering [18]. To comprehend how this works, consider an image as an input, which the model must classify correctly to some label. This input image can be projected to a lower dimensional representation by parsing it through the model. This representation is known as an “embedding,” which acts like compression. A fascinating characteristic of deep learning models is that these output compact representations (embeddings) are mostly unaffected by intra-class variations all while retaining information about class divisions. Images of similar classes will have embeddings clustered together, and those of different classes will be far apart. This is further visualized in Fig. 2. Learning this distance function between an embedding for a new unseen image, with respect to other embeddings in the model’s meta-knowledge, enables classification without re-training/over-fitting.

The simplest form of **metric-based** approach in deep learning is the use of a Siamese twin neural network, comprising of twin input heads. The deep learning model learns the relationship between the two inputs and thereby the distance metric [20]. If the two inputs are substantially different, i.e., from a different class, then this distance is large, and if they are similar, i.e., intra-class, it is small enabling classification with their respective label. Furthermore, Vinyals et al. [21] took this idea further by learning a classifier directly that infers the conditional probability

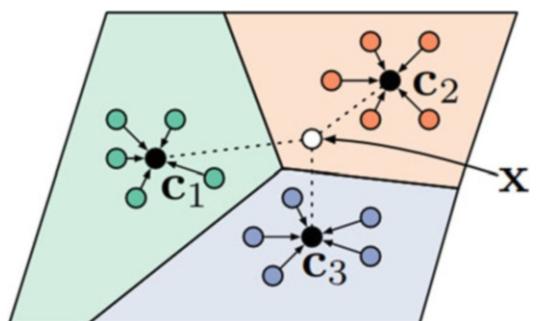

Fig. 2 Displaying embedding space visualization where the embedding of x is being classified among other learned embeddings, where each cluster centroid embedding is shown as c and x being the new sample embedding. (Figure source: [19])

distribution of the different input types itself. Similarly, there have been more advancements in few-shot learning building on top of the aforementioned work like [22] which is similar to the Siamese network with some differences in the training procedure and the architecture itself. [19] directly learns an embedding function to encode each input into a user-defined feature vector referred to as “prototype feature vector.” A distance is then calculated between the prototype clusters and the unlabeled image embeddings to perform few-shot classification.

The **model-based** approach still relies on the notion of embeddings; however it focuses more on the model design process, specifically for fast learning. The objective is to design a model capable of rapid parameter update in just a small number of training steps. This swift parameter update is achieved via architecture design capable of harnessing prior knowledge to reduce training time and size of hypothesis space or via an external meta-learner model. Examples of this type of approach include a family of architectures which use internal memory modules to read from and write to and a learning process which can be later exploited for learning in new cases [23]. This includes [24] which introduces a model and training process specifically designed for rapid generalization, by relying on “fast weights.” This is an interesting approach, but unfortunately there is limited agreement on a concrete definition. However, it can be understood by comparison to traditional techniques. Usually, deep learning models are trained with gradient descent-based algorithms which are slow and take time to converge to the optimal minima. A faster approach would be to utilize another neural network to predict the parameters of the target/candidate neural network. These predicted parameters are then further optimized and known as “fast weights.”

Optimization-based approaches aim to innovate on the methods utilized for the optimization process in deep learning. Currently, deep learning relies on gradient-based optimization, i.e., gradient descent, which struggles for convergence when there is lack of data and when the learning rate is small. The objective thus is to design optimization algorithms such that the models can learn, despite availability of only a few samples

of data. Methods encompassing this type of approach include [25] where the authors propose a long short-term memory (LSTM)-based meta learner network that learns the optimization algorithm itself to train the “learner” neural network for classification. [26] proposed a model-agnostic meta learning algorithm (MAML) that is a general optimization algorithm, which is compatible with any model and any problem, i.e., supervised, unsupervised, reinforcement learning, etc., as it learns through traditional gradient-descent algorithms. Similar to MAML, Reptile was introduced by [27]. It builds on MAML and works by sampling a new task from a dataset repeatedly and moving the initialization of parameters toward the trained weights on that task.

Some examples of few-shot learning applied in the medical domain include segmentation, in particular 3D segmentation of volumetric medical images (CT scans) by [55]. Here the authors proposed their own few-shot learning framework in the context of pixel-wise classification, utilizing only a few annotated slices. [56] experimented with few-shot learning in the context of dermatological disease classification. The authors tried to address the problem of intra-class variability in disease types being too large and the lack of balanced data to support. In particular they extend [19] for clustering. Furthermore, [57] utilized one-shot learning for drug discovery, reducing the necessitating on large quantities of data to make meaningful predictions in such applications. They utilized a long short-term memory-based hybrid architecture combined with graph neural networks to improve the distance metric learning between molecular structures.

Continual Learning

There is still a lot of ambiguity in how humans learn. However, it is certain that humans can continuously learn and accumulate new knowledge and skills to be reused in new problem case scenarios. This ability of retaining knowledge of past experiences for fast adaptation is what continuous learning aims to mimic when training machine learning models. Hence, it is also referred to as “cumulative learning” and “life-long learning,” as

the objective encapsulates around ensuring that the model does not forget its previous knowledge. Hence, the objectives are the following:

1. Accelerate future learning by exploiting previous/existing knowledge regarding the task
2. Avoiding overwriting or interfering with previous knowledge while acquiring new knowledge – this is commonly known as *catastrophic forgetting*

The ability to store knowledge in memory is innate to humans. For example, when a human tries to learn a new language, they do not forget their original tongue to do so; instead they retain the original knowledge while learning new information. However, this limitation is continuously seen in many deep learning systems [28], even in state-of-the-art models, which raises serious concerns regarding scalability of systems in the real world, especially in medicine which is a dynamic environment with multiple changes occurring for which data collection cannot necessarily be planned. Hence, the aim of continual learning is to simply never stop the training process of the model, via an endless stream of data being processed by the model. The model thus has to learn from multiple tasks, based on the knowledge of previous tasks, enabling it to generalize even if it has never observed some future task. This is typically used in self-driving cars [29] and in recommendation systems [30]. The idea is to continually train our prediction models, in small increments as new data samples become available. This aids in **efficiency** of AI models, since training from square one is no longer required hence conserving computational power while ensuring models are up to date. Adabtability is improved when a system trains faster and can guarantee adaptation to new situations using the training methodologies described above like few-shot learning or transfer learning. Lastly, for **scalability**, the memory overhead remains low throughout the model life cycle, since data is not stored but directly learnt from, while processing data in real time.

However, to make it actually work is non-trivial, requiring engineers to balance the *stability-plasticity dilemma*. The stability-plasticity dilemma stems from biological neural networks,

where the so-called synaptic consolidation gives rise to continual learning via reduction of the plasticity of synapses that are vital to previously learned tasks. This enables neuro-synaptic adaptation to changes in the environment and thus allowing it to change the neurons physical structure as a result of this learning. However, for this effect to take place, a balance must be maintained such that episodic memories are retained (memorization) and generalizability is not affected via maintenance of some amount of plasticity, hence the stability-plasticity dilemma. [28] introduced a new method of updating weights via *elastic weight consolidation*. This method of addressing the catastrophic forgetting issue falls into the category of modification of the online update to retain knowledge. There are additional methods of tackling this problem that involve designing the model itself in an innovative fashion. An example is [31] which introduced “progressive neural networks” which are immune to catastrophic forgetting, by progressively growing the neural network with each task. Additionally, networks can be equipped with episodic memory such that task-based features are retained and memorized to be reused in new tasks [32]. Finally, another interesting approach comprises of generating samples of past tasks for more updates via the popular generative adversarial networks framework [33] and via using semi-distributed representations. Due to the key three features continual learning offers, efficiency, adaptiveness, and scalability, this paradigm can be applied to any model that would be potentially deployed in the clinical world. Medical AI models that are production level and to be deployed in real settings can have a huge advantage by exploiting continual learning. Since the models will actively learn from incoming (infinite) data, it will self-update and adapt, enabling a dynamic prediction/decision-making model.

Multi-task Learning

Up till this point, in most of the aforementioned types of learning the tasks defined still belonged to a similar category (e.g., classification). Multi-task learning focuses on endowing the AI model with the capability of conducting multiple tasks that

can be divergent in category, i.e., in the example of computer vision, predicting depth and optical flow (which are two separate tasks). The aim is to design deep learning models or optimization strategies that enable the model to learn shared representations from the multi-task signals. These shared representations provide substantial benefits, such as data efficiency and faster future/transfer learning speeds for future downstream tasks and thus also aiding in alleviating the common aforementioned weaknesses in deep learning.

However, there are complications associated with multi-task learning: since the model has to optimize for multiple tasks, there is a possibility the different tasks may have conflicting feature requirements. Therefore, the model may perform really well on one of the tasks but in turn hurt the performance on the other tasks which require a different distribution of features, a problem commonly known as *negative transfer*. It is vital that such models/optimization techniques balance the flow of information between tasks: yielding positive transfer in the model weights while learning to discourage sharing when the potential of negative transfer rises. The goal thus becomes designing such techniques and is the essence of multi-task learning research.

As stated above, there are two approaches to multi-tasking. First is the architecture design that enables the model to learn both features that should be shared across tasks and features that should be task-specific, such that a generalizable representation is learned. Second is designing the optimization strategy (i.e., the loss function) that is capable of balancing the learning signal across different tasks, providing equal importance to all.

Architecture design must achieve a shared representation learning across tasks. Typically there are two methods of achieving this sharing: (1) hard- and (2) soft-parameter sharing. In hard-parameter sharing, the model is divided into two parts, initiating with a fixed part, i.e., like a backbone that consists of a shared encoder, which learns inter-task features directly from the input. This encoder then branches out into the second part, which are task-specific heads. These heads learn the inter-task features that are specific to the task output itself. Fig. 3 exhibits this visually.

The task-specific heads use the features learned from the backbone, to then learn inter-class-specific features to hone the output. Having a shared backbone reduces the risk of overfitting for one particular task since feature distribution is saturated across them. However, it also raises design concerns, like: where would be the best point to initiate task-specific heads? Or how large should the backbone be? etc. Such concerns are usually alleviated heuristically based on design and experimentation. The objective therefore is to find the best potential configuration of such models. Some of the earliest examples of this method include [34], which utilized a shared backbone followed by task-specific heads for facial landmark detection, joint head pose estimation, and attribute inference.

There were several works following the aforementioned one that proposed variations of this shared backbone design, i.e., [35, 36]. [37] introduced Multi-task Network Cascades, for instance, level segmentation. The architecture is very similar to [34] with the exception that the output of each task-specific head is appended to the input of the next sequential task-specific head, thereby creating the “cascade” of information flow. [38] aimed to jointly tackle a large number of vision tasks via multi-head design. Their model not only featured multi-head design but extends it across different network layers and scales too. In all cases, the network connections between shared backbone and the task-specific heads are heuristically determined via trial-and-error which is marginally suboptimal. Hence, some of the latest works try to overcome this issue by proposing adaptive techniques for automatically designing such networks and perform decision-making for determining the optimal position for sharing information. Such methods include neural architecture search (described further in section “Conclusion”) to design such architectures [39–41].

In contrast, in soft-parameter sharing, each task has its own assigned set of parameters (i.e., individual network architectures), with some method of sharing these features across other task-specific networks. This is illustrated as the dotted lines in (b) in Fig. 3. This method of sharing features across individual task-specific networks is

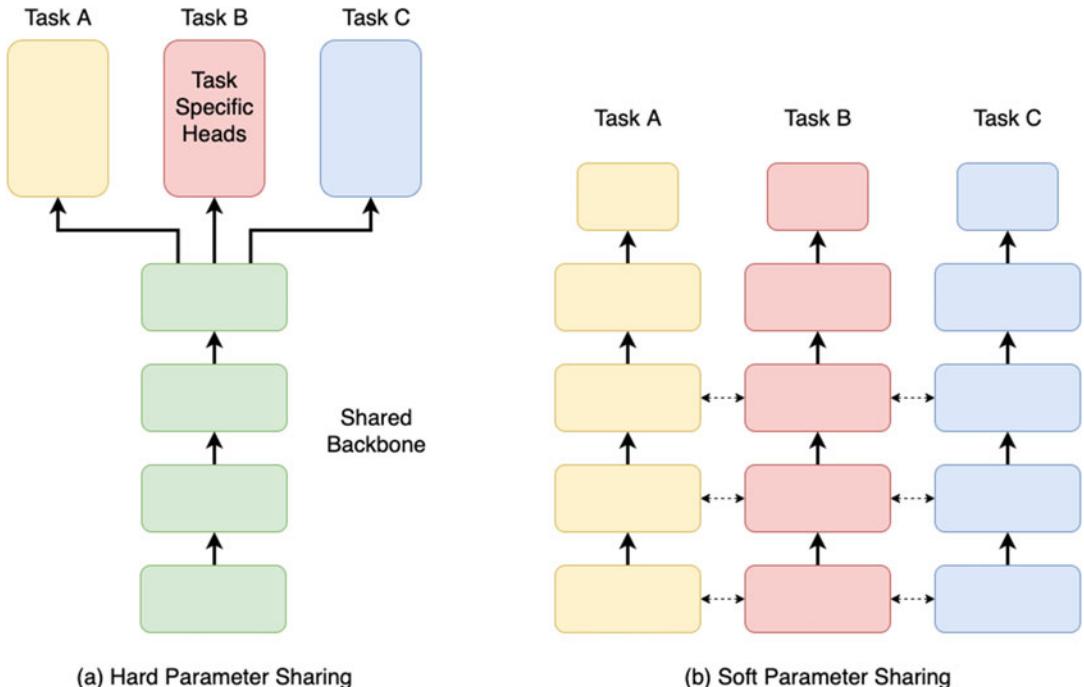

Fig. 3 Exhibiting architecture design for (a) hard- and (b) soft-parameter sharing. (a) A backbone is created as a shared trunk that learns the inter-task features. Followed

by individual task-specific heads, (b) each task has an individual architecture with cross-sharing of features between them

commonly known as “cross-talk,” allowing for information to flow between all layers in parallel. The objective is to find the most effective way of conducting this cross-talk across the task-specific networks. One of the earliest works to achieve this is [42], which introduced “cross-stitch” networks. Here the input of every layer is a linear combination of previous layer outputs. The linear combination weights were optimized for a specific task, such that each layer could decide autonomously which inter-task information to leverage. Later, Sluice Networks were introduced by [54], who adopted the idea of cross-stitch networks and extended it by allowing it to directly learn the selective sharing capability of the layers and shared sub-spaces. [43] further added dimensionality reduction via 1×1 convolution, to the feature fusion components of the network.

From the optimization point of view, the objective is to balance the inter-task loss with intra-task loss. This is done automatically by back-propagating multiple task-specific loss values, while regularization is achieved, whereby the

risk of overfitting is lowered. Each task-specific loss function has to be aggregated into a single loss, which the model minimizes. Hence, to maintain stability the losses need to be weighted, usually based on task importance, i.e., weighting for the main task may be different to that for the auxiliary tasks [44]. Another method [45] is to weight by uncertainty, by treating the network as a probabilistic model. The aim is to weight the loss function by maximizing the Gaussian likelihood of the output being the same as the ground truth. Moreover, one can weight by performance, where the authors [46] achieved this by Dynamic Task Prioritization (DTP). DTP employs focal loss [47] as its basis and prioritizes complex tasks by assigning them higher weights, since networks should spend more time learning the difficult tasks.

An example of multi-task learning applied in the medical domain is multi-modality image segmentation [58]. Here the authors trained a single convolutional neural network to segment six tissues in brain MRI, breast MRI, and cardiac CT

angiography images. They were able to achieve comparable performance to models trained individually on each specific task. [59] explored multi-task learning for phenotyping with electronic health records data. Traditionally phenotyping is performed as a supervised learning task; however, the authors in [59] explored when multi-task learning is effective in ascertaining such phenotypes accurately even for rare phenotypes where data availability is low. Their work showed the efficacy of multi-task learning by outperforming models learned only for single tasks.

Neural Architecture Search

This is an extension of “learning to learn.” If one can learn how to best train an AI model, then why not learn to design an AI model itself. This research paradigm focuses on finding optimal methods for designing the best deep learning model architectures. Many state-of-the-art complex deep learning architectures are manually designed by engineers. However, this doesn’t mean every possible configuration has been explored to select the best model option. Ideally a method that could explore different configurations and find the most optimal solution would result in an automatic development of high performance architectures. Neural Architecture Search (NAS) is a sub-field of AutoML (automatic machine learning) and overlaps with meta learning and hyperparameter optimization. The methods in this field of research are usually optimizing the following three categories:

- **Search space:** This defines the network topology. This includes the potential type of operations within the neural network, i.e., convolution, pooling, etc., including how they should be wired to form valid neural networks. Setting and designing this search space requires human expertise and thereby also introduces some level of human biases which may prevent selection of novel architectural building blocks.
- **Search strategy:** This is the algorithm that efficiently explores the search space and finds

the best configuration of models fast while avoiding premature convergence to suboptimal architectures.

- **Evaluation strategy:** The aim is to find models that attain high performance on unseen test data. Hence, it is vital that a metric for the proposed models is measured to determine the quality of the proposed NAS algorithms. Generally, the process of such candidate model evaluation is expensive. Hence, many algorithms innovate by finding methods to save time and computation resources.

The search space in general is quite large, especially if the aim is for the NAS algorithm to start designing a neural network from square one. However, this is possible to do. For example, [48] introduced “NEAT,” a method based on genetic algorithms that optimize for both connections and weights. Like evolutionary algorithms it initiates a population of candidate networks, ranks them, and applies mutation to both weights and connections to the best ranking candidates. This mutation creates a new population and the cycle repeats, thereby selecting the best mutated candidates at the end. However, the total number of possible connection configurations can easily go to infinity, making this system arduous to train. Hence, many methods constrain the search space, by defining a skeleton-like structure [49]. This is typically referred to as cell-based search. Here a user-defined skeleton is developed comprising of multiple cells, as shown in Fig. 4. The search space for NAS thereby becomes limited to that cell, i.e., NAS algorithms must optimize connections and weights for those particular cells as opposed to designing the full connection flow from nothing. This reduces the complexity of search significantly.

Similar to evolutionary algorithms, NAS search strategies are based on sampling from a population of candidate neural networks. The most obvious method is to perform random search as a strategy; however yielding best results can be a hit or miss. [49] utilized reinforcement learning as their search strategy. In particular they define a controller recurrent neural network model which performs classification of the operations to be

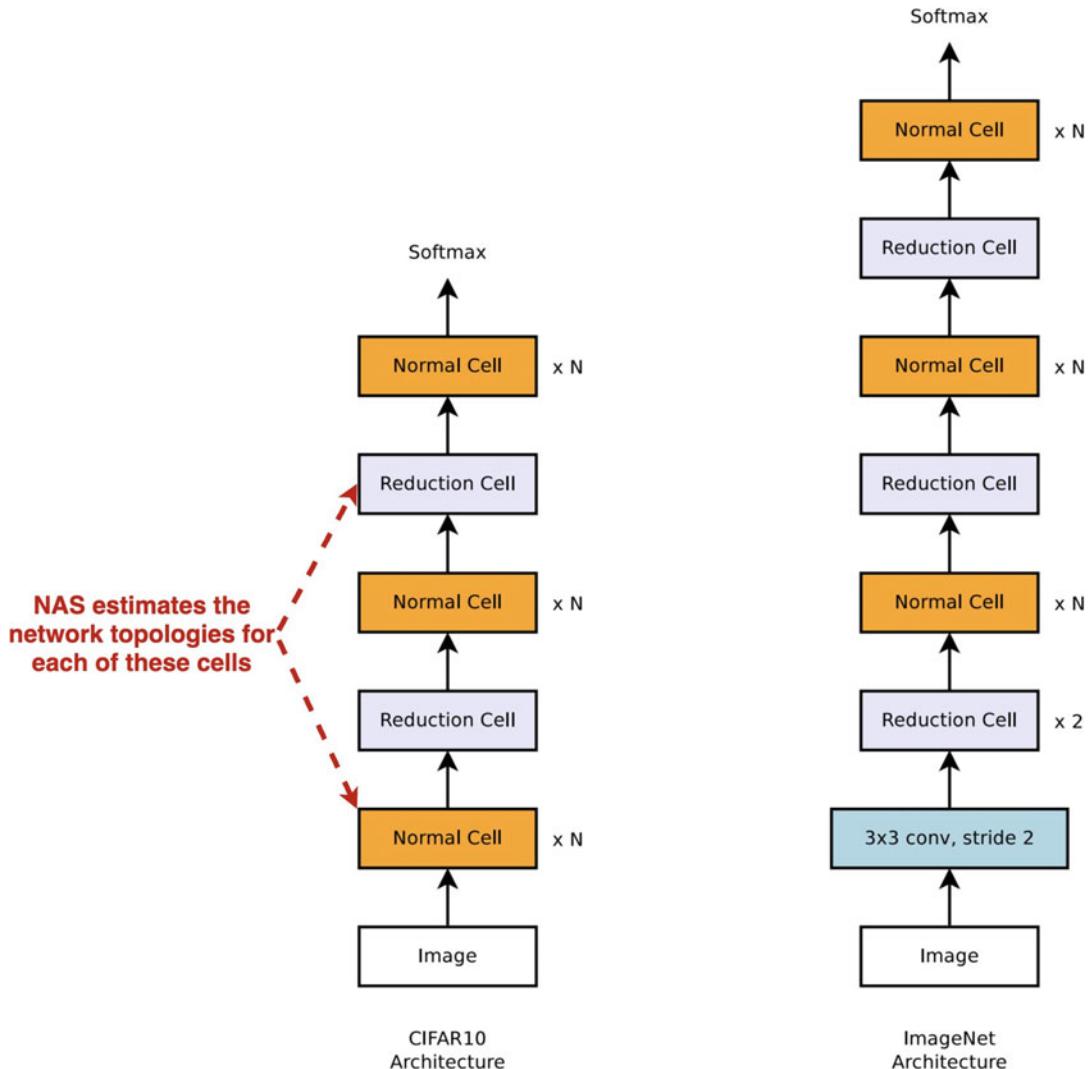

Fig. 4 Displaying cell-based search space for NAS, where the overall information flow is predefined by the user as repeated stacks of cell connected sequentially. NAS

thereby searches for network topologies for these particular cells. (Figure adapted from [49])

selected for building the candidate model (the model to be deployed). As the candidate network is built, it is also trained and evaluated on a given task (i.e., classification). The controller is trained by reinforcement learning where the rewards attained are based on the accuracy level achieved by the candidate network during evaluation. Hence, as the candidate network performs better, the rewards received by the controller are higher and thereby enable the controller to select better operations for the cell.

Furthermore, [50] introduced “AmoebaNet” which further developed on the evolutionary algorithm of “NEAT” as their search strategy. In particular they apply the “tournament selection” method, which at each iteration discards the oldest candidates and favors the younger candidates. These younger candidates at that time may not be the best; however this allows AmoebaNet to explore the search space more, in contrast to NEAT which narrows down the search space to good performing models, sometimes converging

early. Basically they aim to strike a balance between exploration and exploitation. Since designing such models is a gradual process (layer by layer), the complexity increases sequentially. Hence, development should also be sequential such that the complexity can be handled over time. [51] introduced Progressive NAS which uses a similar search space as shown in Fig. 4. Progressive NAS addresses the problem by progressively growing the network, thereby searching for topologies of increasing complexity over time. Instead of reinforcement learning or evolutionary algorithms, the Progressive NAS search strategy is based on model-based Bayesian optimization, similar to the A* search algorithm used widely in robotics.

Lastly, the evaluation strategy is crucial for determining the performance of every possible candidate network, such that in the end the best candidate is selected for inference. One simplest strategy would be to train each candidate model until convergence and measuring the final accuracy. However, this sequential train-converge-evaluate loop would be too slow and computationally expensive. Instead, it is usual to evaluate on a smaller subset of the dataset and train the candidate model for only a small number of epochs. The features learned are enough to evaluate the performance as shown in [49] or to predict the performance itself using time-series regression [52]. Furthermore, [53] achieved an incredible speed-up in performance by conducting parameter sharing among the candidate models. The assumption was that the candidate model topologies can be seen as sub-topologies of a larger conglomerate topology representing the final model. Hence, the candidate model's parameters in these sub-topologies must share the weights for representing the final, enabling convergence to the final model faster.

Conclusion

Currently most AI systems focus on optimizing for single tasks and require huge quantities of data for the learning process. However, this type of AI training procedure is not feasible in the long run, since it is not possible to collect data with respect to

every single potential variation. Especially in the context of medicine, which is a highly dynamic environment, with multiple tasks and ever-changing data. To have a translational AI that can be utilized in the medical industry, it is vital that AI is capable of adapting and continuously learning to adhere to such unseen cases and, more importantly, generalize by retaining its meta-knowledge. As stated, meta learning is still an open question with many new methods being proposed. Although its adoption in medicine may still be limited, it is certainly a direction to move toward. Meta learning is the field that will bring us closer to general intelligence or at least machine learning 2.0. With methods to endow AI with the capabilities of self-designing, self-learning continuously and that too with small data requirements will have an enormous impact in medicine. We must understand that the real world does not comprise of cleanly aggregated balanced data samples; rather it is the opposite, comprising of messy, imbalanced, and highly divergent data. Hence, our AI models should learn to adapt to these situations, instead of forcing us to use collections of data that do not represent the reality, and meta learning is a step toward this achievement.

Abstract

The concept of quantum computing has evolved over nearly a century to a point now where it is no longer science-fiction. However, conceptual extensions of quantum computation and many body systems to quantum clinical medicine and quantum surgery are completely original areas that are yet to be realized in terms of their development and full potential. Novel formalisms and approaches will have to evolve to enable these areas to fully materialize and mature into safe clinical applications that will benefit mankind.

Nevertheless, factors paving the way for this exciting area of medical and future surgical science include the exponential advances in computational power gained through newly evolved mathematical formalisms for algorithmic design such as quantum mechanics, category theory, quantum algebraic geometry and others, coupled with advances in precision nanoengineering.

This chapter offers a cursory non-exhaustive primer to the topic of quantum

machine learning for medicine, surgery and healthcare, highlighting some of the areas where the authors theorise that quantum computing will help augment medicine, surgery and healthcare to usher in next-level precision medical diagnostics and therapeutics. In the not-too-distant future, quantum medicine and surgery will offer the ability to re-calibrate the continuous state of flux that occurs in conditions like cancer and neurological diseases to a manageably consistent curative state.

Introduction

For centuries we have sought to harness analytical techniques to understand scientific processes including how the human body functions on a molecular level, and we have been rewarded by identifying key behaviors of what constitutes matter on the atomic scale. We now appreciate the discovery of several elementary particles within the universe ranging from photons, protons, electrons, neutrons, neutrinos, muons, tau, hyperons,

positrons, etc.; most of which are being or have already been harnessed for medical applications [1]. With the limited tools we have at our disposal, we have gained some understanding of how the universe and its myriad of constituents can be modelled to follow a very rudimentary and consistent pattern of atomic and molecular architecture. The Niels Bohr model of the basic atomic structure is very familiar to both non-scientist and scientists alike. We now accept that the atom has a nucleus with fundamental particles like electrons arranged in their probabilistically predictable orbitals in a quantized precise energy domain. This led to discoveries by many scientists like Erwin Schrödinger, whose wavefunction equation laid the foundations for the advancement of quantum mechanics. This was further explored by Nobel Laureates like Richard Feynman who gave the world a detailed exposition of quantum mechanics through his famous lectures [2]. Louis de Broglie described the wave-particle duality of matter and helped us to fundamentally appreciate quantum behavior in all matter.

The collective flow of electrons modelled as charged particles enables electricity and electromagnetism, but the movement of electrons could include their spin with respect to their axis or in relation to other electrons and atoms. Whether they are paired or not and how they interchange between energy-dictated quantized levels has provided added insights into what permits quantum optical phenomena, such as fluorescence and several others, to be respected. Many of these are now used in medical diagnostics. Unsurprisingly the spin of the nucleus itself also allows unique properties to be appreciated and observed, which are necessary for quantum computing applications in the field of spintronics.

Newer discoveries from using the large hadron and large electron-positron colliders continue to surface including the identity of stable and unstable matter particles at a subatomic level, classified into respective quarks, leptons (collectively known as fermions), and bosons [1]. However, it is generally agreed that in stable terrestrial form, matter is fundamentally composed of atoms with electron orbitals that can also generate quantized electromagnetic fields in a constant state of flux. This is an area we have implemented to develop medical

imaging technologies like nuclear magnetic resonance imaging, which leads to exploiting magnetic field alignments of the hydrogen atoms that forms the make-up of the human body. Our earthly chemical make-up remains mostly either organic hydrocarbon based as life-forms or inorganic with elements such as silicon being abundant in various unaltered states. Silica and other inorganics have allowed the development of semi-conductors for which the transistor technology underscores the classical computer on which we depend.

Through transistors and other tools arranged in a very precise and specific way, and for which we now have replicable blueprints, we have designed algorithms that control the flow of electrons within transistors in a very precise way. This is one fundamental view of how machine learning works where high-level programs are written in syntactically sound programming languages like Python and C++, either respectively interpreted or compiled to machine code using assemblers, but in general explains how software communicates with the transistors in computing. The behavior of some of these transistors can be explained at a fundamental quantum level in some form using quantum mechanics and include principles of quantum interference, quantum entanglement, quantum tunnelling and quantum superposition.

Carbon-based systems like graphene and diamonds can also behave as quantum computers to facilitate quantum information transfer and sensing at a fundamental level with potential for other hydrocarbon-based systems like polycyclic aromatic hydrocarbons being demonstrated [3–6]. Through advances in imaging technology, we have been able to appreciate and harness these molecular interactions into the development of techniques that allow us to even reconstruct matter from thin air using carbon capture as an example of modern chemistry [7], precisely control the flow of electrons in Bose-Einstein condensates [8], precisely move atoms from one location to another and several other feats that two centuries ago would have been deemed impossible.

Another area where we have exploited a quantum system to discover other systems with quantum potential involved leveraging X-ray diffractometry, which aided the discovery of the deoxyribonucleic acid in the 1950's- a molecular

system that facilitates the blueprint for the construction of the organic being in its entirety for which its counterpart in the inorganic domain is yet to be unveiled [9]. DNA technology has now led to the ability to clone Dolly the sheep and other organisms, but it is the quantum information associated with it that is becoming a growing area of interest [10–12]. Suffice to say that this has interestingly allowed the appreciation of quantum molecular interactions and information flow through dynamic signal processing and precision recordings that are only recently becoming accessible through quantum computing. The potential for quantum biology using DNA nanotechnologies like DNA origami [13], DNA for quantum information processing and personalized cryptographic encoding for healthcare data using DNA makes this an even more attractive area of recent research focus [14].

As a consequence of the aforementioned, one could model the human body as an entropic quantum information system where Shannon's information theory may apply on a quantum level and become necessary for exploration [15, 16]. Clearly, there is a need to at least consider dispelling the myths associated with the fact that the human body has no quantum potential- a topic of considerable ongoing debate as very few people know about quantum physics.

History

Our generous universe comes equipped with the ability to compute.

David Bacon

The ability to adopt and effect computational superiority for problem solving has been with us well before Charles Babbage's "difference engine" concept sparked our curiosity about computers in 1833 [17]. However, the concept of quantum computation has been hidden in plain sight for nearly two centuries. The above quote from David Bacon sums it up best. The fifth Solvay conference on physics was held in October 1927 and is thought to be the birthplace of quantum theory with over 17 Nobel Laureates in

attendance arguing for and against various concepts of photon and electron behavior. We summarize the history of quantum computing in Fig. 1, looking at some of the modern landmark developments since the 1930's that propelled the field forwards towards its physical realizations in the mid-late twentieth century until quantum supremacy was attained in 2019/2020 [18–20]. Many computational theories evolved since the 1930's. The Church-Turing thesis in 1939, laid important foundations about the nature of computable functions in an attempt to resolve the Hilbert-Ackermann "Entscheidungsproblem" ("decision problem" to use mechanical functions to separate mathematical truths from falsehoods) [21–23]. This significantly contributed to developing the Turing machine and the abstract quantum variants of which became heavily researched and initially formulated by David Deutsch allowing for any quantum algorithm to be expressed as a particular Turing machine [22]. Another extension of the Church-Turing theory called the feasibility theory was presented for Quantum Complexity theory and is a foundation for the Bernstein-Vazirani quantum algorithm presented later [24, 25].

The Basics of Quantum Computing and Quantum Machine Learning

Types of Quantum Computers

Despite the digital technological revolution in classical computing steering us into a wave of spectacular scientific and medical discoveries, limitations have also left us with additional challenges needing advanced computational improvements to overcome [11]. These limitations of silicon-based integrated chips mean newer approaches need to be considered for computation. Quantum computers boast superior computation over their classical equivalents in a 1 million to 1 operational ratio and are intended to be useful for problems that classical computers would be unable to solve [11]. Quantum supremacy have been achieved both through semiconducting qubit computers and optical/photonics-based quantum

computers [18–20, 26]. A non-exhaustive list of their current forms with some in physical realizations is provided below:

1. Superconducting Quantum Computers [20],
2. Ion-trapping-based Quantum Computers [27],
3. Quantum Annealing & Adiabatic Quantum Computers [28–30],

quantum computing has evolved over the years with some key landmarks; time-line was created using EdrawMax software, but for detailed look at some of the milestones see https://en.wikipedia.org/wiki/Timeline_of_quantum_computing_and_communication

20. Bose Einstein Condensate Quantum Computers [47]

The above operate on four main currently applicable computational models with a fifth being the Quantum Turing Machine yet to reach full physical realization. The current four models are:

- Adiabatic quantum computing
- One-way quantum computing
- Gate array quantum computing
- Topological lattice-based quantum computing

Current quantum computers have a significant degree of quantum noise related error and as such they are known as noisy intermediate-scale quantum computers (NISQ) leading to decoherence. This means only a limited number of operations can be computed on a qubit before it loses its quantum state leading to random noise as the output. Figures 2 and 3 illustrate the current quantum computer and chip. Newer computational models will evolve for quantum platforms that will be useful for future medical applications.

Fig. 2 Image of a Quantum Computer demonstrating that most of the spaces have to be achieved using a dilution refrigerator cooling to around 10–20 millikelvin greater than the temperature of outer space. With specialised cables that transmit microwave pulses to the chip shown in Fig. 3 An IBM Quantum Computer; Image Source: <https://www.research.ibm.com/ibm-q/network/> and [64]

Companies

Some of the companies developing quantum computing include, *Google's Sycamore, Atom Computing (a quantum computing hardware company specializing in neutral atom quantum computers), Xanadu, IBM (IBM Q), ColdQuanta, Zapata*

Computing, Azure Quantum, D-Wave, Strangeworks [22, 48–54]. Shenzhen Spin-Q Technology is a Chinese founded company aiming to release the first 2-qubit desktop quantum computer for schools [55].

This section aims to guide the reader towards areas of specific enquiry, investigation, knowledge discovery and as such not meant to be exhaustive. Its aim is to introduce the medical reader to some of the notations that they will need to be familiar with when reading papers going forward. The authors however do highlight a few new ideas underpinned by fundamental quantum principles of superposition, entanglement and quantum tunnelling as the field is still very new. For all these areas, we will discuss the potential impacts and where in-roads can be made for medicine and surgery.

Basic Anatomy of a Quantum Versus Classical Computing Circuit

This section discusses how quantum circuitry differs from their classical counterparts and how this applies to the design of newer medical devices that one would aim to use for efficient quantum computations. We follow this with an explanation of the quantum phenomena that makes computing superior to its classical equivalent.

The Bit and the Classical Logic Gate

Classical computation occurs with operations and information encoded in a binary format that arises through a combination of bits of information. According to Shannon's information theory, a binary digit averaged forms one bit of Shannon information. The bits can be isolated states of either 0 (False) or 1 (True) in a Boolean logic state analogously behaving as a gate that opens and closes to allow or restrict information flow. This bit of information is the binary classification system that underscores how the transistor-based logic gates behave. These Boolean logic gates, in classical computers enable operations like AND, OR, XOR, NOT, NAND, NOR, and XNOR to be

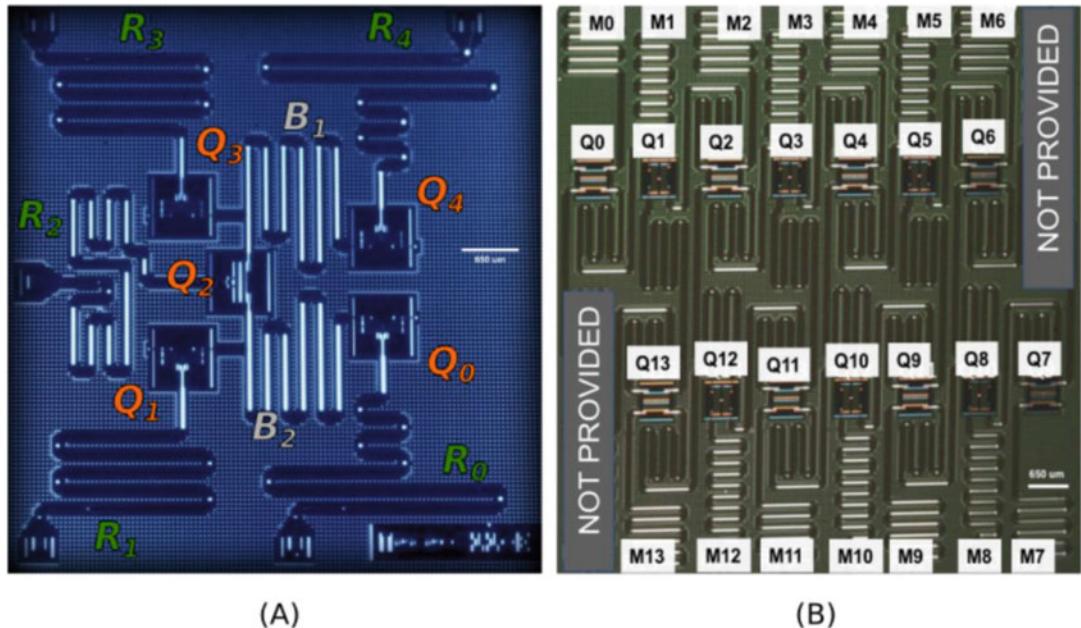

Fig. 3 Quantum Chip photos and layout example courtesy of IBM open-source quantum. Melbourne **(b)** and Tenerife chipsets **(a)**, the Chip layout of a 5-qubit (ibmqx4) and 14-qubit (IBM Q 14 Melbourne) quantum

achieved where the resulting value of 0 and 1 from the combination of bits in this way executes the equivalent of a True or False to either propagate or restrict information flow respectively (see Fig. 4). These gating mechanisms also underly how computers can understand higher level human languages converted into their lower-level equivalents to aid the execution of algorithms by the hardware. The combinatorial mixture of these gates is how operations are carried out in a functioning computer. Additionally, the combination of these bits of information in a specific well-defined order allows intelligent information processing and transfer. This phenomenon of True/False gated signaling also routinely happens in biology. Common examples include the conduction of action potentials and neuronal depolarization which is a gated threshold-activated, ion-channel system operating on an all-or-nothing basis. Here, subthreshold excitatory post-synaptic vesicular release of neurotransmitter stimulation of the post-synaptic membrane does not facilitate and propagate an action potential; the on-signal/True.

Classical computing techniques have been harnessed in modern medical and surgical devices

processors [51]. The chipset is sensitive to radiofrequency, noise, temperature, etc. and require cooling as discussed in Fig. 2

that compute diagnostic information, and require additional methods of convertible analogue-to-digital bitwise sensing and post-processing. This feat is also necessary for designing robust encryption/decryption systems. Pitfalls of classical computation involve the impaired ability to rapidly factorize large prime numbers. Something that the healthcare and other sectors require to safeguard clinical information. Prime number factorization function is one that also models exponential growth and is something that our current classical computers struggle to overcome. The security of healthcare and surgical tele-robotic systems as well as medical diagnostic and therapeutic devices, which all depend on robust public and private key cryptographic encryption systems obey the prime factorization archetype. Thus, as quantum computing evolves, these encryption systems can be put at risk and need more sophisticated computational methods.

Another area worth considering is our current suboptimal infrastructure to quickly model pandemics which follow the exponential growth and decay equation. This field could also benefit from the efficient speedups that classical computation

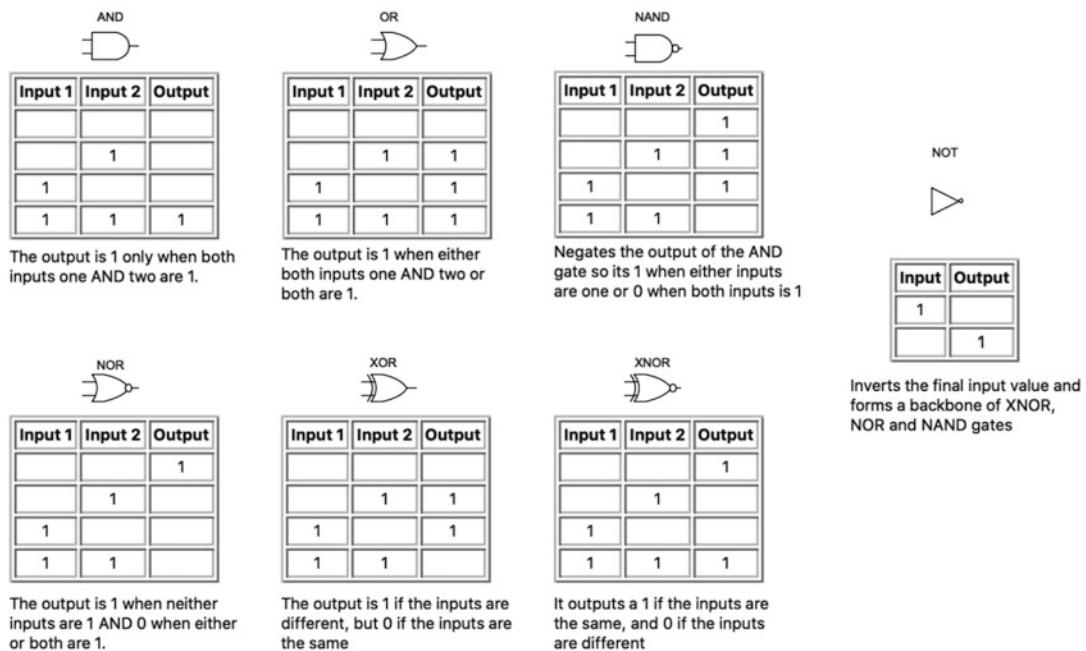

Fig. 4 Illustrates classical logic gates in digital electronics and their truth tables of computational outputs. Specific combinations of these Boolean logic gates enable all

classical digital computation. Contrast this to Fig. 7, which demonstrates some of the quantum logic gates

currently lacks. This together with impaired and suboptimal approaches in the probabilistic resolution of simulating molecular bonding interaction information in disease warrants other more advanced computational alternatives far superior to any classical purview of exascale supercomputing [56, 57].

The Qubit and the Quantum Gate [58]

On the contrary, quantum logic gates are unitary matrices, which operate on quantum bits (qubits) of information. Qubits allow the phenomenon of what is known as coherent superposition of states to occur. A single qubit has a vector representation whereby in addition to the presence of single independent Boolean binary-style logic states in either a $|0\rangle$ or $|1\rangle$ (pronounced Ket 0 or Ket 1) or spin state of an up $|\uparrow\rangle$ or down $|\downarrow\rangle$, a superposition represented as $|\psi\rangle$ can also exist. The medical reader is also directed to the institute of advanced study for further simplification [59].

These two states can be available simultaneously giving either an $\alpha|0\rangle + \beta|1\rangle$ or $\alpha|\uparrow\rangle$

$+ \beta|\downarrow\rangle$ configuration. Alpha (α) and Beta (β) are usually complex probability amplitudes, hence squaring the magnitudes $|\alpha|^2$ or $|\beta|^2$ gives the actual probability that its corresponding state of 0 or 1 will occur. The sum of these two probability amplitudes must be equal to 1. Also, these probability amplitudes can be complex vectors. The significance is the thorough capacity for the quantum system to holistically parallelize resources for information inquisition and rapidly explore all probable permutations of information flow simultaneously. The underlying scientific ideas are based on Heisenberg's uncertainty principle and paradigms like the De Broglie wave-particle duality in atomic scale quantum systems [60, 61].

Figure 5 illustrates this concept well using a simple maze analogy. It is only when one chooses to measure which observable state the quantum system is in that it collapses into a single measurable state, otherwise it remains in superposition of multiple states, similar to the paradigm of Schrödinger's cat, which is simultaneously both dead and alive until it is observed. This collapse of the quantum state

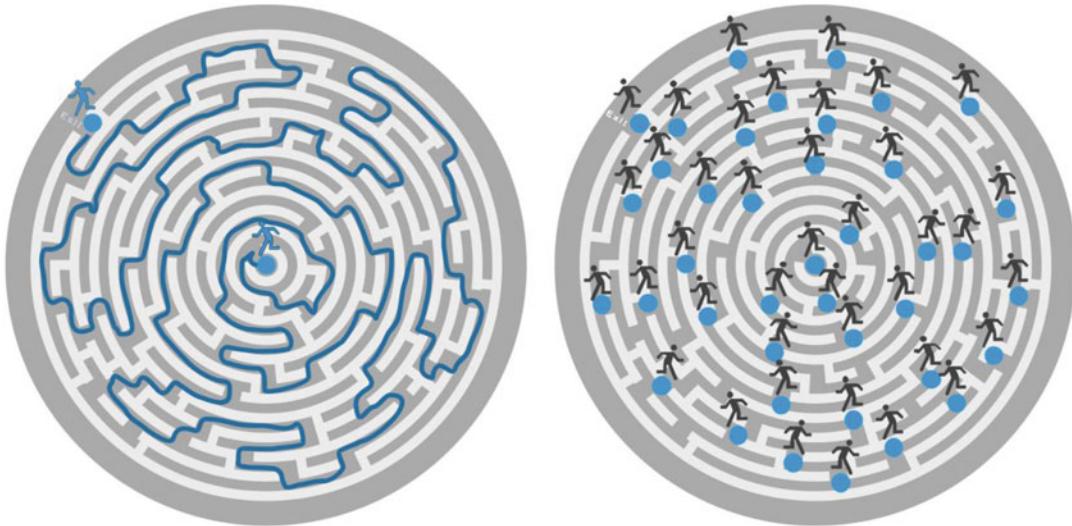

Fig. 5 Maze-like concept for experiencing how a quantum system behaves versus the classical equivalent. The quantum maze phenomenon has been observed in photonic quantum systems in biology [98]. (a) Is a classical system maze. The blue classical particle without any quantum ability brute forces it's way and explore every sequential eventuality before it finds its way out. At each level of the maze, it will attempt to seek a True or False answer to the question of whether an opening exist to move to the next level of the maze. (b) Represents a quantum system maze.

The blue quantum particle searching for the quickest exit path is able to explore all probabilistic eventualities using the principles of (1) superposition exploring eventualities simultaneously, (2) principles of entanglement where the fundamental particle behaves as if it has multiple copies of itself and omnipresent to explore all possible paths and areas of the maze, and (3) principles of quantum tunnelling (where it has the ability to pass through obstacle or a boundary in its path to the other side of the maze). This figure was created with EdrawMax Software

occurs when the system has been perturbed by measurement. The significance here is that with quantum computation, information classification can be very rapid. Decryption of encrypted systems based on pre-quantum public and private cryptosystems takes a fraction of the time it would otherwise take for a classical computer to break. It is therefore prudent to design algorithms for post-quantum cryptographic encryption to mitigate against security vulnerabilities inherent in electronic devices and database information management systems used in medicine, surgery and healthcare.

Mathematically, the above concepts of the various states can be encoded as state vectors using the dynamical representations/pictures of quantum mechanics, which mainly consist of Schrödinger's and Heisenberg's picture with an intermediate/Dirac picture [62]. Various other mathematical formulations exist with as many as nine explored in reference [63].

State Vectors

To appreciate the function of the quantum logic gates one must first understand the quantum state.

In quantum mechanics the state is an entity that provides a mathematical probability distribution of where the fundamental quantum particle (electron, photon etc.) is at a particular point in time and space. This is necessary for us to obtain a possible outcome when we measure it. The measurement of the particle or molecule can be its momentum, spin, color change, interference pattern, bond length, force interaction, thermodynamics through Brownian motion, entropy, etc. Knowledge of the state and the rules of the quantum systems appears sufficient to predict the behavior of the system. Additionally, the quantum states can be mixed to give new states called mixed quantum states, otherwise they are referred to as pure quantum states. Pure quantum states are represented by a projective

ray over a Hilbert space vector over complex numbers. The space that describes a qubit can be explained using this complex projective ray and this projection can be represented on a specialist sphere known as the Bloch sphere [64]. Figure 6 illustrates the Bloch sphere [64].

The quantum state of a qubit is therefore a linear superposition of its orthonormal basis vectors and it is written in Dirac's Bra ($\langle \cdot |$) Ket ($| \cdot \rangle$) notation using angle brackets. The Ket is a linear vector in the Hilbert's space denoted as $|0\rangle = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$ or $|1\rangle = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$.

A two-qubit system can be represented by:

$$|xy\rangle = |x\rangle \otimes |y\rangle = \mathbf{r}_{00}|00\rangle + \mathbf{r}_{01}|01\rangle + \mathbf{r}_{10}|10\rangle + \mathbf{r}_{11}|11\rangle \rightarrow \begin{bmatrix} \mathbf{r}_{00} \\ \mathbf{r}_{01} \\ \mathbf{r}_{10} \\ \mathbf{r}_{11} \end{bmatrix}$$

As well as single-qubit systems, there can be other multi-qubit systems like the above where the tensor/Kronecker product \otimes combines quantum states. Such multi state systems have representational circuits which can undergo the phenomenon of quantum entanglement discussed later.

The Quantum Gates [58]

The quantum gate is mathematically represented as a unitary operation and acts on the qubits, which are in various states as described by the example vectors above. Figure 7 illustrates what a quantum gate looks like. Generally, a gate can act on n qubits, where n is the number of qubits represented by a $2^n \times 2^n$ matrix. How the gate behaves on a specific quantum state can be derived by multiplying the Ket state vector (e.g., $|\psi_A\rangle$) by the gate's unitary matrix M_U

$M_U|\psi_A\rangle = |\psi_B\rangle$. Such an operation results in a new quantum state vector being created.

An example is the Hadamard gate, which acts on a single qubit to equalize the probability of both states 0 or 1 occurring and hence it is the

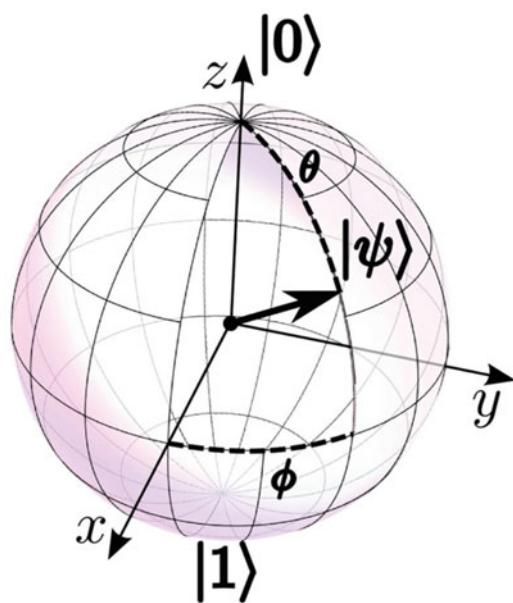

Fig. 6 A computational quantum particle – qubit – represented as a unit (Bloch) sphere [64]. Unlike regular bit that takes values of 0 or 1, a qubit can take any values on a sphere, as represented by two angles. The poles correspond to classical 0/1 bit values. (Image source: https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6205278/figure/f2-ms115_p0463/)

gate to create a superposition of states. The Hadamard gate uses a special unitary matrix called the Hadamard matrix shown in Fig. 7 and represents a π rotation on the block sphere about the axes $(\hat{x} + \hat{z})/\sqrt{2}$.

Several gates exist and the common ones are illustrated in Fig. 7. The Pauli X gate is equivalent to the classical NOT gate. Squaring the Pauli gates results in an identity matrix. Others include the Toffoli, Fredkin, CCNOT, SWAP, 2-qubit Ising coupling gates (native to trapped ion channel quantum computers), 3-qubit Deutsch gates, etc.

Quantum Superposition and Machine Learning Applications

Theoretical Medical Applications

At a fundamental level, applying the above principles of gate-linked qubit quantum superposition to machine learning and clinical practice

Operator	Gate(s)	Matrix
Pauli-X (X)		$\begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$
Pauli-Y (Y)		$\begin{bmatrix} 0 & -i \\ i & 0 \end{bmatrix}$
Pauli-Z (Z)		$\begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$
Hadamard (H)		$\frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$
Phase (S, P)		$\begin{bmatrix} 1 & 0 \\ 0 & i \end{bmatrix}$
$\pi/8$ (T)		$\begin{bmatrix} 1 & 0 \\ 0 & e^{i\pi/4} \end{bmatrix}$
Controlled Not (CNOT, CX)		$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}$
Controlled Z (CZ)		$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & -1 \end{bmatrix}$
SWAP		$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$
Toffoli (CCNOT, CCX, TOFF)		$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$

Fig. 7 Some very common quantum gate circuitry like the Hadamard and Pauli Gates. Contrast these unique gates to the classical logic gates in Fig. 4. (Image Source https://upload.wikimedia.org/wikipedia/commons/e/e0/Quantum_Logic_Gates.png)

would see the potential for gate discoveries acting as operators that may potentially lead to the modelling of various diseased states theoretically simplified here with a mathematical generalization:

$$M_U \text{ operator } |\psi_{\text{Norm Tissue}}\rangle = |\psi_{D \text{ State A Early}}\rangle + |\psi_{D \text{ State B Intermediate}}\rangle + |\psi_{D \text{ State C Final}}\rangle + |\psi_{D \text{ State error}}\rangle$$

The operator M_U would be a quantum disease gating matrix that acts in some form on the normal tissue state matrix to lead to an altered superposition of diseased states. This will be feasible through clever design of quantum machine learning powering operator-dependent surgical tools, devices, and treatment platforms including brain machine interfaces.

A most recent application leveraging quantum mechanical behavior and predictive machine

learning in the brain is seen in Elon Musk's Neuralink platform, which draws from quantum mechanical properties of fabricated nanomaterials for sensing and information processing [65].

Quantum Machine learning algorithms derived from newer gating combinations will also enable the potential to better delineate these intermediate disease states that lead to rapid progression into advanced forms to either prevent progression, slow down progression or potentially reverse disease.

Quantum Tunnelling and Machine Learning Applications

Quantum tunnelling is a phenomenon whereby a wavefunction (wave-particle duality paradigm) propagates through a barrier or obstacle as if the obstacle was not present. Figure 8 illustrates this phenomenon well.

Derivations of tunnelling arise from both the Helmholtz equation and Schrödinger's time-dependent equation that unites the Galilei and Lorentz invariants, as well as Einstein's energy relations and this allows one to calculate the wave number of a fundamental particle with a degree of precision. Evanescent tunnelling arises when the Helmholtz equation loses its Lorentzian invariant [61]. The boundary interaction time of the wavefunction does not depend on the length of the barrier. Table 1 demonstrates the tunnelling times for some of the common fundamental particles in quantum computing. Dynamic and Chaos-assisted tunnelling are two forms of this phenomenon that enables machine learning methodologies on a quantum scale.

This property and the speed-up that it offers makes this attractive to the scientific and medical community when it comes to building machine learning algorithms for medicine that can be

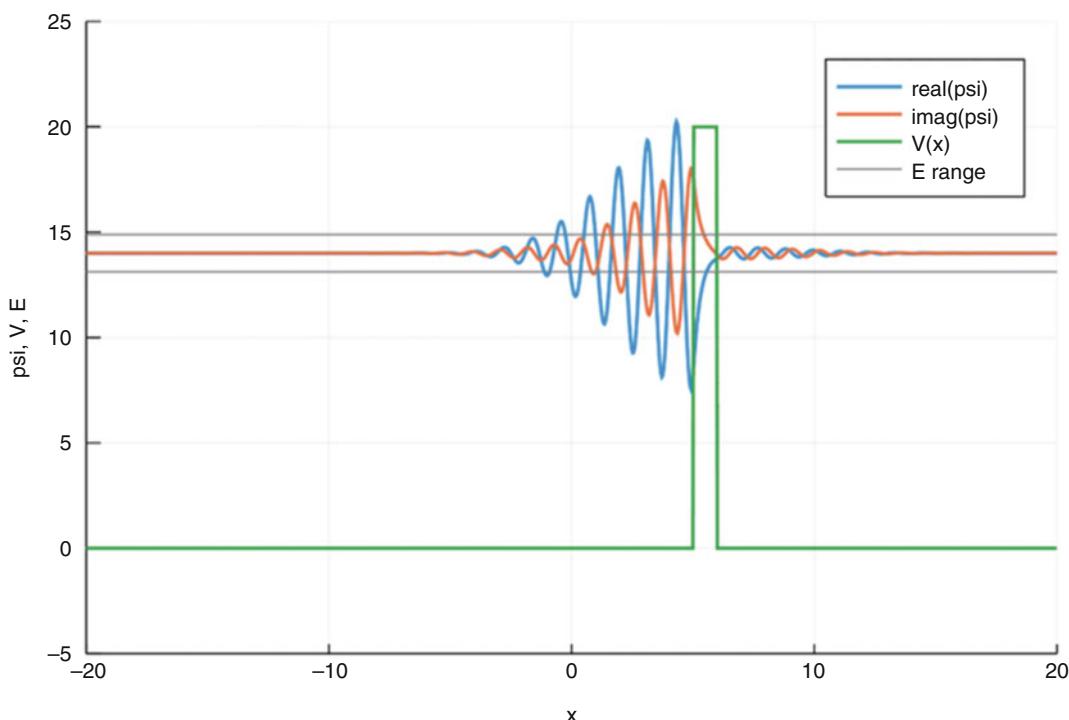

Fig. 8 Illustrates the quantum tunnelling phenomenon. A wave can propagate through a barrier of a particular size to the other side of the barrier. (Source BeCarlson <https://upload.wikimedia.org/wikipedia/commons/4/48/E14-V20-B1.gif>)

Table 1 Demonstrates the tunnelling times for some of the common fundamental particles in quantum computing. It is clear that comparable speed-ups are seen for photonic methods over electron methods

Tunnelling barriers	Tunnelling Time τ	Transmission Time $T = 1/v$	References
Photonic lattice	Between 2.13 femtoseconds (10^{-15}) and 2.7 femtoseconds	Between 2.34 femtoseconds and 2.7 femtoseconds	[61, 66, 67]
electron field-emission tunnelling	7 femtoseconds	6 femtoseconds	[68]
electron ionization tunnelling	≤ 6 attoseconds (10^{-18})	Not reported	[69]
Acoustic (phonon) tunnelling	Between 0.8 microseconds (μs) and 0.9 milliseconds (ms)	Between 1 μs and 1 ms	[70, 71]

implemented and these quantum algorithms are superior to classical algorithms.

Scanning Tunnelling Microscopy has been used in medical imaging to image disease processes like Amyloid protein deposition in Alzheimer's Disease [72]. Tunnelling has also been seen in quantum biological tunnelling junctions [12]. Machine learning applications will involve designing algorithms that can efficiently harness the tunnelling process for healthcare applications. Quantum annealing is one area that allows efficient quantum machine learning through leveraging quantum tunnelling to enable effective algorithmic optimization [28, 30]. Screening and resolving genetic disease pathophysiology especially for the brain, which hosts nearly a trillion neurons, in an information network using quantum machine learning may benefit from methods using quantum annealing.

Quantum Entanglement and MachineLearning Applications for Medicine and Surgery

Entanglement is a quantum mechanical concept that Albert Einstein called "Spooky action at a distance" and vehemently rejected when it was first proposed [8, 11, 73]. This is where two particles become twinned and linked so that an action on one particle simultaneously affects the other particle's behavior and characteristics. Moreover, even when the particles are separated by great distances, Particle A's observables like momentum, spin, polarization, etc. are immediately reflected in Particle B's observables in perfect correlation when measured. What Einstein would not accept was that an intervention at one

place on Particle A can immediately affect the other Particle B as well, which he felt violated the principles of communicating at the speed of light.

Basic Mathematical Formalism of Entanglement Applied to Medicine [58, 74]

We will use pure states and Bra-Ket notation as we described above to illustrate a philosophical example. Let's consider two composite random quantum systems here, which we conjecture to represent a normal system and a diseased system with operators within the Hilbert Vector Space \mathbb{H}_{Norm} and $\mathbb{H}_{Disease}$.

These composite systems are represented by the Kronecker product \otimes of the two systems as described earlier in the chapter.

$$\mathbb{H}_{Norm} \otimes \mathbb{H}_{Disease}$$

$$\begin{aligned} \mathbb{H}_{Norm} &\text{ is in an initial state } |\psi_{Norm}\rangle \\ \mathbb{H}_{Disease} &\text{ is also in an initial state of } |\psi_{pre-Disease}\rangle \end{aligned}$$

An assumption here is that these are composite yet separable states, which can therefore be represented as:

$$|\psi_{Norm}\rangle \otimes |\psi_{pre-Disease}\rangle \text{ with their basis fixed such that we have } \{|i_{Norm}\rangle\} \text{ for } \mathbb{H}_{Norm} \text{ and } \{|j_{pre-Disease}\rangle\} \text{ for } \mathbb{H}_{Disease}$$

As well as the separability assumption for boundary conditions, which exists if \forall vectors like $Tissue_i^{Norm}$ and $Tissue_j^{pre-Disease}$, there exist at least one vector space wherein $Tissue_{i,j} \neq$

$Tissue_i^{Norm} Tissue_j^{pre-Disease}$ and also $Tissue_i^{Norm} \neq Tissue_j^{pre-Disease}$.

Logically it would make sense that within a universe of cells that make up the tissue encoded as a vector, there is a potential for at least one of these vector spaces to also exist where the above assumptions hold true.

As such this would be generalizable to:

$$|\psi_{Norm\&pre-Disease}\rangle = \sum_{ij} Tissue_{ij} (|i_{Norm}\rangle \otimes |j_{pre-Disease}\rangle).$$

Meaning that under such potential conditions, entanglement can therefore be defined for a given two fixed basis vectors as follows in a numerical example:

$$\{|0_{Norm}\rangle, |1_{Norm}\rangle\} \text{ for } \mathbb{H}_{Norm} \text{ and} \\ \{|0_{pre-Disease}\rangle, |1_{pre-Disease}\rangle\} \text{ for } \mathbb{H}_{Disease}$$

An entangled state could therefore be represented as follows:

$$\frac{1}{\sqrt{2}} (|0_{Norm}\rangle \otimes |1_{pre-Disease}\rangle - |0_{Norm}\rangle \otimes |1_{pre-Disease}\rangle)$$

This would suggest that in future it may be theoretically feasible to completely disentangle disease and normal states arising in the same setting to optimize treatment. Techniques may become available to study ways to potentially flip diseased states back to their normal states. However, while in-vitro this may be achievable using tools like Bose-Einstein condensates, etc., in-vivo there usually may be too much noise and interference to render these states undetectable, hidden or collapsed to a single observable. Quantum machine learning could facilitate identification and better delineation of these states, may enable finer control of the system's state and help manage decoherence, but would require innovations that allow noise-reduced multi-qubit computation at room temperatures.

Nonetheless, theoretically one can immediately see potential clinical usefulness for this interesting behavior of entanglement for various medical applications. Potential applications

include in the management of metastatic cancers, which are usually a poor prognostic marker for some of the most aggressive cancers known to man. Through the use of entanglement in medicine/surgery, one can attain the ability to diagnose and manage two location-separated yet identical disease processes simultaneously reducing treatment complication risks and side effects. In metastatic cancer management for instance, the ability to differentiate diseased-state from the non-diseased state and obtain the desired effect from chemoradiotherapy treatment could offer prolonged and improved clinical outcomes to extend life or reverse disease course. As an example, radiotherapy could be performed using entangled positron particles where its effect on one location of metastatic disease would be linked to another area with metastasis leading to uptake and simultaneous dose-calibrated treatment. In worst outcome tumors like glioblastoma multiforme, there is evidence of trans-hemispheric muscular tumor cell migration even prior to tumors being detectable [75]. Imaging of these tumors may not show their metastatic nature at other sites, which often look normal even to the expert eye through imaging. Since the exact mechanisms for how these tumors spread is still incompletely understood. In theory, quantum entangled machine learning systems could be used in medicine and surgical oncology as a way to not only predict and track this behavior to detect when these changes could occur/are occurring, but to facilitate effective treatment. Depending on the particle used for the computational modality one can even apply theranostic principles, where quantum algorithmically-guided nanoscale robotics can be implemented as illustrated in Fig. 10. This will allow complete access even to areas of the brain where conventional minimally invasive surgical methods are limited. Quantum machine learning could enable us to build better triangulation algorithms for simultaneous peri-operative highly targeted adjuvant and neoadjuvant chemoradiotherapy platforms. This then becomes useful depending on the location of the tumor and the eloquent tissue that may be affected, newer treatment modalities and more options will become available.

Important Quantum Computing Algorithms and Quantum Machine Learning Algorithms

This section is not meant to be an exhaustive overview of all the algorithms, but is meant to guide the reader to some of the main quantum algorithms currently available for research and how they can be implemented or applied for future medical disease discovery and management. Quantum machine learning still remains a heavily theoretical field at present, but there are

simulators built to allow some practical implementations for research and experiments. Currently quantum algorithms have been designed to aid the optimization of tasks achieved by classical machine learning algorithms. Further current approaches also involve classical machine learning on quantum problems such as learning Hamiltonians. Open-source quantum computing has become assessable now and no longer confined to the laboratory [48–54, 58]. The circuitry of the algorithms is represented below for reference.

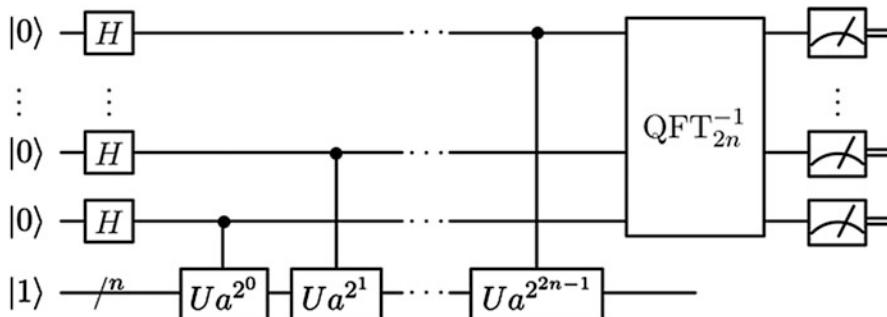

Fig. 11 Quantum subroutine in Shor’s algorithm for order finding, subsequently based on a Circuit for Shor’s algorithm using $2n+3$ qubits by Stephane Beauregard. Beauregard, Stéphane. “Circuit for Shor’s algorithm using $2n+3$

qubits.” Quantum Inf. Comput. 3 (2003): 175-185. (Image Source https://en.wikipedia.org/wiki/Shor%27s_algorithm#/media/File:Shor_s_algorithm.svg)

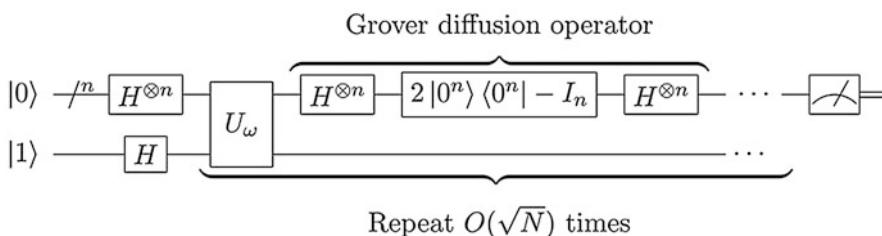

Fig. 12 A Quantum circuit representation of Grover’s algorithm (Image source by https://en.wikipedia.org/wiki/Grover%27s_algorithm#/media/File:Grover_s_algorithm_circuit.svg)

Quantum Fourier Transform

This algorithm invented by Dan Coppersmith is the classical discrete Fourier transform algorithm applied on a quantum state amplitude vector and is a linear transformation of qubits [76]. It forms the basis of several quantum algorithms useful for identifying the properties of qubits such as their phase in the phase estimation algorithm etc. This is useful for biomedical signal processing and also machine learning [73].

Shor’s Algorithm

This algorithm is a polynomial time integer factorization algorithm that was developed by Peter Shor to allow efficient prime factorization; a challenging feat for classical computers [77]. Its efficiency is linked to the efficiency of a Quantum Fourier Transform algorithm [73]. It was the first such

algorithm to demonstrate the vulnerability of RSA encryption to quantum computing. However, Shor’s algorithm fully depends on a functioning universal fault-tolerant quantum computation, which is yet to be made available in the NISQ era.

Grover’s Search Algorithm

An algorithm developed by Lov Grover that is able to probabilistically search through a database [78]. This quantum search algorithm is capable of finding a specific name among 100 million names in only 10,000 operations. It is characterized by Grover’s diffusion operator that is repeated over $O(\sqrt{N})$ time [11]. Quantum machine learning implementations of Grover’s search is being used to improve classical unsupervised learning algorithms like K-medians and K-nearest Neighbors and operate by amplitude augmentation of the wavefunction [79]. The classical equivalents

of these algorithms have been adopted in medicine for disease clustering and the quantum versions will improve disease pattern recognition and clustering as well as execution speed.

Deutsch-Jozsa Algorithm

This deterministic quantum algorithm proposed by David Deutsch and Richard Jozsa and one of the first of its kind to prove the exponential speed-up of a quantum computational algorithm [80]. It models the quantum computer as a black box to assess a function's ability to produce a balanced or constant deterministic output and poses the question of whether a *balanced* output (where the function returns 1 for half of the input domain and 0 for the other half) or a *constant* output of 0 for all outputs or 1 for all outputs can be returned. Pathologies linked to impaired homeostasis are common in the body, monitoring of homeostatic functions within the human body may benefit from the application and development of these algorithms (see Figure 13).

Bernstein-Vazirani Algorithm

Developed by David Bernstein and Umesh Vazirani, this is a restricted version of the Deutsch-Jozsa algorithm able to learn a string encoded function [24, 25]. This provides the most efficient function to identify a secret string of a particular length. Pathologies linked to genetic sequence abnormalities like missense mutations (e.g., sickle cell anemia) may benefit from the use of this algorithm (see Figure 14).

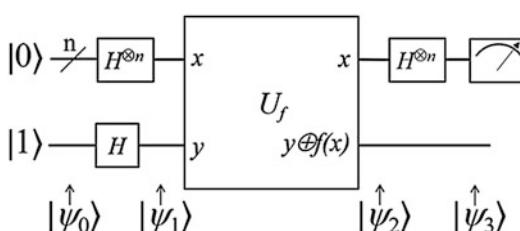

Fig. 13 Deutsch-Jozsa algorithm's quantum circuit (source from https://en.wikipedia.org/wiki/Deutsch%20%80%93Jozsa_algorithm#/media/File:Deutsch-Jozsa-algorithm-quantum-circuit.png)

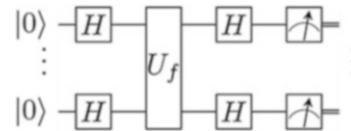

Fig. 14 Demonstrates a quantum circuit of the Bernstein-Vazirani algorithm (Image source https://en.wikipedia.org/wiki/Bernstein%20%80%93Vazirani_algorithm#/media/File:Bernstein-Vazirani_quantum_circuit.png)

Quantum Hidden Markov Chain Algorithm

These are the quantum equivalents to their classical hidden Markov chain algorithms for sequential and timeseries based modelling useful in various fields including robotics and natural language processing [81, 82]. These may be useful for modelling and predicting disease behavior related to stochastic probability distributions such as the randomness that exist in cancer cellular migration and tumor excision boundary conditions [75].

Quantum Natural Language Processing

The ability of computers to understand the higher-level information we give them is an important area of continuous study. University of Oxford's Robert Coecke, global collaborators and other institutions have been investigating applications of categorical quantum mechanics to computational linguistics and natural language processing [83]. Promising future extensions of this work to healthcare may include developing platforms to better model and aid the management of speech disorders for stroke, brain injuries and patients with mutism using quantum natural language processing algorithms and useful for improving AI-based radiology reporting systems.

Quantum Annealing and Quantum Neural Networks

Analogous to classical neural networks quantum neural networks are computational models based on quantum mechanics and aim to optimize sampling from higher dimensionality datasets and probability distributions [28, 30, 84]. It can also

enable an exponential augmentation in computational power compared to the classical computer.

Energy based models such as Boltzmann machines that obey the rules of entropy are usually very slow to train using classical computing. Multiple groups are exploring the use of quantum approaches to optimize the training of Boltzmann machines. Quantum annealing is able to generate samples from a Boltzmann distribution and is being generated as a potential to help train Boltzmann Machine [11, 73, 85]. NASA's D-Wave quantum system is one such example [53]. QNNs offer significant increases in computational power. They are deemed to be extensions of the Deutsch model of quantum computations. We have seen the tremendous potential for pattern recognition that neural networks are capable of and clinical practice will see its use-cases in improving computer vision systems image recognition and filter development for medical diagnostics.

Quantum Enhanced Reinforcement Learning

This distinct branch of classical machine learning adopts an agent-based approach and methodology to machine learning. Here the quantum agent interacts with the classical environment [73, 85]. Reinforcement learning using Quantum Boltzmann machines has been described recently in the literature [73, 85]. Here too there is a potential for developing improved quantum robotic platforms that can autonomously manage complex computations and navigate through the body without interference and will be useful for future nanorobotic surgery see Fig. 10 [86].

Quantum Phenomenon in Disease

Quantum biology was established in the 1920s and studies how the subatomic world of quantum mechanics plays a role in living cells. Current advances in research have identified phenomena like proton tunnelling, where the proton spontaneously disappears from one location within the cellular atom to another location, as a potential for

disease propagation [87, 88]. What allows such a phenomenon to occur is that the human DNA molecule is a helical structure with disulfide bridges and hydrogen atoms arranged at its periphery. These hydrogen atoms are protons and as a consequence could be observed in protonic exchanges across the helical structure. In fact, quantum proton tunnelling was identified as occurring at room temperature in DNA and has been hypothesized as a cause for cancer formation as this process can be propagated as mutations that arise during DNA replication [87]. Whether this contributes to an association with oncological disease states like Glioblastoma multiforme and others remains to be explored, but is an area of potential research enquiry.

Quantum Computing in Healthcare

In the healthcare industry, quantum computing could enable a range of disruptive use cases for providers and health plans by accelerating diagnoses through improved medical imaging analysis, personalized medicine, and optimized pricing. Quantum-enhanced machine learning algorithms are particularly relevant to the sector. Quantum computers are ideally suited for solving complex optimization tasks and performing fast searches of unsorted data. This is going to be relevant for many applications, from sorting and predicting the effects of climate data on health and disease or predicting healthcare financial data, to optimizing healthcare supply chain logistics, or global healthcare workforce management and deployment for disaster relief and robust integrations of healthcare ecosystems. Quantum encryption systems will offer us tremendous potential and safeguards for clinical data integrity. Quantum computing will also be useful for next generation drug discovery and reduction of pharmacokinetic and pharmacodynamic error, computational molecular optimizations and overall reducing false positive receptor interactions [12, 89–92]. Initiatives such as the planned National Quantum Computing Centre in Oxfordshire United Kingdom can foster a multidisciplinary environment for disease treatment discovery for healthcare, including optimised cancer

theranostics and complex genetic treatment discovery strategies.

Future Translational Considerations for E-Healthcare

The ability to simulate disease process and perform quantum Monte Carlo simulations will allow potential significant developments and discoveries in treating diseases or finding reversible paths for diseases in future. The simulation hypothesis and other controversial concept like the many universe construct would eventually be better studied and understood through quantum computing [93]. Quantum safety is another area where quantum computing and machine learning will benefit us greatly. With the quantum revolution, the safety of classical computers will be at risk. Cybersecurity and newer forms of cyberwarfare against e-healthcare are also areas where one would need quantum computers to safeguard against leading to a trend towards absolute security and via Quantum Diffie-Hellman and Quantum Group Key Agreements and other systems [94, 95]. Other areas such as the already demonstrated quantum teleportation will also allow us to establish methods to achieving healthcare information transfer across far greater interplanetary distances and perhaps teleportation of man will not be a far-fetched science fictional concept that will present its own medical challenges to overcome.

Currently, the issues affecting effective design and operations of quantum computational systems include quantum decoherence of the definite phase relationship between all the superposed states [96]. This is attributed to systematic noise and work to reduce quantum noise has made significant progress in the recent years. However, methods for decoherence needs to be overcome and fully understood for the human body as a quantum system in order to fully unlock applications of ensembles quantum computation and building devices like effective quantum efficient brain machine interfaces. There's a belief that this will be achieved in the distant future. Through better tools for quantum computation, there will also be a better understanding and delineation of

various forms of fuzzy logic from quantum logic and provide medically relevant applications. In the near term, we see small qubit quantum computers aiding boosting machine learning algorithms. However, it remains unclear about the timeline for most of these future developments outlined above and would depend on funding avenues for translational collaboration between government, industry and academic institutions to benefit healthcare.

Ethico-Legal Implications and Considerations

Insurance systems for healthcare economies look at the potential risk of individuals developing conditions and uses that to forecast whether monthly payment contributions are appropriate for that individual. From one perspective individuals might be forced to pay more based on the predictive use of quantum and machine learning methodologies for probabilistic disease course prediction. This opens up new regulatory challenges. Consider a scenario where an individual with a high probability of a genetic disorder is identified. Not only will it have repercussions for information and data protection, stigma control and psychological burden control, but also perhaps may cause undue distress to family particularly if there is only a single potential avenue of treatment for them [97].

One would counter-argue that this same individual will be helped if we could predict the probabilities of various disease states and the pathophysiological patterns that would lead to an unfavorable outcome. This would guide lifestyle choices and provide treatment avenues that would lead to better outcomes for them and hence the model of healthcare insurance will need to change to support or factor in this process.

There is an argument for both, and multidisciplinary consortia of computer scientists, physicists, chemists, mathematicians, economists, medics and policy-makers will need to be established in order to enable consensus decisions around medical use-cases of quantum computation and machine learning.

Summary Remarks

It is conceivable that quantum computers have significant medical potential. From the ability to improve diagnostics through the analysis of medical images, including processing steps, such as pattern recognition and image matching, to improving the medical image acquisition speed that can be accelerated using quantum machine learning algorithms. These use-cases as well as those described above will significantly help advance healthcare's quadruple aims. The combination with AI will not only make patient care more efficient leading to improved population health, improved quality of life and earlier diagnoses, such as diagnosing and perhaps reversing cancer at an early stage, but will truly provide the quantum leap for mankind. However, significant challenges still remain, but the medical community has a lot of positive areas to inspire research enquiry.

Nearly 200 years after Charles Babbage proposed his innovative idea of the “difference engine” and it was subsequently prototyped, we may finally be making the leap towards realizing his dream through quantum computing.

Abstract

Deep learning has been shown to be of benefit in a number of areas of medicine. This chapter gives a recent topological explanation of the efficacy of deep learning in terms of internal transformations of dataset topologies by deep neural networks. This is followed by medical examples including imaging and genomics.

Introduction

Of the various machine learning techniques that have been applied to medical problems, the use of neural networks has arguably been the most prominent, and this has been the case since the early 1990s [3] (This chapter assumes that the reader is familiar with the basic concepts associated with neural networks as detailed by Bishop [4, 5].).

Before the 1990s, the main AI approach to clinical decision-making was to attempt to use knowledge-based systems [20]. These systems supposedly encapsulated medical expert knowledge, but the development of these so-called expert systems was beset with difficulties [44];

R. Dybowski (✉)
St John's College, Cambridge, UK
e-mail: rd460@cam.ac.uk

consequently, attention turned to data-based approaches, and to machine learning in particular.

Rosenblatt [38] developed the Perceptron – a neural network without a hidden layer – but it was limited to classifying feature vectors that are linearly separable [32], a limitation that brought about the first “AI Winter.” It was not until the publication of the back-propagation algorithm by Rumelhart et al. [39] for the training of neural networks with a hidden layer that an explosion of interest in neural computing took place (However, the back-propagation algorithm was first discovered by Werbos [45].).

Despite the interest in neural networks that occurred during the 1980s and 1990s, frustrations were also present partly because of limitations with the methodology used at the time; for example, the use of sigmoidal activation functions such as the hyperbolic tanh. It were improvements such as the introduction of the ReLU activation function [33] to overcome the vanishing gradient problem [16], and the use of the “dropout” method to suppress overfitting [42], that helped to bring neural networks to the standard they are today and establish the renaissance in neural computation ($\text{ReLU}(x) = \max(0, x)$. ; Coupled with the availability of faster computers and more data.).

Deep Neural Networks

The terms “shallow” and “deep,” when applied to neural networks, simply refer to the depth of a network: A shallow neural network has no more than one hidden layer whereas a *deep neural network* has several hidden layers.

Consider the data points displayed in Fig. 1a. These are *linearly separable*, which means that the classes can be completely separated by a single (hyper)plane between them. Consequently, a linear discriminant function [15] such as a logistic regression model (Fig. 2) can be considered as a classifier with respect to the data. In contrast, the distribution of the data in Fig. 1b is not linearly separable; however, note that a nested regression model (Fig. 3) is able to produce nonlinear decision boundaries.

A single-layer perceptron (Fig. 4) with a logistic activation function is equivalent to a logistic regression model; and a feed-forward neural network (FNN) with a single hidden layer can be viewed as a nested logistic model, but the analysis can be taken further as follows.

The Universal Approximation Theorem and Its Limitation

Cybenko [6] and Hornik [17] proved that an FNN with a sufficiently large single hidden layer can, in theory, approximate any continuous function (the *Universal Approximation Theorem*). Although this is true, the hidden layer may have to be extremely large in order to achieve this for a given task, and the larger the hidden layer, the greater the number of weights (parameters) required for that layer. Moreover, determining the number of nodes needed in that hidden layer for a given task is difficult. On the other hand, as argued by Mhaskar et al. [31], fewer parameters are required when more than one hidden layer is used.

Internal Hierarchical Feature Extraction

In the context of statistics and machine learning, the term *feature extraction* refers to the derivation of new values (features) from measured data to facilitate the analysis of the data and/or perform predictions. And, when used in the context of deep neural networks, the phrase “hierarchical feature extraction” is primarily applied to convolutional neural networks.

Convolutional neural networks (CNNs) are spatially invariant deep networks that use convolution in place of the matrix algebra of feed-forward networks in at least one of their layers [12]. The architecture of a CNN, originally proposed by LeCun [25], was inspired by the Hubel and Wiesel [18] model of the visual primary cortex.

The *convolution* of a layer of values within a CNN uses local kernels to detect local features.

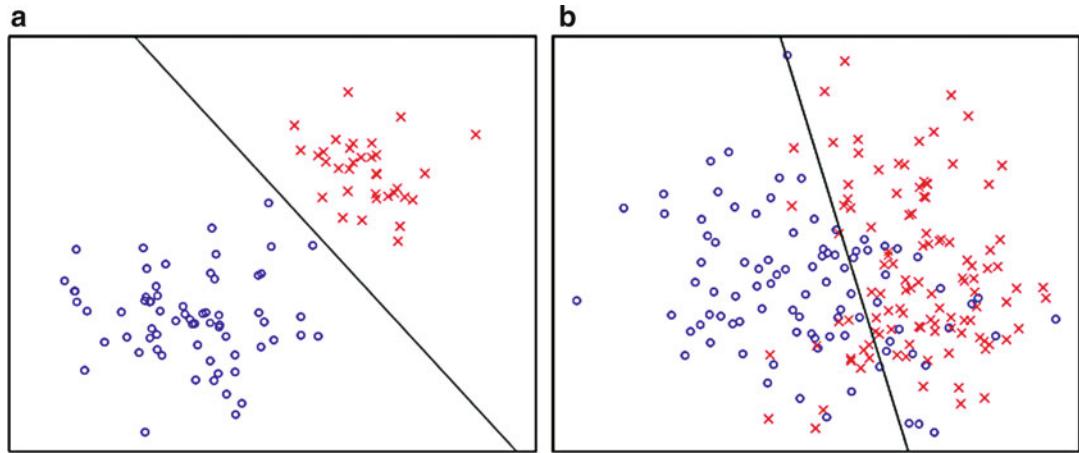

Fig. 1 Class-labeled data points: (a) linearly separable and (b) not linearly separable. The line in (a) provides a decision boundary for classification

$$\mathcal{E}[Y|x_1, x_2] = \frac{1}{1 + \exp [-(w_0 + w_1x_1 + w_2x_2)]}$$

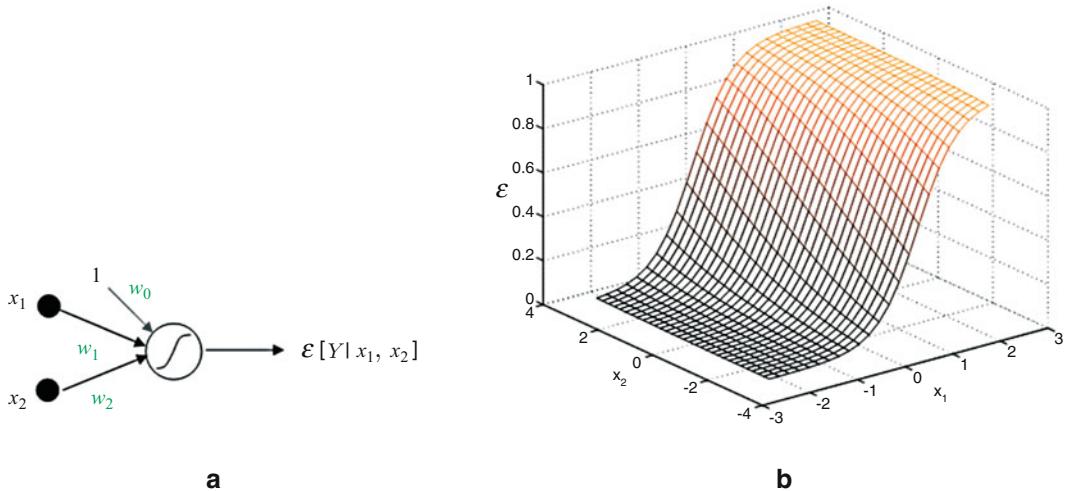

Fig. 2 Conditional expectation $\mathcal{E}[Y|x_1, x_2]$ is equal to the logistic function $\text{Logistic}(x_1, x_2; w_1, w_2, w_3)$. Classification can be based on whether $\mathcal{E}[Y|x_1, x_2]$ is greater than some

threshold value τ (e.g., $\tau = 0.5$), and the resulting decision boundary (not shown) will be linear

This results in a type of feature map at the next layer. Another technique called *max pooling* reduces the dimensionality of a feature map but retains the most important information to be passed on to the following layer. A common architecture for CNNs is to have alternate

convolution and pooling layers, with a shallow feed-forward neural network for the final layers to provide a probability output.

The use of convolution and max pooling produces a successive abstraction of information held within a series of layers. In their [26] paper, in

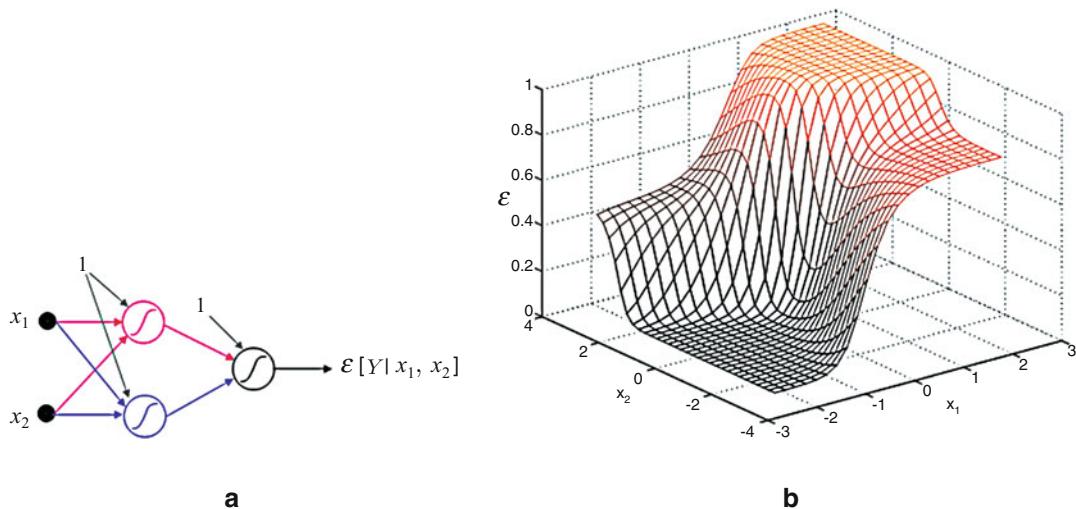

Fig. 3 A nested logistic regression model, which provides a nonlinear decision boundary for classification

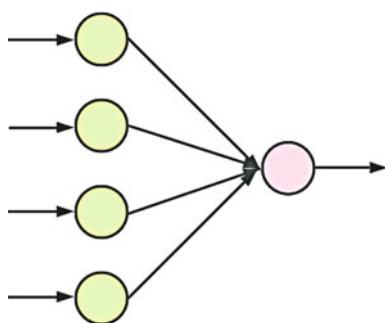

Fig. 4 FNN with no hidden layers (a “perceptron”): $Net(\mathbf{x}) = f_{out}(\mathbf{x}) = Logistic(\mathbf{x}; \mathbf{w})$, where \mathbf{x} is the vector of input values and \mathbf{w} are the weights

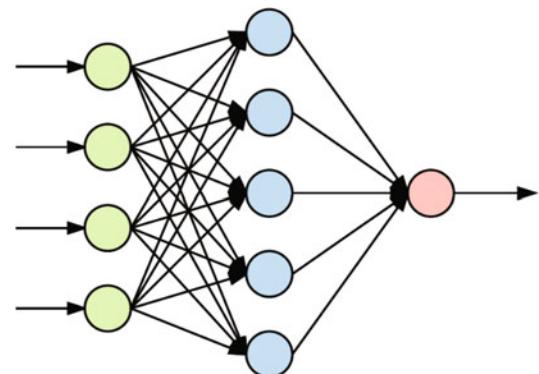

Fig. 5 FNN with one hidden layer (blue): $Net(\mathbf{x}) = f_{out} \circ f_1(\mathbf{x})$

which they focused on CNNs, LeCun et al. wrote “Deep neural networks exploit the property that many natural signals are compositional hierarchies, in which higher-level features are obtained by composing lower-level ones.” Each layer in the network can be thought of as performing an abstraction of the information held within the preceding layer so that a sequence of layers provides a hierarchy of increasing abstraction. This can obviate the need for the manual selection of input features once required for most neural networks [43] (Fig. 5).

Internal Transformation of Dataset Topologies

The deep FNN, $Net(\mathbf{x})$, shown in Fig. 6 can be deconstructed into two FNNs. One FNN, $Net_1(\mathbf{x})$, has all the hidden layers but not the output node (i.e., $Net_1(\mathbf{x}) = f_3 \circ f_2 \circ f_1(\mathbf{x})$), the other FNN is just the logistic output node function f_{out} ; consequently, $Net(\mathbf{x}) = f_{out} \circ Net_1(\mathbf{x})$.

A mathematical manifold is a topological space that locally resembles Euclidean space near each point, and there is evidence that real-

Fig. 6 FNN with three hidden layers: $Net(\mathbf{x}) = f_{out} \circ f_3 \circ f_2 \circ f_1(\mathbf{x})$. Note that there can be more than four input nodes as well as more than one output node and many hidden layers in an FNN

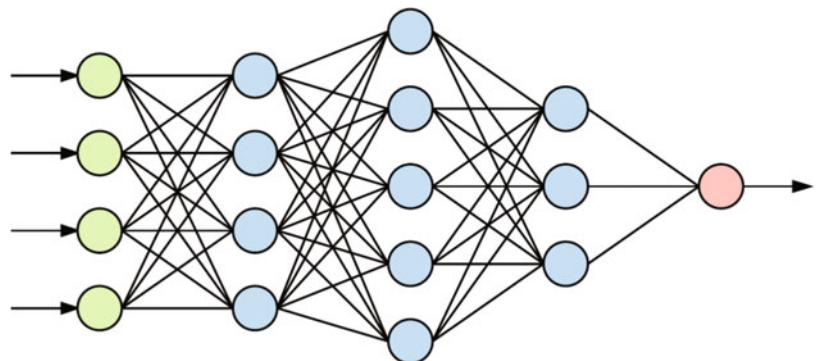

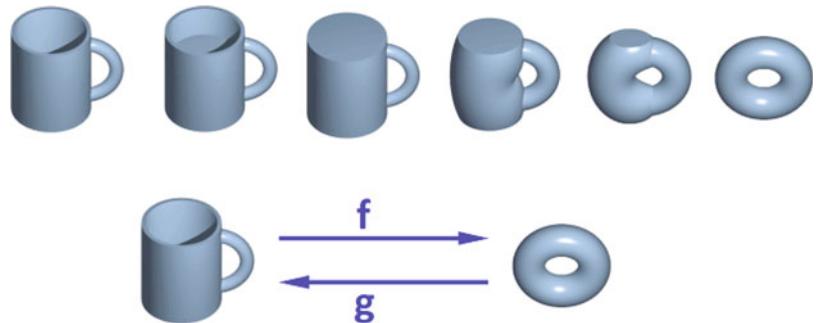

Fig. 7 Homeomorphism f of a mug to a doughnut. g is the inverse

world data points exist on manifolds [10] – the *manifold hypothesis*. Topology is a branch of mathematics concerned with the properties of geometric objects that are preserved under continuous deformations, such as stretching, twisting, crumpling, and bending, but not tearing or gluing [1], and Olah [35] looked at the efficacy of neural networks topologically. He proposed that a deep FNN $Net(\mathbf{x})$ learns the topological transformation required to create a homeomorphism of the original data manifold M such that the mappings of the data points on M onto the resulting manifold via $Net_1(\mathbf{x})$ are linearly separable according to f_{out} (A *homeomorphism* is a continuous function between topological spaces that has a continuous inverse function. An example is shown in Figure 7.). The inverse Net^{-1} creates a nonlinear decision boundary for classification (Fig. 9).

As an example, consider the two sets of data (curves) shown in Fig. 8a, which are on a simple 2D manifold. These are clearly not linearly separable; however, a homeomorphic distortion of the

manifold provides linear separability (Figs. 8b and 9).

Lei et al. [27] posited that the fundamental principle attributing to the success of deep learning is the manifold structure in data, namely that natural high-dimensional data concentrates close to a low-dimensional manifold, and deep learning learns the manifold and the probability distribution on it.

Detailed analysis of deep learning using topology has recently been conducted by Naitzat et al. [34] and Hajij and Istvan [14]. Naitzat et al. used Betti numbers [2] for their analysis and showed that deep networks work by reducing the Betti numbers of manifolds M . They made the following observations:

- **Effects of depth on topology change:** Reducing the depth of a constant-width network beyond a certain threshold makes it increasingly difficult to train the network to high accuracy. Moreover, as the depth is reduced,

Fig. 8 (a) Two curves on a manifold, which are not linearly separable. (b) Curves linearly separable after the manifold is transformed by an FNN [35]

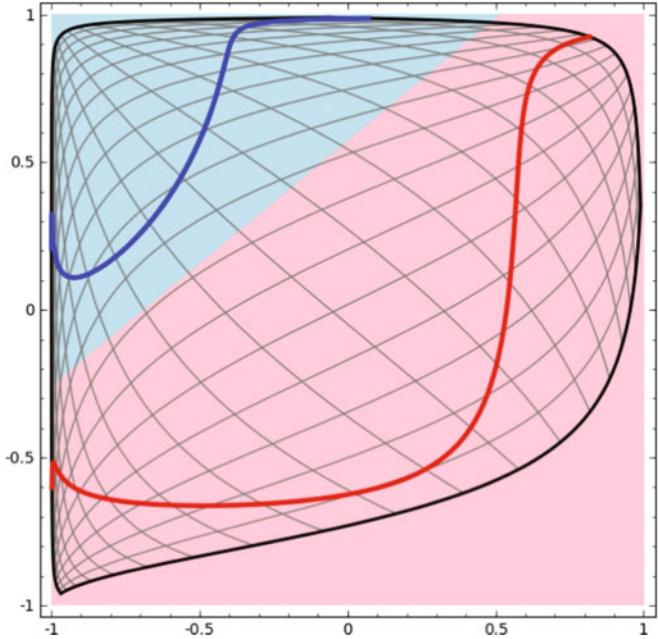

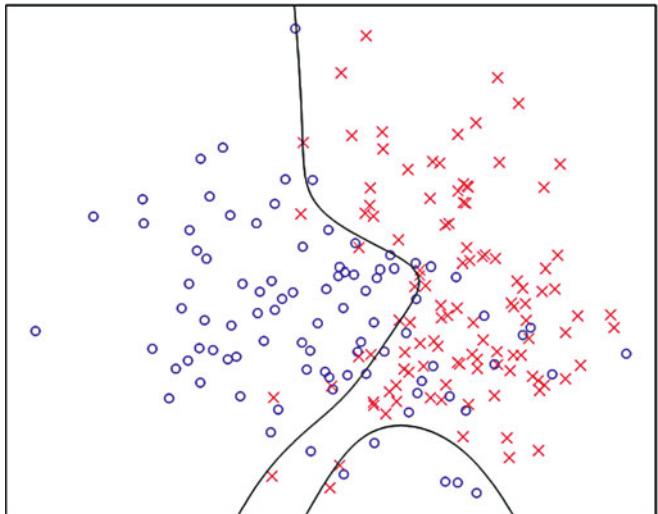

Fig. 9 Classification decision boundary for Fig. 1b obtained from an FNN

the burden of changing topology does not spread evenly across all hidden layers but becomes concentrated in the final layers. The initial layers do not appear to play a big role in changing topology, and reducing depth simply makes the final layers “work harder” to produce larger reductions in Betti numbers.

- **Nonhomeomorphic activations induce rapid topology changes:** The tanh activation

function is less effective at reducing Betti numbers, whereas the nonhomeomorphic activation ReLU exhibits the most rapid reductions in Betti numbers. The effectiveness of ReLU over sigmoidal activations is often attributed to the former’s avoidance of vanishing/exploding gradient. The reduction in Betti numbers is significantly faster for ReLU activation than for hyperbolic tangent activation as the former

defines nonhomeomorphic maps that change topology, whereas the latter defines homeomorphic maps that preserve topology.

In sum, a deep neural network operates by gradually transforming, through its layers, a topologically complicated dataset in the input space into a topologically simple one that is linearly separable in the output space.

As regards autoencoders and deep learning, these learn the manifold structure and construct a parametric representation of it within the latent space of the autoencoder [27].

Medical Examples

The advantages of deep neural networks cited above have led to a variety of successful medical applications [8]. Health care applications of deep learning range from one-dimensional biosignal analysis [11] and the prediction of medical events, such as seizures [22] and cardiac arrests [23], to computer-aided detection [40] and diagnosis [7, 21] supporting clinical decision-making. What follows is far from comprehensive, but nevertheless important, set of examples.

Medical Imaging

Given their impressive capability at processing complex images, CNNs have become the central tool for computational medical imaging (Fig. 10). Deep learning has been applied in radiotherapy

[30], in PET-MRI attenuation correction [28], in radiomics [24], and in neurosurgical imaging [19], among others.

Genomics and Epigenomics

Machine learning methods have been widely applied to big data analysis in genomics and epigenomics research. Although accuracy and efficiency are common goals in many modeling tasks, model interpretability is especially important to these studies toward understanding the underlying molecular and cellular mechanisms. Deep neural networks have recently gained popularity in various types of genomic and epigenomic studies due to their capabilities in utilizing large-scale high-throughput bioinformatics data and achieving high accuracy in predictions and classifications.

Deep learning has been applied to popular bioinformatics problems including DNA/RNA binding sequence motif identification [36], gene expression prediction [46], epigenetic problems such as chromatin accessibility, interaction and DNA methylation predictions [9, 41], as well as various directions in noncoding RNA (ncRNA) studies [29].

Natural Language Processing

When a recurrent neural network (RNN) is unfolded over time, it can be seen to be a deep network [13], and RNNs are effective at

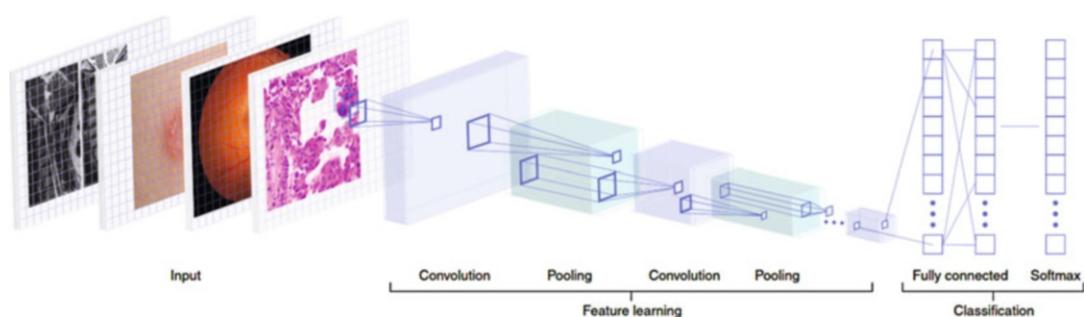

Fig. 10 Use of CNNs for medical imaging. A range of inputs can be used. Shown here are images from radiology, dermatology, ophthalmology, and histopathology [8]

processing sequential inputs such as language, speech, and time series data.

One application for RNNs in medicine is the processing of electronic patient records (EPRs). The EPR of a large medical organization can capture the medical transactions of over 10 million patients throughout the course of a decade, and a single hospitalization alone typically generates about 150,000 pieces of data [8]. One possible pipeline for building deep learning systems for EPRs is as follows [37]. Raw data are first aggregated across institutions in order to ensure that a generalizable system is built. The data are then standardized and parsed temporally and across patients, which makes them suitable for deep learning training leading to patient-specific care.

Conclusion

The topological approach to deep learning provides an eloquent way of not only understanding the nature of deep learning but also, hopefully, to facilitate the design of deep networks in a more principled manner.

It would be an understatement to say that deep learning has played a significant role in modern medicine. From medical imaging to the omics domain, progress has been impressive; however, the interpretation of deep omic-type network models toward an understanding of underlying biological mechanisms is still far from reach.

Deep learning in medical data analysis is here to stay. Even though there are many challenges associated to the introduction of deep learning in clinical settings, the methods produce results that are too valuable to discard.

Abstract

Artificial Intelligence applications have recently demonstrated high diagnostic accuracy and increased workflow efficiency in

radiology. Machine learning models, particularly deep learning, can perform complex tasks in medical imaging, especially when they are trained with a large amount of high-quality data. For effective realization of the potential of artificial intelligence in interventional radiology, some unique challenges involving data storage, interoperability, adoption of standards, and conflict of interest between physicians and developers need to be addressed. With

immense innovation and technological breakthrough, the scope of interventional radiology is continuously increasing in both width and breadth, and so are the opportunities of AI to revolutionize the sector. Artificial intelligence can complement the efforts of the interventional radiologist through decision support, triaging and screening of patients, prevention of error, procedural and periprocedural support, patient monitoring, prognostication of diseases, outcome prediction, image acquisition, image processing, etc. In conjunction with augmented reality systems, it can also help in improving procedural skills of interventional radiology residents and fellows through superior simulation training. Artificial intelligence has a tremendous potential to boost the productivity of radiologists. However, they are unlikely to replace them as there are significant apprehensions regarding the legal accountability, transparency, fairness, equality, bias, or potential misuse by an artificial intelligence system which prevent any independent action or clinical application without the oversight of an expert radiologist.

Introduction to Interventional Radiology

Modern radiology grossly comprises two subspecialties: diagnostic radiology (DR) and interventional radiology (IR). The IR subspecialty started off as an attempt by the radiologists and physicians to use the diagnostic tools available in radiology in the management of the patient. Perhaps the most important breakthrough in interventional radiology and angiography was the introduction and popularization of percutaneous catheter replacement of a needle or a trocar by a novel technique – the Seldinger technique [1]. Since then, IR, as a subspecialty,

has gradually evolved with hundreds of innovations and improvements in the procedures and techniques which have led to significant improvement in patient outcomes [2].

While IR essentially started off as an offshoot of DR, current IR practice is very different. Interventional radiologists today are much more involved in providing holistic care for their patients. Patient evaluation, including taking a clinical history, physical examination, as well as understanding the complete laboratory workup and imaging findings prior to the interventional procedures, can guide the interventional radiologist to personalize and decide the most appropriate management plan for his patient and achieve superior treatment outcomes [3].

AI in Medical Imaging: A Primer

The use of AI in medical image analysis has garnered increased attention since the last few years, and there has been a significant rise in the curiosity and interest of radiologists and non-radiologists alike. There have been a lot of recent advancements in the application of AI in the medical imaging sector along with recent demonstrations of higher accuracy in diagnosis and increased efficiency in clinical care. Radiologists are trained during residency to visually assess medical images by scrolling through different views and sections and write a structured report to localize and characterize the findings. These reports are often subjective and vary with experience. AI can recognize complex patterns and associations from imaging data and can help in automated detection, localization, as well as quantification of lesions, wherever possible. AI-integrated workflows can help reduce workload, time to diagnosis, and errors in reporting [4] (Fig. 1).

AI in health care primarily involves the application of machine learning (ML) techniques. ML gives computers the ability to learn without being specifically programmed. It works on the principle of “backpropagation.” Forward propagation or inference is when data goes into the neural network and makes a prediction. Backpropagation is

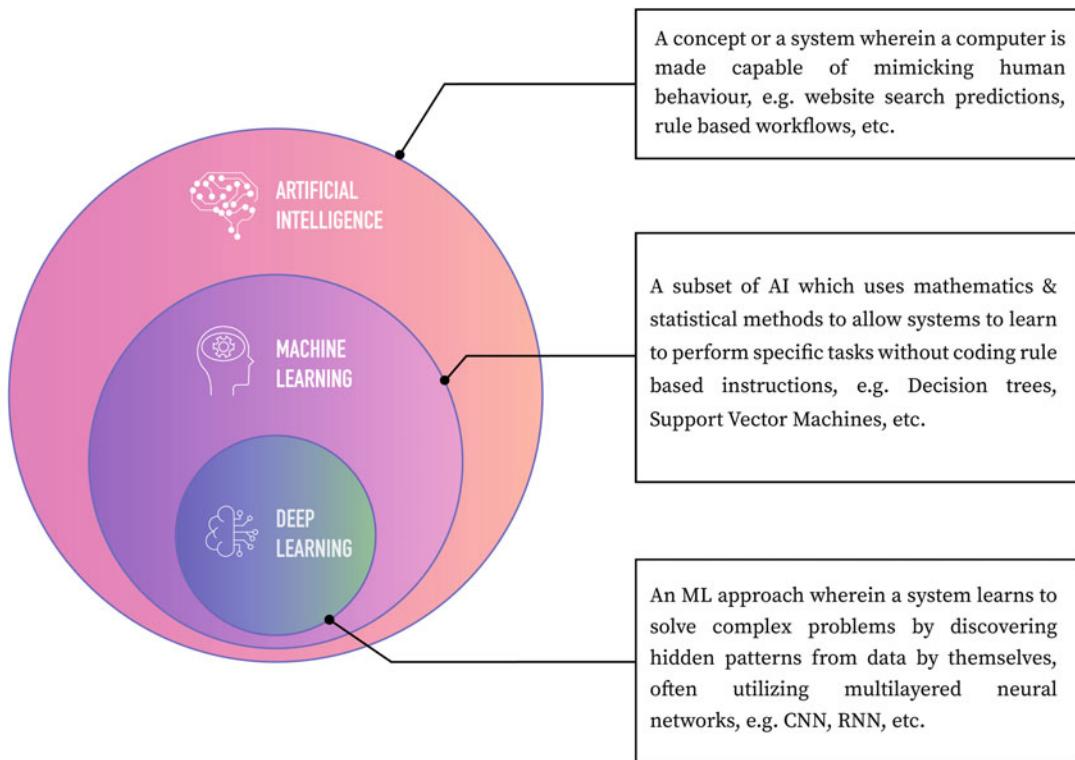

Fig. 1 Artificial intelligence (AI), machine learning (ML), and deep learning (DL)

the process of adjusting the weights by looking at the difference between prediction and the actual result, by computing how much each weight in the preceding layer needs to be changed to bring the expected outcome closer to reality, i.e., bringing the error rate close to 0. During model training, its weights are thus fine-tuned to increase the prediction accuracy. If enough high-quality data is fed to the computers, ML allows them to create algorithms for solving a particular task with high accuracy [5] (Fig. 2).

There are broadly two types of AI methods that are in wide use today – traditional methods and deep learning. Traditional AI uses pre-identified and engineered features (defined in terms of mathematical equations) and focuses on discovering relationships and confidence intervals between inputs and outcomes. These features, though perceived to be discriminative, rely on human expert definition and do not always represent the best approach for solving a particular problem. However, the traditional methods have reached their

maximum performance. Moreover, extracting and selecting classification features take up a significant amount of time and effort [6].

Compared to this, ML methods aim to reach high prediction accuracy without emphasizing on the need for interpretation. However, in health care, interpretability and explainability of any algorithm – as to understanding how and why a program is coming to its conclusions – are of paramount importance. With recent advances in ML, and the ability of the newer models to show us feature/saliency maps which highlight the region of interest (ROI) which led the AI algorithm to make a prediction, the “black box” problem of AI is an area which is being actively explored and addressed so that clinical applications of AI become more popular.

During development of an ML model, it is provided training data and tuned to make accurate predictions for the training data by an optimization algorithm. The main goals of the models are to gain insights from the training data and

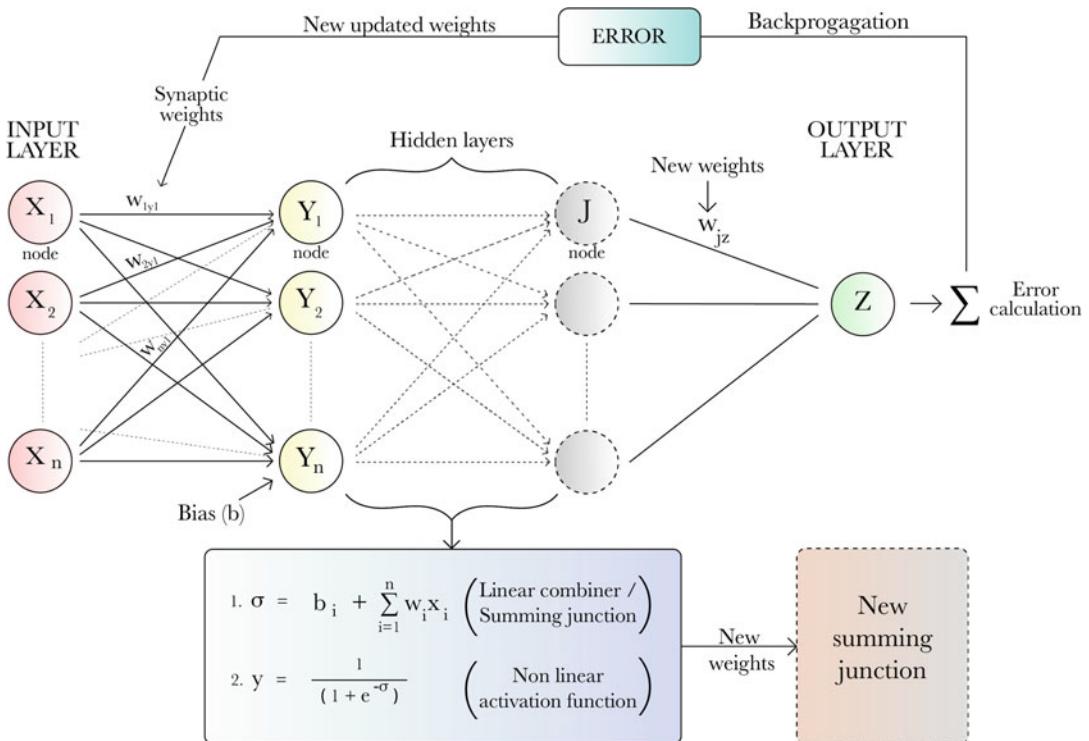

Fig. 2 An artificial neural network (ANN) and the principle of backpropagation

generalize their learned insights to make correct predictions for new, previously unseen data. The generalization ability of an ML model is typically estimated using a separate data set – the validation set and the same is used as feedback for further tuning of the model. After multiple iterations of training and tuning, the final model is evaluated on a test dataset to simulate how the model will perform when faced with new, unseen data.

Deep learning (DL) is a subset of machine learning, and, while it has similar functions, its capabilities are different. DL uses multiple layers of artificial neural networks, with the capability of learning complex tasks. While most ML models may perform fairly well with structured and organized data, DL models have the capacity to process medical images and other high-dimensional and less structured data with excellent results [5].

Without explicit feature selection, DL algorithms have the ability to learn complex interrelationships and associations by navigating the data space which provides them superior

problem-solving capabilities. While various DL techniques have been explored to address different medical imaging tasks, convolutional neural networks (CNNs) are the most well-known DL architecture today. A CNN comprises a series of layers that can map image inputs to desired end points while learning increasingly higher-level imaging features. Starting from an input image, there are multiple hidden layers within CNNs (including convolution and pooling operations) for extracting feature maps and performing feature aggregation. These hidden layers are followed by fully connected layers providing high-level reasoning before an output layer produces predictions. CNNs are often trained end to end with labeled data for supervised learning. Compared to traditional AI algorithms, CNNs can learn and select the features by itself automatically and effectively. However, for the better adoption of CNNs in clinical applications, especially in medical imaging, visualization of ROI is essential for the interpretability of its results [6].

Data in Medical Imaging

Data in medical imaging has tremendous potential to complement efforts of healthcare providers and radiologists in improving patient outcomes. Radiology departments around the world currently have huge databases of images and text. They are often rich in data but poor in information content which can be effectively utilized. In IR, a vast majority of the data are stored as video files which take up significant storage space. “Big Data” in radiology represents an opportunity to utilize reservoirs of information to make medical imaging more valuable to patients, e.g., by providing clinical decision support to radiologists through access to and analysis of information that is otherwise often inaccessible, inefficient, or difficult to integrate in real time for the consulting physician.

One of the key issues which is a primary concern regarding the utilization of medical data is interoperability. Medical information in the form of electronic health records (EHRs) is collected and stored with great variation across different institutes and organizations. Most software programs utilize and share information in proprietary formats, e.g., free flowing text notes for a particular interventional procedure, unstructured or semi-structured radiology reports, etc., and much of the data is often missing, inaccurate, and non-interpretable across other platforms. This poses significant challenges during the analysis of data consolidated from inconsistent and often different sources [7].

Despite advancements in interoperability, such as Consolidated Clinical Document Architecture (C-CDA) and Fast Healthcare Interoperability Resources (FHIR), there are multiple reasons which have hindered the widespread and interinstitutional exchange of medical imaging data, ranging from issues involving selection and adoption of technical and image standards to governance, security, and privacy [8].

Big Data powered by AI and statistical modeling can predict the pre-test probability of a disease for a patient based on his or her profile as extracted from the electronic health record, in real time, and

help the radiologist or clinician in interpreting the reports of a diagnostic imaging study, e.g., during analysis of a pulmonary nodule incidentally detected in a patient or for taking management decisions by determining and comparing the likelihood of success of a particular IR procedure based on patient profile, e.g., decision regarding splenic artery embolization vs. splenectomy in a Grade III splenic trauma.

For complete realization of the prospects of Big Data in medical imaging and radiology, increased information sharing among organizations is a prerequisite. Medical data, especially medical image/video sharing, is very complex and requires patients, radiologists, clinical departments, administrators, and institutions to work together toward democratization of anonymized healthcare information and adoption of safe data-sharing standards. Strategies for creating image data sets from multiple large cohorts for integration and comparison, addressing security and accessibility concerns for researchers and clinicians, and the standardization of information are crucial for the effective utilization of the large volume of medical imaging data available worldwide. Widespread global collaborative efforts sound ambitious but are indeed necessary to unleash the true potential of data in both DR and IR.

AI in Diagnostic Radiology: Brief Overview

One of the most promising clinical applications of AI is in diagnostic imaging, and it is indeed on the road to revolutionize DR as we know of today. Currently, increased attention is being directed at establishing and fine-tuning its performance to facilitate detection and characterization of a multitude of clinical conditions [9].

Improvement in imaging techniques, introduction of newer technologies, and the wider availability of imaging has resulted in increased reporting workload of radiologists over the past decades. This increase in demand is particularly prevalent in more time-consuming imaging such

as computed tomography (CT) and magnetic resonance imaging (MRI), with the additional challenge of completing the reports in a timely manner. Incorporation of AI into the radiologists' workflow can increase reporting efficiency as well as improved patient outcomes.

AI helps in automation of lesion detection, image segmentation, lesion quantification, standardization of radiology reports, or for comparison of scans with previous imaging. Follow-up studies for monitoring treatment response or for disease relapse often take up significant time which can be cut short by AI-assisted lesion measurement and characterization. These mundane and laborious tasks may benefit from automation using AI and allow radiologists to focus on other complex and cognitive tasks. Natural language processing (NLP) of radiology reports is also an area which is being actively explored. DL algorithms can insert recommendations for the clinician at the end of the report whenever critical findings are detected on a scan [10].

AI can also help in the scheduling of orders, triaging or screening of patients for scans or procedural safety, examination protocoling, faster image acquisition, image management and archiving, image registration, quality analytics, dose estimation, and integration of reports or imaging data with EHRs. These can help in improving efficiencies and patient outcomes by reducing missed radiology appointments, decreasing adverse events and mistakes, decreasing imaging time, reducing unnecessary imaging and radiation exposure, optimization of sequences, prioritization of worklists, improved diagnostic interpretation, prognosis estimation, and automatic quantification of lesions/bleeds.

However, despite the tremendous advancements and potential to disrupt the DR sector, a few key challenges still need to be addressed. Collection of high-quality annotated ground truth data, development of generalizable and diagnostically accurate techniques, and workflow integration are the key challenges facing adoption of machine learning in radiology practice. Overfitting is also an important challenge in complex models and tasks. ML develops high-dimensional functions that often cannot be explained. This makes interpretability difficult, thereby hindering

its acceptance in health care where identifying the underlying logic is important. Visual saliency maps are being increasingly incorporated in AI solutions which could highlight areas within images that have grabbed the attention to perform a classification task. The saliency maps could provide a certain extent of explainability for the ML models. Widespread application of ML algorithms in DR is expected to improve radiology workflow, increase productivity, and improve patient outcomes [11].

AI in Interventional Radiology: Unique Challenges

Apart from the challenges common to both DR and IR, there are indeed a few unique issues in the latter which need to be addressed for the successful utilization of AI in interventional procedures to improve workflow efficiency and outcomes. IR images/videos are essentially stacks of image data or sequential scans, which have unique spatiotemporal associations. Such data needs to be stored and retrieved in an organized and sequential manner when an attempt is made to create datasets for ML model development. These datasets occupy a significant amount of storage space.

One major limitation is the significantly less availability of expert interventional radiologists globally. Creation of high-quality datasets often require establishment of ground truth by means of annotations by experts. While there are a large number of diagnostic radiologists who are interested in collaborations for the development of AI tools or in the incorporation of AI in their workflows, the interest among interventional radiologists is comparatively less.

Conflict of interest between interventional radiologists and AI developers is an important issue which needs to be addressed. While many AI developers are enthusiastic about creating a "do-it-all" product which can replace radiologists, they need a lot of support with respect to domain expertise from the radiologists while developing their product. Radiologists are in turn often wary about their own careers and the potential of AI to impact their DR or IR practice. IR is significantly

different from DR as the former involves procedures that alter patient management immediately, and there may be significant ethical concerns when intraprocedural decisions based on recommendations of an “inexplicable” ML model are to be factored in. This may have major medicolegal implications and is a potential barrier to the effective incorporation of AI in IR.

Interventional procedures, empowered by the fast-paced introduction of innovations in the sector, are dynamic, and with rapidly changing practice patterns and new evidence being generated, best practice guidelines for IR procedures are being continuously updated. This limits the pool of homogenous and retrospective data available for training ML algorithms [12].

AI in Interventional Radiology: Opportunities

Before discussing the detailed scope of AI in improvement of IR, it is important to know the different procedures that an interventional radiologist deals with, in his clinical practice. With breakthroughs in technological innovation, the opportunities in IR continue to expand both in width and depth. IR procedures can be broadly divided into vascular and non-vascular interventions [13].

Vascular interventions may be aimed at:

- Improving the vessel lumen by balloon angioplasty, thrombectomy, stents, or stent-graft placements
- Decreasing the blood flow by embolization or endovascular ablation
- Implantation of devices, e.g., filters and transjugular intrahepatic portosystemic shunt (TIPS)
- Intravascular foreign body retrieval
- Transvascular biopsy

Important vascular conditions where IR plays an important role in management:

- Superior vena cava (SVC) syndrome
- Pulmonary embolism
- Pulmonary artery tumors, aneurysms, and pseudoaneurysms

- Aortic aneurysms
- Uterine fibroids
- Benign prostatic hyperplasia
- Mesenteric ischemia
- Gastrointestinal (GI) bleeding
- Solid organ (e.g., liver or spleen) injury
- GI neoplasms
- Visceral artery aneurysms and pseudoaneurysms
- Renal artery occlusive disease
- Renal neoplasms, e.g., angiomyoma
- Arteriovenous malformations (AVMs) and fistulas
- Pelvic congestion syndrome
- Hepatic vein obstruction/Budd-Chiari syndrome
- Venous thromboses and insufficiencies

Important non-vascular IR procedures include:

- Image-guided percutaneous biopsy of intra-abdominal solid organs
- Lung and mediastinal biopsy
- Diagnostic fluid aspiration or drainage procedures of intra-abdominal abscesses
- Thoracocentesis and empyema drainage
- Percutaneous gastrostomy
- Percutaneous gastrojejunostomy and gastrostomy tube conversions
- Stent placement for malignant GI/biliary strictures
- Percutaneous biliary drainage
- Percutaneous extraction of common bile duct (CBD) stones
- Gall bladder aspiration/ablation
- Percutaneous nephrostomy, lithotripsy, and nephrolithotomy
- Balloon dilatation of ureteric strictures
- Suprapubic cystostomy
- Ultrasound, MRI, or stereotactic-guided breast biopsy
- Breast lesion excision systems
- Percutaneous epidural and nerve root block
- Bipolar radiofrequency nucleoplasty
- Percutaneous ablation of bone tumors
- Percutaneous vertebroplasty and disc decompression
- Image-guided ablation of renal, lung, and liver tumors

The Ideal Interventional Radiology Suite

It is a good idea to understand how an ideal interventional radiology suite (henceforth referred to as the “IR suite”) looks like for a better understanding of the possibilities for innovation and integration of AI into the workflow. The IR suite is the actual procedural room and is a component of the broader “IR area” which also includes the adjacent control rooms, corridors, additional storage spaces, and picture archiving and communication system (PACS) workstation. The “periprocedural area” refers to the preparatory (pre-procedure) and recovery (post-procedure) patient areas. The IR area usually should maintain some basic recommended standards to optimize patient flow, efficiency, and procedural safety. The following is a depiction of an ideal IR area compliant with the recommendations by the Society of Interventional Radiology (SIR) [14].

The periprocedural area is in the vicinity of the IR suite which ensures maximum efficiency and workflow. It includes adequate space for privacy during discussions (e.g., for obtaining informed consent) and physical examination. Three to four preparatory and recovery rooms per IR suite with contingency plans to accommodate unanticipated urgent patient referrals should be adequate. Programs providing IR fellowship/residency training should also have adequate facilities and space for the education and training including access to computers. The periprocedural area must have adequate electrical, oxygen, suction, anesthesia, and emergency equipment and services essential for basic resuscitation. Access to advanced resuscitation equipment, medications and fluids, and nursing facilities is also essential. The scrubbing area with sinks is immediately outside the IR suite (similar to an operation theater).

SIR recommends 650 square feet for an IR suite which along with the IR area must be sufficiently big to accommodate the personnel and equipment required for a safe procedural environment and manage emergencies. For an IR/operating room hybrid suite, at least 800 square feet is recommended.

IR suite should have a permanent, mounted, C-arm fluoroscopy unit and also have access to an

ultrasound machine and a CT scanner. In low-volume setups, a portable C-arm unit may be used, if safe. In setups with a high load of CT-guided interventions, the IR suite should have a CT scanner. This improves patient access and workflow efficiency. Equipment for advanced cardiac life support and power injectors must be accessible. Contingency plans should be in place to address procedural complications, intraprocedural conversions, and all possible emergencies.

Apart from the main IR suite, space for controlling the imaging equipment and a dedicated image viewing, processing, analysis, and reporting area for the interventional radiologists should be in close proximity to the IR suite. PACS and EHRs should be readily accessible from the radiologists’ workspace [14, 15] (Fig. 3).

Scope of AI in Interventional Radiology

AI has the potential to complement the interventional radiologist at multiple points of time during the entire course of a procedure – right from the selection of a patient or candidate till the follow-up of a patient following discharge from the recovery room.

AI can help in IR in the following broad areas (each of which will be discussed elaborately in following subsections):

- Decision support
- Triaging of patients
- Prevention of error
- Periprocedural support
- Patient monitoring and procedural support
- Prognostication and outcome prediction
- Image acquisition and processing
- Residency and fellowship training

AI in IR: Decision Support

When a patient is referred to the interventional radiologist, the physician has a lot of decisions to make regarding the procedure which has the best possible outcomes for the patient. AI has a tremendous potential to help the interventionalist

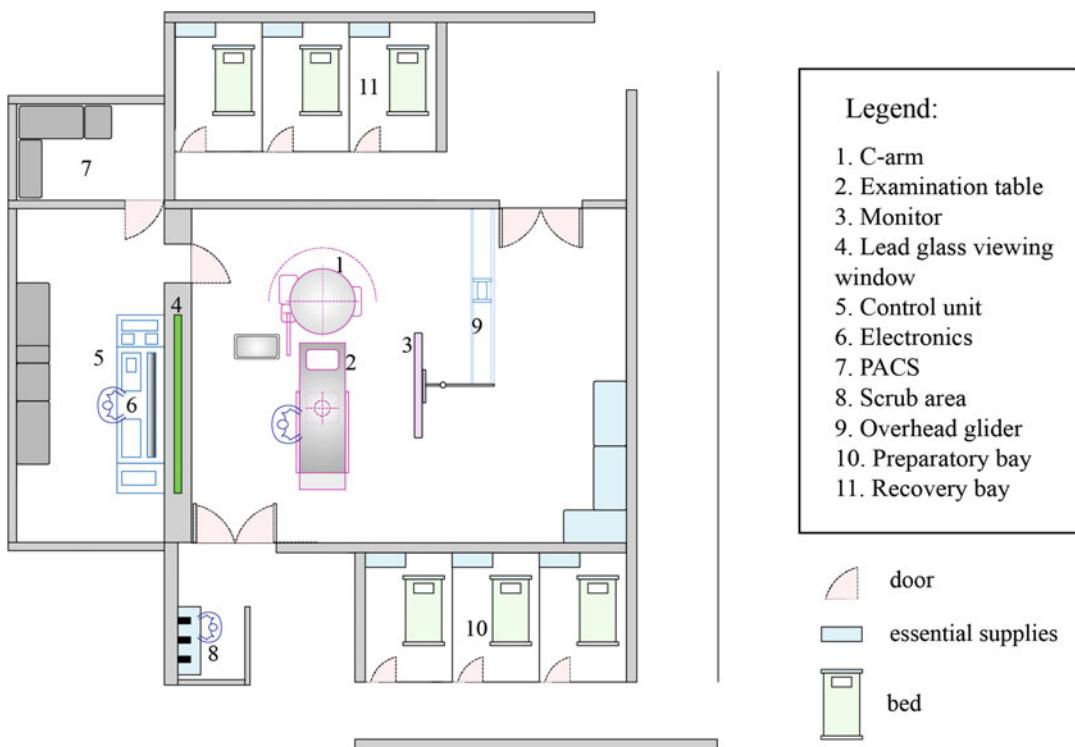

Fig. 3 Floor plan or architectural representation of an interventional radiology (IR) suite

in earlier diagnosis of diseases and also help in making treatment choices. Most of the available and widely used staging/grading systems which guide management of conditions like cancers do not provide personalized treatment choices [12]. AI-powered decision support tools can factor individual patient characteristics based on demographics and clinical and imaging profile and help in arriving at the best IR procedure (if it is at all required). This can significantly reduce treatment costs and also decrease unnecessary procedures which do not alter outcomes (e.g., life expectancy) significantly. An AI-integrated system can extract a patient's physical characteristics from prior scans and help the radiologist in choosing the equipment for a procedure, e.g., appropriate size of instruments like catheters, micro-puncture systems or needles, etc.

AI in IR: Triaging of Patients

AI can help in triaging of patients and help radiologists prioritize candidates in need for a particular interventional procedure (e.g., splenic artery

embolization in splenic injury), particularly in institutes with a high volume of procedures. Triaging of patients based on their radiographic images has already been shown to be successful and fairly accurate [16]. AI can help in analyzing the CT scans done in a trauma/emergency setup, detect suspected lesions/bleeds, and prioritize the scans in the radiologists' worklist. This can help in alerting the IR physician of an emergent procedure (e.g., embolization to stop a life-threatening bleed or for thrombectomy in a stroke patient) and help him modify the ongoing procedures and upcoming scheduled procedures to address the urgent case based on severity and clinical judgment.

AI in IR: Prevention of Errors

To err is human and making errors in medicine is inevitable. Today, we undoubtedly have a better understanding of medical error than we had before, but most organizations fail to respond to adverse events in a way that prevents the recurrence of such errors. Medical errors most likely

occur during routine procedures due to unanticipated patient complexity or system failures. While checklists are an effective way to prevent error, there are barriers to adoption of checklists in IR – lack of awareness, effective leadership, staff attitude, etc. A majority of errors in IR are preventable – ranging from ineffective procedure planning and communication error to equipment difficulties [17].

Incorporating AI into the workflow can automate mundane tasks like procedural planning and preprocedural checklisting (e.g., contrast allergy or previous adverse events from EHRs). In the future, AI-integrated tracking systems in the IR suite will be able to prevent errors of both commission (e.g., injection of wrong solutions) and omission (e.g., missed history of contrast allergy). Intelligent tracking systems can help identify missed foreign bodies and malpositioned/unsecured devices and prevent wrong site procedures. AI can also remind about periodic functionality checks of essential equipment [18].

AI in IR: Periprocedural Support

AI can give preprocedural support by automating procedural consent and curated history taking, tracking physical characteristics like weight, meals, and activity with the data being continuously fed into their EHRs. Automated analysis of all preprocedural data would provide a more personalized and precise risk stratification score which can play a significant role in the procedural planning and determine valuable predictors for post-procedural care and outcome.

Integration and analysis of periprocedural and intraprocedural data can further help in post-procedural discharge/transfer planning, prediction of complications, long-term outcome prediction, and curated follow-up appointment scheduling. Post transfer, post-procedural monitoring of vitals and other relevant data could continue to be integrated with EHRs to predict potential adverse events and set off an alarm. This will lead to achievement of truly personalized and patient-centered care [19].

AI in IR: Patient Monitoring and Procedural Support

Similar to surgeons, interventional radiologists usually make decisions through a three-step process that includes situational assessment, taking an action and reevaluation of the action's consequences [20]. AI could help the radiologist in better assessment of an intraprocedural situation (e.g., empowerment of the interventionalist with preoperative data and intraoperative monitoring of vitals), the types of actions that are taken (e.g., through decision support tools), and the process of reevaluating the impact of an action (e.g., through predictive analytics based on the real time vitals monitoring).

Particularly in IR procedures, AI-assisted analysis of intraprocedural imaging data, e.g., data generated from fluoroscopy, digital subtraction angiography (DSA), or CT has tremendous potential to guide the interventionalist more accurately for the next steps. For example, during CT-guided percutaneous drain insertion for an intra-abdominal abscess drainage, an intelligent AI-assisted instrument/hand tracking system can dictate how much more insertion of the catheter is required and in which direction, for the catheter tip to reach the particular region of interest inside the abscess for adequate drainage. Similar assistance can be provided for negotiating vessels during angiography by analysis of DSA images. This can lead to significant reduction in exposure of both the patient and the radiologist to harmful radiation.

In the future, AI will augment intraprocedural decision-making by the interventional radiologist based on real-time analysis of procedural progress that utilizes integrated data from EHRs, procedural video, vital signs, instrument/hand tracking, and electrosurgical energy usage. Monitoring of such intraprocedural data can facilitate real-time prediction and avoidance of significant adverse events (e.g., accidental exposure of staff or healthcare workers not wearing lead aprons by intelligent logic gates/switches which prevent exposure when any staff inside an IR suite is not wearing protective equipment) [21].

Another interesting application of AI would be in decreasing the documentation workload of the interventional radiologist by real-time update of procedure notes in the patient EHR either by voice-assisted intraprocedural dictations or by more intelligent tracking systems which can write structured procedural notes by tracking intraprocedural events. This would allow the IR physician to focus primarily on complex cognitive tasks and save a significant amount of time.

AI in IR: Prognostication and Outcome Prediction

AI has demonstrated fairly accurate results in the prognostication of diseases and prediction of post-intervention outcomes, e.g., mortality prediction in stroke and outcome prediction in arteriovenous malformations post-endovascular ablation [22]. Currently, multiple prognostic scoring systems for patient stratification are available for a single disease or condition. Clinicians are often unclear on which is most useful. Most of the systems do not factor in all patient characteristics and risk factors while predicting prognosis. AI, powered by big data, can extract useful information from patients' EHRs, identify key determinants, and help in creation of personalized and comprehensive prognostication systems. Traditional AI models in IR have shown promising results in predicting treatment responders from non-responders by preprocedural medical image analysis. These can help in the selection of the best suited IR procedure for a candidate.

AI in IR: Image Acquisition and Processing

Usually at the beginning of any IR procedure, once a baseline scan has been obtained (e.g., via DSA or CT), it is not always essential to have the same high quality/resolution of image for successive scans. Subsequent scans can be obtained at significantly lower radiation doses and optimized by AI-integrated processing systems, by

extracting key anatomical and imaging features from the prior scan. This leads to significant reduction in radiation exposure. Prior works in CT have also demonstrated the capabilities of AI in optimization of data acquisition processes by automating patient positioning and acquisition parameter settings. Post-data acquisition, AI-enabled optimization of image reconstruction, advanced reconstruction algorithms, and image denoising can help in improving image quality [23].

While most interventional procedures are done under ultrasound, fluoroscopy/DSA, and CT guidance, magnetic resonance imaging (MRI)-guided interventions like biopsies involving musculoskeletal system or breast, periradicular therapy and injections, and thermal therapies are also becoming common. Imaging sequences in interventional MRI are different from those used in diagnostic MRI to achieve faster imaging speed [24]. In the trade-off between image speed, signal-to-noise ratio, and resolution, AI can help in faster image acquisition by utilizing DL methods for reconstructing undersampled MRI data and generating high-resolution from low-resolution data [25].

AI in IR: Residency and Fellowship Training

Residency and fellowship training programs in IR are aimed at ensuring that their trainees are capable of proficiently performing interventional procedures which they may encounter in their career with a minimum prerequisite skill level necessary for successful patient outcomes. However, the case load and volume load of patients are different in different setups, and a resident during the tenure of his or her training and rotations may not get exposed to important interventional procedures. AI has a potential to support IR residency training in combination with augmented reality (AR) systems and provide trainees a platform for honing their procedural skills, especially in low-volume cases. Recent work in multiple surgical specialties has demonstrated the effectiveness

of simulation tools for procedural training. Patient-specific anatomic data which is currently obtained by AR systems from cross-sectional imaging by traditional image segmentation methods could be made easier and automated by ML models. Such simulation training can help in the improvement of skills of the next generation of interventional radiologists and indirectly improved health outcomes for the patients [12, 26].

Can AI Replace Diagnostic or Interventional Radiologists?

AI has a tremendous potential to boost the productivity of the interventional radiologist by helping them in various ways mentioned in the preceding subsections. In recent times, the belief that AI is going to replace the human radiologist altogether has gained traction. Such assumptions are due to the perception of radiology as a science where the physician is involved in the analysis of images and that advancement in AI can help build algorithms which could be more accurate and better than humans. AI will indeed replace many of the time-consuming works of radiologists, e.g., detection of rib fractures by scrolling through multiple CT sections and scanning all 24 ribs, thereby allowing radiologists to perform higher-level tasks which require cognitive skills.

Most AI algorithms in medical imaging look at very specific problems. However, a radiologist takes into account the clinical perspective by going through a patient's history and investigations and looks for a number of pathologies in the scan. Current AI models may be better in testing conditions and in detecting specific findings, but they are not yet capable of detecting all findings and integrating all information to provide curated differential diagnoses for a patient. Interventional radiologists also use their cognitive abilities, training, and experience to decide the best procedure based on these differentials. While, in the future, an AI system which works in conjunction with a highly integrated system with access and capability to extract information from standardized EHRs and PACS may be able to factor all available

information for a patient and provide a diagnosis, to assume that an AI-powered robot will be able to utilize clinical, laboratory, and radiological information of a patient to arrive at a diagnosis and subsequently select and perform an interventional procedure without the involvement of an interventional radiologist seems to be a far-fetched dream [27].

The tendency for humans to favor machine-generated decisions, ignoring contrary data or conflicting human decisions, also known as automation bias, can lead to significant errors when an operator is overly dependent on an AI system for taking decisions. While AI promises to improve health care in resource-poor setups, automation bias risks may be significant in such populations because there is no local expert/radiologist to effectively veto the decisions taken by the AI system.

AI performs relatively well with a lot of complex tasks, but it is important to note that it is not human. Accountability is a major issue with AI products, and it is essential that its results and actions be monitored by a human expert. Transparency, fairness, and equality are not, in particular, concepts which a machine understands. Human operators are responsible for these insights who must be trained enough to anticipate how changing AI models may perform incorrectly or misused and protect against an unethical outcome before one may occur [28].

Thus, even with massive technological advancements, multiple key issues and ethical dilemmas need to be addressed before AI models are permitted to take even minor decisions which can affect or alter patient management. An independent AI system which can perform all the functionalities of a human diagnostic or interventional radiologist without their oversight does not seem to be a possibility in the foreseeable future. How much ever advanced an AI system might become, they need to be operated by an expert who can oversee, detect, and prevent adverse outcomes. The decision-making and legal accountability still lie and will continue to lie with the expert operator, i.e., the radiologist [29].

Modern training programs should teach radiologists the advantages, limitations, and clinical use

of AI-based systems. Without radiology expertise, an accurate outcome and successful translation of AI systems from research to clinical practice will not be possible. Thus, the way forward for AI developers is to work together with the radiologists (both diagnostic and interventional) to achieve successful clinical translation of their products and complement them in improving patient outcomes rather than being over-ambitious about replacing them.

Abstract

Automated deep learning is a subset of machine learning. It aims to automate the machine learning workflow allowing those with limited or no coding expertise to create deep learning algorithms. It is available on a number of commercial platforms. A number of limitations still exist for automated deep learning that clinicians must be aware of. Datasets must still be curated and labelled and data governance obstacles must be navigated. Additionally, the challenges of interpretability, generalizability, and bias still exist. Automated deep learning for medical imaging has demonstrated promising results within the clinical literature when compared against bespoke machine learning models. It has generated considerable excitement as it offers the potential to democratize artificial intelligence in healthcare. In the following chapter, we will explore the role of automated deep learning within the rapidly progressing field of clinical artificial intelligence. We will examine its challenges and limitations, the principles and process of use, and what we consider the future directions of automated deep learning to be.

Keywords

Introduction

They are a dream of researchers but perhaps a nightmare for highly skilled computer programmers: artificially intelligent machines that can build other artificially intelligent machines. New York Times, 2017 [1]

Deep learning has emerged as a form of machine learning anticipated to transform a variety of industries, with major breakthroughs in technology, government, science, and healthcare [2–4]. However, along with great promise comes an array of challenges. These are particularly relevant to the clinical research field, where lack of resources and specialized technical expertise can represent significant barriers. In 2017, the New York Times spotlighted the emerging area of automated deep learning, described as “part of a much larger effort to bring the latest and greatest A.I. techniques to a wider collection of companies and software developers” [1].

The need to increase accessibility of deep learning is well recognized, and initial efforts have included open sourcing of libraries (e.g., TensorFlow, PyTorch), the use of techniques such as transfer learning, and automation of parts of the machine learning pipeline [5]. However, these approaches still require computer expertise. The arrival of automated deep learning has been a major step forward in opening deep learning to a greater range of users. Automated deep learning is a subset of machine learning and aims to automate the machine learning workflow, enabling those with limited or no coding experience to create deep learning algorithms (Fig. 1). It is available on a number of commercial platforms including

MACHINE LEARNING: Dotted Lines represent parts of the process that can be automated (AutoML)

Amazon Rekognition Custom Labels (Amazon), Apple Create ML (Apple), Clarifai Train (Clarifai), Google Cloud AutoML Vision (Google), MedicMind Deep Learning Training Platform (MedicMind), and Microsoft Azure Custom Vision (Microsoft). Automated deep learning has generated considerable excitement across multiple industries. In medicine, it offers the potential of empowering clinical researchers, enabling them to much more easily explore new novel clinical applications of AI and develop new research tools.

Herein, we will investigate the role of automated deep learning within the greater evolving medical machine learning landscape. We will describe an overview of the challenges and limitations, the technical principles, and the process for users. Finally, we will discuss what we envisage the future directions of automated deep learning to be.

AlexNet in the ImageNet Challenge in 2012, major technology companies such as Google and Facebook began recruiting researchers with expertise in deep learning [6] significantly reducing the availability of deep learning experts for clinical academic research. While the basic concepts of deep learning are not difficult to grasp, expertise in its development and application requires significant mathematical knowledge beyond that normally attained by computer science and engineering graduates. As a result, the competition for graduates is now intense: deep learning specialists with little or no industry experience can expect considerable financial remuneration for their knowledge [7]. The advent of automated deep learning platforms will significantly address this, although awareness of best practice for machine learning, as well as medical statistics, will still be essential.

Challenges of Deep Learning for Clinical Researchers

Prior to the introduction of automated deep learning platforms, a number of barriers existed to the development of deep learning systems in medicine.

Highly Specialized Technical Expertise

Until recently, sophisticated technical expertise was a fundamental requirement for deep learning research in healthcare. Following the triumph of

Compute Resources

Access to significant computing resources, in particular graphical processing units (GPUs), is also a prerequisite for state-of-the-art deep learning. However, most large clinical datasets reside in hospitals where, aside from a few major centers, there is little if any access to GPUs. Since 2012, the amount of computing resources used for major advances in AI has grown by more than 300,000 times. This equates to doubling of requirements every 3.5 months – by comparison Moore’s Law (relating to the number of transistors on an integrated circuit) has an 18-month doubling period.

It is estimated that each of these major advances employs hardware that costs in the single digit millions of US dollars to purchase. AlphaGo Zero and AlphaZero from DeepMind are the most visible public examples of this trend, but many other applications at this scale are now algorithmically possible. More recently, OpenAI has released a series of language models called Generative Pre-trained Transformers (GPTs). These models have drawn criticism for a number of reasons [8, 9], one of which is the sheer size of the models. The authors report that GPT-3 has a capacity of 175 billion parameters [10]. As progress with GPUs reaches a ceiling, there is also likely to be a move toward AI-specific integrated circuits, such as tensor-processing units (TPUs) (designed by Google) and intelligence processing units (IPUs) (designed by the UK company, Graphcore). Thus, it is already clear that it will be difficult for small research groups, working alone in hospital and university settings, to accommodate these huge financial costs and rapidly evolving landscape. Automated deep learning platforms are typically hosted on major public cloud infrastructure. These systems offer the potential for flexible, scalable access to compute resources, as well as providing the potential for unlimited storage. As these systems become more widespread, the cost of credits on these systems is also likely to reduce.

Large, Well-Curated Datasets

The third major challenge for AI-enabled healthcare is the requirement of deep learning systems for large, well-curated datasets. The advent of automated deep learning addresses this, at least in part, by facilitating training of models within a hospital setting, where the best clinical datasets reside. However, the requirement for meticulous labelling of such dataset for supervised learning remains a challenge. The various automated deep learning platforms have begun to address this. The recent release of services, such as Google Cloud AutoML Vision Human Labeling, Clarifai Scribe Label, and Amazon Automate Data Labeling, has offered a promising solution to

these issues. AutoML Vision Human Labeling will label datasets once provided with comprehensive labelling guidelines [11]. Amazon Automate Data Labeling [12] uses a combination of human workers and active learning to automatically label datasets. These services are still in their early stages, and so further work will be required to determine their clinical applicability. The authors have not yet had the opportunity to explore the usability of these features but acknowledge the potential they offer to further increase accessibility of deep learning to smaller research groups without the manpower required to label large datasets.

Data Protection and Privacy

Other barriers to data use include strict data governance and hospital ethics committees which must give appropriate approvals. For many projects, the data must also be de-identified through either anonymization or pseudonymization. Anonymous information is defined as information which does not relate to an identified or identifiable natural person or to personal data rendered anonymous in such a manner that the data subject is no longer identifiable [13, 14]. Pseudonymization is defined within the GDPR as the processing of personal data such that it can no longer be attributed to a specific data subject without the use of additional information, such as a key [14]. Yet with “de-identified” or pseudonymized data, there remains the risk of re-identification, and this must be taken into account with as much risk mitigated as possible [15]. Given these challenges, the number of publicly available datasets has played a major role in health data research. However, the widespread use of a small number of datasets may result in models which do not generalize well to specific populations, diseases, or outcomes [16]. Fortunately, there are a number of cloud-based tools that address the challenge of de-identification of data such as Google Cloud Healthcare application programming interface (API), Amazon Comprehend Medical API, and Microsoft Sensitive Data Discovery and De-Id Tool. An API, essentially,

allows multiple applications to interact with each other. It is likely that these features will play a significant role in the future of automated deep learning clinical research, thus reducing the dependency on publicly available datasets.

Principles

Automated machine learning describes methods for dataset management, algorithm selection, and optimization of model hyperparameters. Quanming et al. describe these methods as machine learning *tools*, accurately conveying the residual requirement for computer expertise [5]. Examples of such applications within the machine learning industry include Auto-sklearn, H2O AutoML, Auto-keras, and Auto-Weka [17]. In this chapter, we focus more specifically on automated deep learning platforms, a subset of this field where limited if any coding experience is required (i.e., the platforms typically offer drag-and-drop graphical user interfaces for model development). These platforms are typically based on a recent advance in machine learning, termed neural architecture search.

Neural architecture search aims to make the model design process easier and more accessible. Described by Google CEO, Sundar Pichai, as “neural nets to design neural nets,” [18] neural architecture has received a lot of scientific and media attention. Neural architecture search is typically achieved using one of two methods: [1] reinforcement learning algorithms and [2] evolutionary algorithms. The former forms the basis of the commercially available automated deep learning platforms. Zoph and Le described a reinforcement learning approach to neural architecture search [19]. This seminal work is based on the observation that the structure and connectivity of an artificial neural network can be typically specified by a variable-length string (i.e., a linear sequence of characters). It is therefore possible to use a “controller” neural network to generate such a string and then to train the neural network specified by the string – the “child” network – on the real data (Fig. 2). The resulting network will ultimately provide an accuracy measure obtained on a validation set. This accuracy signal can then be used to update the controller network. As a result, the successive iterations of the controller network will give higher probabilities to model architectures that

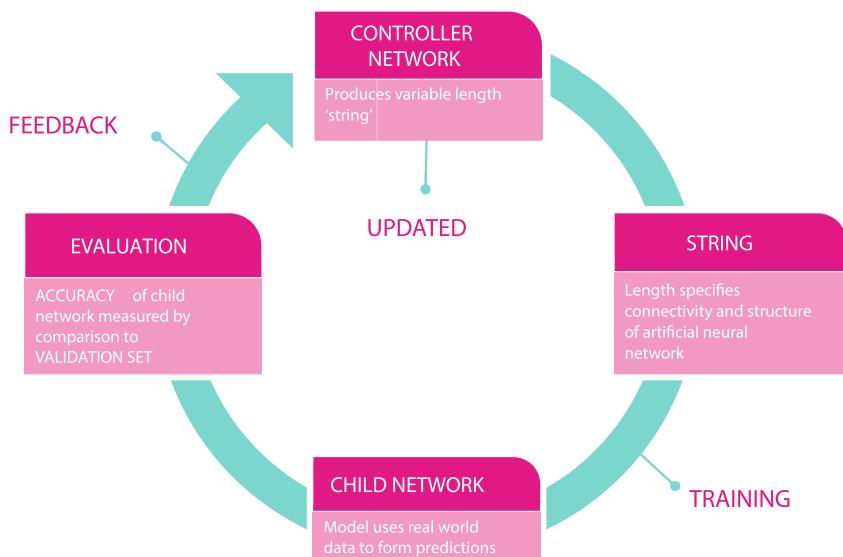

Fig. 2 Illustration of the “reinforcement learning algorithms”

receive high accuracies – i.e., it will learn to improve its search over time. In their initial 2017 work, Zoph and Le apply this approach to two heavily benchmarked deep learning datasets: [1] the CIFAR-10 image recognition dataset and [2] the Penn Treebank language modelling dataset. In both cases, they show that their approach can generate models that achieve accuracies on a par with the state-of-the-art handcrafted models. In April 2018, they extended this work to achieve similar performance on large, more challenging datasets (e.g., ImageNet) – a novel approach that they term NASNet [20].

Although neural architecture search has undeniably resulted in significant advances, it is still largely dependent on expert design and restrictive search spaces. Evolutionary algorithms offer an alternative approach to automating the discovery of deep learning algorithms. Based on the process of biological evolution, these algorithms use mathematics as the building blocks [21]. The approach typically starts with an initial population of one thousand simple models and continues through a number of steps. Each model is a trained network. Initially, a pair of networks are randomly selected to carry out a specific machine learning task. The network that performs more accurately is selected as a *parent*, while the other network is *killed*, analogous to natural selection. This *parent* network is mutated to create a *child* network which is trained, evaluated, and then submitted back into the population. The mutation applied to the *parent* network is selected at random from a prespecified set of actions chosen to be similar to those a human expert may use when designing a network [22, 23]. With the continuation of this process, the population evolves. The practice of selecting the *fitter* of the two models is described as “tournament selection” [24] or non-aging evolution. Alternatively, Real et al. propose the process of aging evolution whereby at each step, the older of the two networks is killed. This avoids the potential pitfall of models reaching high accuracy by chance and instead forces the architecture to re-train each time it is inherited [22].

Initial Work Utilizing Automated Deep Learning in Medicine

In 2019, we reported our initial experiences using automated deep learning for medical imaging applications [25]. Using five publicly available, open-source datasets, members of our research group with no coding expertise were able to develop medical image classification models with comparable performance to state-of-the-art bespoke deep learning models. We further expanded on this work to closely review and compare a number of the commercially available cloud-based platforms using four medical imaging datasets to create image classification algorithms. In this study, we found a difference in performance when comparing both the different platforms and comparing the various models against different datasets, with the best outcomes detected using the OCT image modality. It was also noted that certain platforms were unable to process large imaging datasets [26]. Kim et al. explored the use of AutoML Vision (Google) to classify pachychoroid disease using a dataset of 783 ultrawide-field (UWF) indocyanine green angiography (ICGA) images [27]. They constructed two models using the platform. Using the original dataset, Model 1 was trained to distinguish between pachychoroid eyes and non-pachychoroid eyes. The UWF ICGA images of the left eyes were then horizontally flipped to obtain image orientation of the right eye. Model 2 was trained with the flipped images in order to increase the diagnostic performance. On evaluation, it was reported that Model 2 outperformed physicians in terms of precision, accuracy, and kappa score. Of note, the authors comment that the “platform’s self-evaluation yielded better accuracy and recall when compared to the performance of the deployed model applied on the test sets.” This emphasizes the importance of robust validation and external evaluation. Zeng et al. examine the use of AutoML Vision for the identification of invasive ductal carcinoma using a public dataset of 278,124 labeled histopathology images [28]. As the original dataset was heavily imbalanced, augmentation was performed by “rotating a large portion of the positive image

samples” resulting in a total number of 378,215 labeled images. The AutoML Vision model demonstrated an average accuracy of 91.6% as measured by area under precision-recall curve. The authors also reported that their model showed superior performance compared to the results of bespoke models published in earlier studies. In the near future, it may be possible for a clinician to develop a highly effective model that can be implemented into clinical practice in a manner that is applicable to the specific population without reliance on an artificial intelligence expert.

Automated Deep Learning Process

Although specific features vary across platforms, there is a common process behind the creation of an automated deep learning model. Most platforms (Amazon, Apple, Clarifai, Google, and Microsoft) allow for creation of image classification, segmentation, and object detection models. Some platforms support classification models with both multi- and single-label approaches. For each platform, the graphical user interface (GUI) contains three main components – data upload, data visualization, and model evaluation. We will now describe the process behind each part in detail as it relates to image classification models (Fig. 3).

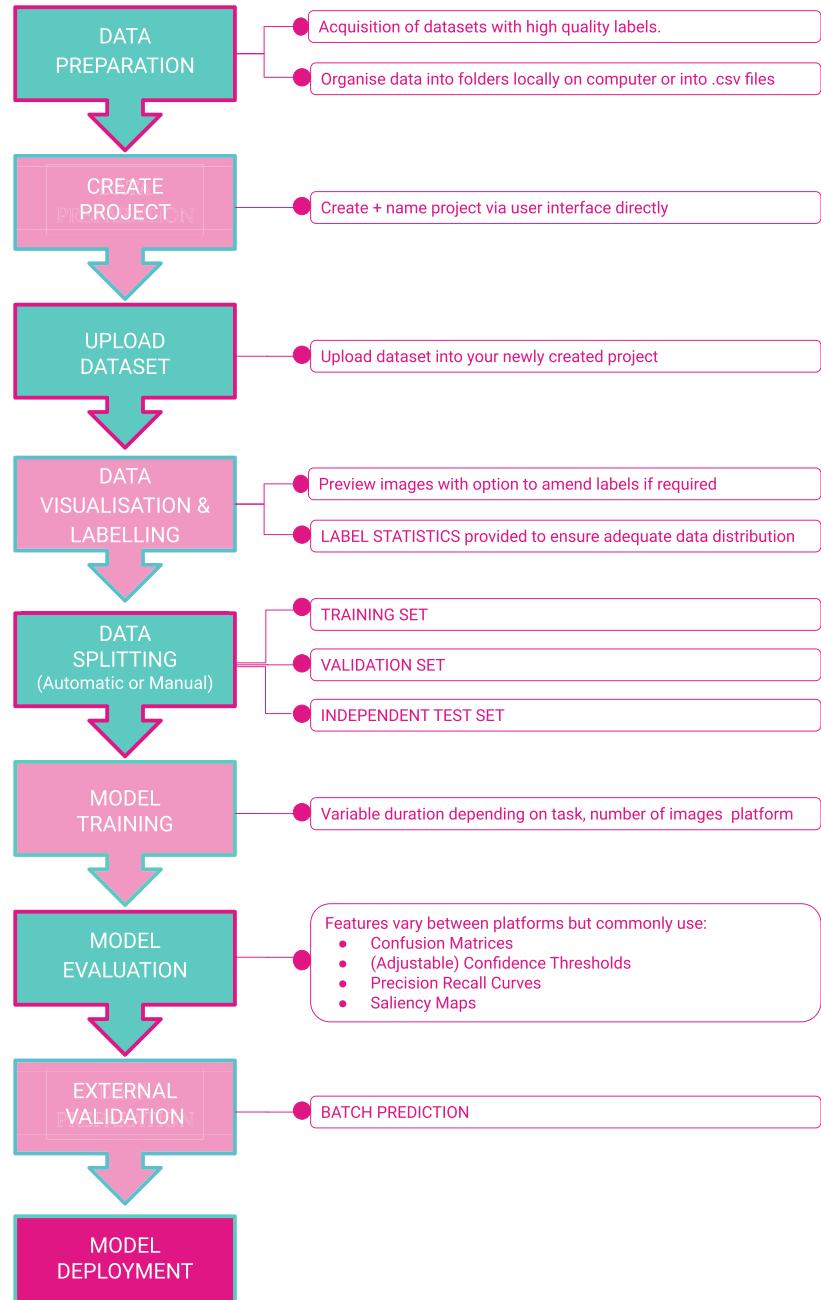

Data preparation, similar to bespoke deep learning projects, must be carried out initially through the acquisition of datasets with high quality labels, navigation of data governance, and organization of the dataset into either folders locally on the computer or with spreadsheet .csv files. The project can be created and named via the user interface directly. The dataset can then be uploaded to the new project. The majority of platforms require for the dataset to be pre-arranged into labelled folders with labels assigned accordingly once uploaded (Amazon, Clarifai, MedicMind, Microsoft). Google allows for data to be converted locally into .csv files and uploaded onto a cloud storage bucket. The images can then be annotated either via the .csv files containing labels or through the user interface. MedicMind allows for data to be manipulated

locally via .csv files, although it does not offer management through a cloud bucket. The Amazon platform can also be linked to a bucket with images labelled accordingly. As Apple does not use cloud computing, labels are assigned based on local folders divided by label.

Once the dataset is uploaded, the images can be previewed with the option of amending any labels. Label statistics are provided to ensure adequate distribution. This is an important process as imbalanced data can be problematic for model training. Google requires a minimum of ten images per label. Amazon Rekognition allows bounding boxes to be assigned, with multiple labels per image. The datasets are divided into three groups – a training set, a tuning set, and an independent test set. Usually 60–80% of the images are allocated to a training set and thus used to set the neural network model parameters. Ten to twenty percent of the images will be allocated to a validation set which will be used to optimize the parameters of the models. Finally, 10–20% of cases will be set aside in independent test sets – this will be used to assess how well the best model from the validation set will generalize to real-world data. Of note, images should be separated at the patient level, to ensure that data acquired from the same patient will not be present in both training and test sets. The training data should be as close as possible to the data on which predictions are to be made. At times, the optimal model parameters used in the validation stage can result in biased metrics. The test dataset provides the training process with an unbiased assessment of the quality of the model. Common issues that arise can include imbalanced data, bad splits, and data leakage [3, 29, 30]. The leakage of data from training to validation sets can result in falsely increased performance. This is something clinicians and researchers must be cognizant of when creating models. The datasets can be split automatically, or alternatively, Amazon, Apple, Google, and MedicMind allow for custom division. Furthermore, Apple uniquely offers the option to perform data augmentation, including cropping, flipping, rotation, and the addition of noise and blur.

Following completion of data preparation and upload, the model is ready to be trained.

Fig. 3 Illustration of the automated deep learning process

The goal of the training process is to enhance the model parameters, so that when a test image is input, the error rate remains at a minimum [31]. The majority of platforms do not have computer system requirements as they can train and evaluate the model using cloud hosted GPUs. Apple runs locally limiting the user to

their available computational resources. Google and Microsoft allow the number of hours for training to be selected, although the model will automatically stop training once it stops improving. Once the model has completed training, detailed statistics for the model will be available.

The results can be reviewed in the evaluation page. Evaluation features vary between platforms. Confusion matrices are generated by Apple, Clarifai, Google, and MedicMind, demonstrating true positives and false negatives. Threshold is provided by Amazon, although it cannot be adjusted. Clarifai, Google, and Microsoft allow the confidence threshold for prediction to be moved to generate new precision and recalls for that confidence. This is useful when evaluating varying operating points for different use cases. For example, if a clinician is to develop a screening test requiring high sensitivity, the confidence threshold will be low in order to create a high sensitivity but result in lower positive predictive value and specificity. Precision recall curves are provided by Amazon, Clarifai, and Google. Clarifai additionally provides ROC curves for each label. Saliency maps are produced by MedicMind which are designed to highlight the components of the input images that are important to the algorithm prediction. They are usually presented as a heatmap with the hotter areas corresponding to the part of the image contributing the greatest impact to the final prediction [32]. MedicMind also allows for a .csv file to be downloaded of the final classification performance. Only Google and Microsoft allow for the final model to be downloaded. Finally, external validation is facilitated only by Google and MedicMind platforms. Batch prediction allows for large amounts of data to be used to ultimately assess the model. Google also allows for images to be uploaded directly onto the graphical user interface for prediction, but this is limited to ten images, making batch prediction a crucial process [26].

Limitations of Automated Deep Learning

Despite the promise of automated deep learning, many of the limitations of bespoke deep learning models also apply. In addition, this is an emerging area so there are a number of platform-specific limitations also.

General Limitations

Explainability

“The strength of machine learning, but also one of its vulnerabilities, is the ability of models to discern patterns in historical data that humans cannot find” [3]. This is often referred to as the “black box” in artificial intelligence. Even if the underlying mathematical principles of a model is understood, it is difficult and often impossible to determine the inner workings to ascertain how and why it made a certain decision. This lack of explainability is intensified by automated deep learning platforms, where the underlying model architecture is opaque.

At present, in order for a new pharmaceutical drug or medical device to be approved for patient use, it must undergo rigorous testing. This must also be the case when it comes to implementing automated deep learning models to ensure the safe development, use, and monitoring of systems. The term “AI chasm” has been used to describe the fact that accuracy does not necessarily represent clinical efficacy [33]. Healthcare is one of the predominant fields in which explainability is essential, given the potential for devastating consequences from prediction errors. The ability to interpret the algorithm could also enlighten researchers to patterns not previously detectable by humans and lead the way toward new scientific advances [30].

Generalizability and Bias

Although automated deep learning has somewhat alleviated the requirement of advanced computer expertise, it cannot provide a “one-size-fits-all” model. Clinicians must be aware of the dangers of overfitting. Between training sites, there can be differences in equipment, coding definitions and, electronic health record systems. There are also minor differences between the various commercially available automated deep learning platforms in terms of training and evaluation. Furthermore, the issue of bias must be addressed. In some instances, the dataset on which the model is trained can reflect societal inequalities, including bias toward those who contributed the most data [29]. Model bias occurs when the model is

selected to best represent the majority, potentially resulting in underperformance on underrepresented groups. Model variance occurs due to inadequate data from minorities. Discriminatory bias was demonstrated by Esteva et al. where the deep learning algorithm developed for the detection of skin cancer could classify skin lesions with similar accuracy to that of board-certified dermatologists in fair-skinned patients but showed underperformance on images in skin of color. This is largely based on the fact that the model was trained on open datasets of predominantly fair-skinned patients emphasizing the critical need for a diverse dataset that accurately represents the population it is intended for [34]. It is possible that the increased accessibility that comes with automated deep learning platforms may further exacerbate this problem. Clinicians must be acutely aware of this issue when developing algorithms and question whether they are appropriate for their specific population.

Automated Deep Learning-Specific Limitations

In our previous work, assessing six commercially available automated deep learning platforms, we noted a difference in performance between our automated deep learning models and bespoke models published in the literature using the same datasets. We postulate the reasons behind this to be “automated deep learning’s lack of task-specific image augmentation pre-processing, inability to specify task-specific base models for transfer learning approaches, and the inherent performance variations resulting from bespoke model construction and tuning” [26]. Even for those with some technical background, the automated deep learning platforms have limitations. There is no flexibility in choosing between models to train – AutoML Vision uses a mobile neural architecture search with no other available option. Furthermore, the user is frequently not provided with information on which model architecture is being utilized. This is an obvious barrier to

clinical implementation. As discussed, similar basic tasks are implemented on all platforms, e.g., image classification, object detection, and segmentation. However, other potentially useful model designs are frequently not available. For example, regression models are not supported by Google AutoML Vision or Amazon Rekognition for predicting continuous variables. Semantic segmentation was previously only possible with Amazon Rekognition but has recently become available with Google’s Unified AI Platform. Additionally, it is not possible to specify task-specific base models for transfer learning approaches on automated deep learning platforms at present. Once the model has been trained, there are differences in the evaluation and result metrics provided by various platforms. Saliency maps are provided by MedicMind; however, these maps should be interpreted cautiously as it has been shown in some studies that they can lack sensitivity to the model and the insights obtained from them may be subjective [32, 35]. Confusion matrices are frequently not provided, which are needed to calculate other clinically relevant metrics such as specificity.

External validation is an essential step when training an automated deep learning model and one that must be carried out prior to implementation. The ability to perform batch predictions for the purpose of external validation is only available with Google and MedicMind platforms. Models that are unable to be externally validated cannot be implemented without assessing their performance on local populations. It is not possible to export Google AutoML Vision cloud models at present, although it is possible to export edge models for mobile devices. Even with comprehensive external validation, implementation will require an ongoing performance monitoring process. As automated deep learning becomes accessible to a broader range of clinicians and researchers, it is essential that the principles discussed above are adhered to in order to maintain responsible and safe AI that is of benefit to the population it is being used on.

Future Directions of Automated Deep Learning

Use Cases of Automated Deep Learning

Undoubtedly, there are significant barriers to overcome before an automated deep learning model can be implemented into the direct clinical care pathway. Nonetheless, it is possible for such models to considerably benefit patients indirectly, in ways that do not require extensive regulatory approval. This is particularly relevant in the field of clinical research. In order to create algorithms in healthcare, close collaboration between clinicians and data scientists is required. Automated deep learning looks set to drastically alter the clinical research landscape affording clinicians the independence to create their own models. Automated deep learning models developed as part of a research toolkit could liberate clinicians from the time-consuming tasks associated with research. For example, a model could be trained to distinguish between the left and right eyes from a folder of unlabeled retinal images rapidly leading to a cleaned and usable dataset. Moreover, a model could be trained on a smaller dataset to then label large unlabeled datasets, saving the clinician considerable time and effort. Automated deep learning models could aid the clinical researcher by allowing for a model specifically representative of the target population to be designed. Alternatively, models could be created within an institution to assist with image quality assurance and improvement. An automated deep learning model created to monitor the quality of retinal photographs could be deployed to run continuously and detect any decreases in image quality. This could help alert hospital management to specific problems, allowing for rapid identification and resolution. Additionally, an automated deep learning model that could automatically analyze certain imaging modalities to search for specific features would greatly enhance identification of patients suitable for clinical trials. This would

help clinical researchers to rapidly identify a patient cohort and reduce the time taken to commencing the trial.

Packaging and Deployment of These Models

The efficient packaging and deployment of these models is a crucial step in the pathway toward real-world implementation of automated deep learning. Some platforms allow models to be served through the cloud via APIs. Despite the previously mentioned advantages of cloud computing, remaining issues include latency, scalability, and privacy. These issues particularly become problematic when applied to clinical uses, which depend on quick transfer of data, robust privacy features, and high bandwidth. A possible option is to deploy the automated deep learning algorithm via a local edge model [36]. By keeping data local, the issues of decreased bandwidth, greater latency, privacy, and reliability concerns are potentially avoided [37]. Moreover, edge models do not require continuous Internet for the model to run, making them particularly advantageous in under-resourced areas. Bellemo et al. describe how artificial intelligence can directly enhance a diabetic retinopathy screening program in Zambia, where there is a limited number of ophthalmologists for a large population. Nonetheless, they report the affordability of the model as a limitation, particularly with poor Internet infrastructure [38]. A similarly effective model, created using automated deep learning and deployed on an edge model, could greatly reduce costs and allow for scarce resources to be redistributed. The recent COVID-19 pandemic has further emphasized the crucial role automated deep learning algorithms could play using edge computing. Deployment of real-time and contactless screening tools could aid with rapid diagnosis and the detection of clinical deterioration, allowing for limited resources to be directed appropriately [39]. With the approaching widespread availability of 5G technology, greater bandwidth and lower latency are predicted. The

new 5G base stations are expected to “benefit network science and efficient management by providing cost-effective and efficient systems to support massive data collection” [40]. Additionally, the computational power of smartphones is increasing exponentially – a phone with 512GB of RAM today has seven million times more than that of the Apollo 11 guidance computer [41]. All of these reasons emphasize the role edge-based computing is likely to play in the future of automated deep learning.

Conclusion

Automated deep learning may serve to democratize AI in healthcare. At present, machine learning is challenging due to limited resources. This is particularly relevant to clinicians and clinical researchers. Automated deep learning allows those without coding experience to create their own models. The true potential of this emerging field is yet to be seen as researchers take advantage of the ever-expanding amount of clinical data and begin to create their own models for their own use cases to enable fundamental improvements in patients’ lives.

Digitalization and artificial intelligence (AI) have reached orthopedics and traumatology. AI improves diagnostic accuracy in knee osteoarthritis according to the latest clinical guidelines and facilitates the (radiological) monitoring of the progression of various bone and joint diseases. AI makes it possible to detect early radiological signs and allows conclusions with respect

to progression of the disease and prognosis. By automating the report generation, patient throughput can be increased and the radiologist's workload decreased. AI also reduces the impact of inter-rater variability in the assessment of radiographic X-ray morphologies and creates more standardized outcome measurements.

Artificial intelligence · Imaging digital data · Machine learning · Deep learning · Neural networks · Muscular skeletal disease

Introduction

Digitalization is a phenomenon that has accompanied us for decades and has spread to many processes in our social life, society, and economy and thus also in medicine. The process of digitalization was already so far advanced that only a few years ago action had to be taken to further develop and finalize the whole concept. With the COVID pandemic, digital processes have anyway permeated our world and largely taken over. This is also the case in the diagnosis of X-ray images in orthopedics/traumatology, where rapid developments of digital image processing and analysis are on the way. However, the diagnosis of X-ray images is still largely carried out manually with narrative image descriptions, which are very subjectively impacted. This is also reflected in the high inter- and intraindividual variability of the findings, and thus, especially in the assessment of diseases such as osteoarthritis, a low accuracy and comparability is present. Despite the fact that we hold five megabytes of image data in our hands in digital X-ray procedures with DICOM formats, these are subjectively assessed on the screen in a quantifying and qualifying manner – actually in the same way as X-ray images were held up to the light and analyzed a hundred years ago. Artificial intelligence (AI) are computer programs – so-called algorithms – extracting and recognizing characteristics and patterns of typical changes caused by

diseases from the digital data material and subsequently learning to make diagnosis on the basis of objective data analysis. This process is called “machine learning” whereby data material and information about the criteria must be uploaded. Deep learning includes the use of deep neuronal networks. In those algorithms, the data learns itself their own characteristics and analyzes and reinforces them in forward and backward loops, so the data itself learns which patterns it contains. This significantly surpasses our limited ability to assimilate, since all digital data enters here and not just limited criteria that we include in the manual diagnosis. The result becomes more objective, more accurate, and almost 100% reproducible. Furthermore, structural analyses can be performed, which cannot be detected with the naked eye – not even with a magnifying glass. As an example, we can see constellations in the sky, connecting particularly visible stars to form a symbolic image. When we look through a high-power telescope, so many stars become visible that we cannot longer identify those constellations, although they are of course still there, but we actually have too much information to coin out the symbolic figure. Therefore, we need digital methods that help us to understand this flood of information and also to interpret this data in order to get a much more objective result, since much more data contribute to the result. AI uses this digital data, learns itself what characteristics and patterns it contains, and then gives this information back to us.

Machine/Deep Learning

Machine learning is a field of computer science and a component of artificial intelligence. Computer programs, which are based on machine learning, can find solutions for new and/or unknown problems by means of algorithms independently. Different types of algorithms are distinguished:

- Supervised learning: Here algorithms are defined by specific examples. Thereby it is

tried to find the solution for further similar problems by the generalization of a solution.

- Unsupervised learning: Here algorithms are processed with arbitrary examples. The goal is to recognize a structure within the dataset.
- Transduction: This method tries to find new solutions based on specific cases.
- Learning to learn: In this method, algorithms draw derivations from experience already gained.
- Developmental learning: Here, a software learns almost independently through exchange with human “teachers” [1].

Deep learning is similar to machine learning but goes beyond it. It uses neural networks. The goal of deep learning is to process and analyze large amounts of data. By using neural networks, already existing information can be interpreted and further processed. This allows learned information to be merged with new content and used for future tasks [1] (Fig. 1).

In order for neural networks to recognize a disease on an X-ray image, all characteristics must be presented beforehand, if possible, so that the network can later evaluate new X-ray images correctly in practice. Therefore, all different disease stages, patient morphologies, and image qualities

must ideally be present in the training data. Artificially, additional variance can be generated by “augmentation.” To train, a reward system is used that employs numerical optimization. The more the findings are available in numbers and categories, the easier this optimization can be done. The more consistent the training data, the more accurate the training on less data.

Example 1 Two radiologists have different opinions on the same dataset of an image. If we train on this data, the network will reflect the difference in opinion and will perform poorly. A solution would be to have a third radiologist arbitrate and harmonize the disagreements.

Example 2 A radiologist at Stanford started 10 years ago to annotate every X-ray with 1 or 0 if there is an anomaly or not. From the 40,000 consistently found images, extremely accurate anomaly detection networks could now be trained. Conclusion of this case: The more variance there is in the radiological appearance or annotations, the more data is needed.

In recent years, a portfolio of AI-driven decision support tools for musculoskeletal (MSK) disorders has been developed to help radiologists and

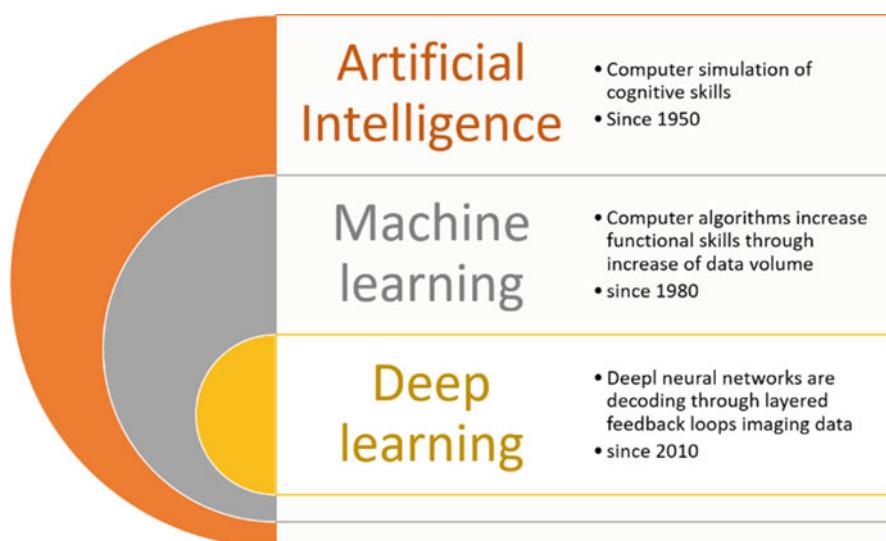

Fig. 1 Deep learning is a special form of machine learning and part of artificial intelligence (AI)

orthopedists quickly and accurately assess skeletal radiographs. Some of these products are already CE certified, such as modules for bone age, knee, whole-leg, and hip assessment, covering the majority of radiologists' and orthopedists' skeletal X-ray workload. Calculations take less than a minute. Usually, the processing is started automatically, and the results are then immediately attached to the original study as a separate series. In the following, the impact of AI in imaging is described and some examples of the application are explained.

Musculoskeletal (MSK) Diseases: A Rapidly Rising Global Burden

The global aging population is currently at the peak in human history. Understanding the healthy, aging population and reducing the socioeconomic impact of age-related diseases are a key research priority for industrialized and developing countries, along with a better mechanistic understanding of the physiology of aging. MSK conditions were the leading cause of disability in 4 of the 6 WHO regions in 2017, affecting approx. 1.3 billion people globally and more so when taking into account additional MSK burden from long-term sequelae of fractures and dislocations.

Musculoskeletal conditions can be classified by more than 150 diagnoses that include, but are not limited to, a single region of muscles, joints, bones, and surrounding tissues such as tendons and ligaments. This includes sudden and short-onset conditions, such as fractures strains and sprains, all the way to slowly progressing lifelong problems with chronic pain and disabilities, all of which significantly reduce the quality of life.

One out of five people (20%) in the EU-28 suffered from a chronic back or neck disorder in 2019.

The prevalence and impact of MSK conditions is predicted to rise as the global population ages.

Needless to say that this scenario is not accepted by the scientific community and a number of recent advances have led to many significant changes in treatment decisions and health pathways. However, even though in some cases

these new approaches have enabled people to regain function and mobility, factual cures for the most common disorders remain elusive.

Nonetheless, the clinical goal of preventing disability is attainable.

Among the most common MSK disorders, osteoarthritis (OA) presents (the most common type of arthritis) itself as affecting 237 million people globally, expanding at a rate of 33% within the last 10 years. It is the fastest-growing cause of disability worldwide. In Europe and the United States alone, more than 70 million people have some kind of physician-diagnosed form of OA.

The US Centers for Disease Control (CDC) presented numbers from 2013 to 2015 that showed an estimated 54.4 million US adults (22.7%) had been physician-diagnosed to have some form of arthritis, rheumatoid arthritis, gout, lupus, or fibromyalgia.

Furthermore, there is an estimated projection of 78 million US adults to suffer from physician-diagnosed arthritis, by 2040.

MSK conditions affect people across the life course in all regions of the world. While the prevalence of MSK disorders increases with age, younger people are also affected, often during their peak income-earning years, accounting for the greatest proportion of lost productivity in the workplace.

In Germany, for example, MSK disorders accounted for €17.2 billion of production loss in 2016 and €30.4 billion in loss of gross value added. This represents 0.5% and 1.0% of Germany's gross domestic product (GDP), respectively. (European Risk Observatory Report—Work-related musculoskeletal disorders: prevalence, costs and demographics in the EU.)

The US CDC estimates that back in 2013, the total national arthritis-attributable (direct and indirect) medical care costs and earnings losses among adults with arthritis were \$303.5 billion or 1% of the 2013 US GDP. OA is also among the most expensive conditions to treat when joint replacement surgery and elaborate post-surgery rehabilitation are required (2015: more than 600,000 end-stage surgeries annually). In fact, OA was the second most costly health condition treated at US hospitals in 2013. In

that year, it accounted for €16.5 billion, or 4.3%, of the combined costs for all hospitalizations. Future projections show that the (indirect and direct) costs for OA are rapidly rising to become a one of the leading burdens of healthcare systems.

In the United States, more than 53 million people either already have osteoporosis (OP) or are at high risk due to low bone mass (<https://www.bones.nih.gov/health-info/bone/osteoporosis/conditions-behaviors/osteoporosis-arthritis#fyi>). Osteoporosis is known as a silent disease because it can progress undetected for many years without symptoms until a fracture occurs. OP is diagnosed by a bone mineral density test using an often challenged radiological method called DXA (dual energy absorption) which provides different classifications based on standardized scores (T-/Z-score, Singh Score, FRAX Score, etc.). The main concern with this method is the low sensitivity in detecting patients at fracture risk. Digital X-rays provide a cost-effective alternative or CT imaging for a high image-resolution assessment of (e.g.) vertebral fractures.

Further MSK-related traumatic incidents include injuries such as cartilage tears or bone fractures due to accidents or excessive stress. For children and adults younger than age 45, trauma accounts for an estimated 79,000 deaths each year, and in the United States, trauma is the single most important cause of potential years of life lost for persons under age 65. Trauma-related injuries account for more than 400 million medical imaging procedures every year, including mostly X-rays and CT (for bone-related examinations) as well as MRI (for cartilage-related examinations).

Bringing Disease Management into the Digital Age

The key for a successful disease management is an accurate identification of relevant imaging biomarkers (bone/cartilage anomalies, biomechanical parameters, clinical scores, etc.) and to monitor the progression using established (and novel) imaging biomarkers in order to adjust the treatment regime.

Currently, the existing paradigm is purely reactive. Disease diagnostics are based on manual assessments, often dependent on personal experience, time allocation, and medical specialty. Result documentations are often based on verbal descriptions rather than standardized disease report findings. Moreover, as a result of the growing number of cases, physicians are faced with an ever-increasing number of low-risk, high-volume MSK image data to analyze.

This results in a combination of missing critical disease parameters (thus discharging a patient too early or not applying the optimum treatment pathway), while at the same time there is not enough time/resources available to provide the required diligence in image reading and result documentation. The consequences are drastic: a rising number of patients suffering from inadequate treatments and healthcare systems overwhelmed by avoidable procedures.

Musculoskeletal Radiology

Musculoskeletal (MSK) radiology is a subspecialty of diagnostic radiology focused on imaging of the bones and joints, as well as the spine and soft tissues. MSK imaging is used to gain a better understanding of human anatomy and to evaluate MSK diseases using diagnostic methods and criteria developed from that understanding.

Within the context of AI, MSK radiology can be broadly classified into 2D and 3D imaging modalities, with each presenting unique challenges and opportunities.

Recent advances in AI have arisen in large part due to breakthroughs in deep learning, a branch of machine learning which uses multilayered models, or networks or models, to transform raw input data into predictions of some higher-level set of features. Deep learning has shown particular promise in the area of computer vision, including image segmentation, object detection and recognition, and scene understanding to name a few.

These computer vision problems are almost exclusively based on 2D color digital photographs taken from the real, physical world. The pixel

representation of digital photos is usually in the RGB space, meaning that there are three color channels (red, green, and blue), and each pixel holds a value between 0 and 255 for each channel, for a total of over 16 million possible colors at any given pixel. This numerical range as well as the spacing of pixels is dictated by the imaging detector used to capture a digital image.

With the success of deep learning on photographic image data, many researchers have adapted models to fit the paradigm of 2D medical imaging. In MSK radiology, this includes computed radiography (CR), a strictly 2D modality, as well as CT and MRI, which are volumetric but nevertheless rely on stacks of 2D images.

CR images are composed of pixels whose values represent the amount of X-ray radiation that hit the detector at a given point for a given exposure time. Unlike digital photographs, CR image pixels hold a single intensity value, although the bit depth of intensities is often higher, with systems producing 12-bit and sometimes 16-bit images. The additional bit depth leads a larger range of values at each pixel and thus higher contrast.

Because CR images are acquired by shooting an X-ray beam at a patient and capturing the signal after it passes through the patient on a flat detector array, the resulting image is a 2D projection of the 3D objects. In addition, since X-rays are attenuated differently depending on the tissue types, with bone being the most “radiopaque,” followed by muscle, low-density muscle, and adipose tissue, CR images are ideally suited for assessment of MSK anatomy, among other uses.

CT and MRI follow a similar principle to CR but represent 3D *in situ* measurements of tissue and produce stacks of images that form a volume. The volumes are composed of voxels, short for “volumetric pixel,” which represent a physical volumetric location within the patient. The intensity of a CT or MRI voxel represents some characteristic of a signal detected at that given position within the patient. Unlike CR imaging, CT and MRI data are not projections, which map directly to a detector array, but rather are reconstructions of signals which pass through the body and are captured by detectors surrounding the patient.

As CT imaging is based on X-ray radiation, the resulting images have similar intensity and contrast characteristics as CR images, with an emphasis on bone and muscle. MRI relies not on radiation but rather on the excitation and relaxation of protons within water molecules in living tissues when in the presence of fluctuating magnetic fields. MRI can be tuned to produce different intensities and contrasts for different tissue types and generally features soft tissue contrast rather than bony structures.

Both CT and MRI are advanced imaging techniques which have the benefits of producing 3D representations of 3D objects, thereby removing the uncertainty in localizing findings and anatomical features in CR projection images. However, CR imaging produces higher-resolution images compared to CT or MRI. A typical CR image has a pixel size of between 0.05 mm and 0.25 mm, whereas CT images have resolutions which typically range from 0.5 mm to 1.0 mm depending on the field of view. For MRI, in-plane voxel resolutions of 1 mm to 2 mm are common. In addition, CT and especially MRI are both susceptible to noise and motion artifacts resulting from the physics involved in each modality as well as the time required to obtain an image.

All of this is to say that, while 3D imaging such as CT and MRI provides clinical advantages owing to the 3D volumetric imaging, their complexity, costs, and requirements result in higher variability of outputs and less overall images acquired in comparison with CR. In terms of AI suitability, the ubiquitousness and ease of CR imaging, along with standardization of imaging protocols and the high contrast features inherent in X-rays, make X-rays the best analog to digital photos when considering applications of deep learning in medical imaging.

AI in Computed Radiographs

As discussed above, CR imaging is well suited to the implementation of AI based on the technical characteristics of X-ray imaging and the capabilities of ANNs. Nevertheless, the motivation for applying AI to MSK radiographs goes beyond

technical compatibility and encompasses the needs of clinicians, patients, and the public. Those needs are best summarized in terms of efficiency, accuracy, standardization, and overall patient well-being. Development of AI-based tools on MSK radiographs should be undertaken with these needs in mind in order to ensure successful adoption by stakeholders.

Implementing AI for MSK applications on CR radiographs can be understood as the automation of specific tasks which are normally performed by radiologists, radiography technologists, and various referring physicians. Those tasks range in scope from image quality control and measurement of anatomical features to detection anomalies like fractures, lesions, and tumors to reporting of more high-level assessments like bone age or osteoarthritis grade. Common to all of these tasks is the requirement for large amounts of annotated example images in order to train and validate AI models designed to automate them to the point of clinical acceptance. The next sections discuss considerations for building and validating AI models, followed by a deeper look at specific problems in MSK radiology where AI automation can have an impact on stakeholder needs.

Building and Validating AI Models for MSK Radiographs

One of the main advantages of focusing on MSK X-rays for building AI models is the widespread, standardized use of CR, which has led to the availability of millions of images for training and testing AI models. Nevertheless, a number of steps should be taken in order to obtain data which is appropriate for the desired task, and to ensure patient privacy and safety is maintained. First and foremost, ethical approval from any and all institutional review boards (IRBs) for the use of retrospective imaging should be sought and obtained prior to carrying out model training or validation. In particular, patient-informed consent must be obtained if necessary, or alternatively, a waiver of the requirement for informed consent should be obtained.

In addition, IRB approval should be contingent on the protection of patient privacy, which will usually entail the pseudonymization or anonymization of imaging data prior to release to the investigator(s). Special attention should be paid to ensuring that protected health information (PHI) is removed from images and that, where required, personal identifiable information (PII) is also removed. Again, any and all relevant regulations should be followed (e.g., HIPPA in the United States, GDPR in Europe).

Pseudonymization refers to the blinding of PHI and/or PII from the investigators, but maintaining the ability to link back to that information. The investigators would receive data that is coded with an identifier which, when given to a designated representative at the data source (e.g., a study nurse or PACS administrator), would allow them to reidentify the patient and associate them with the image data. Pseudonymization allows for investigators to carry out studies with knowledge of clinically relevant information, without being aware of the identity of study subjects.

Anonymization is a means of completely removing the association between imaging data and the patient identity. Anonymization is the safest method of sharing data with an investigator from the standpoint of patient privacy, but it presents limitations in terms of traceability of image data. Training data used to train AI models can be anonymized as long as the requirement for patient traceability is not applicable. For example, training data might be obtained from Hospital A to build a model for predicting the presence of rib fractures from thoracic X-rays. The image would be fully anonymized and sent to the investigators, who would then obtain annotations of the images externally and train their models.

Where traceability becomes a concern is when the model is to be validated on an independent set of data, also known as standalone performance testing, which is generally required for regulatory clearance. If the standalone performance data is also sourced from Hospital A, then the anonymization of the training data may make it impossible to ensure that image sets obtained for standalone testing do not contain images that were part of the model training.

The ultimate goal of building AI models for MSK X-rays is usually to automate a task related to the visual evaluation of an image by a trained expert. A successful AI model must therefore account for the variability of image data in terms of the patient population, imaging parameters, anatomical features, and disease manifestations. The most effective way to achieve robustness in an AI model is to provide training data that encompasses the variability expected in the real world and to provide lots of it. Deep learning thrives on more of everything: data, variety, and annotations.

When training AI models, a number of augmentation techniques can also be used on the data at hand to improve robustness. These techniques include applying various filters and transformations to the images which help simulate image quality issues that are typically found in real-world images.

Advances in synthetic data generation have also shown promise for AI in other application domains and have also been used for generating realistic X-ray images for rare conditions. These developments are particularly interesting for AI in medical imaging applications due to the burdens of acquiring patient data and the challenges in building robust datasets. Ultimately, the clinical acceptance of AI models for any medical imaging automation task will rely largely on standalone performance testing on data not involved in the training of the models. For that reason, the inclusion of synthetic data in model training may prove to be effective, so long as the performance testing targets can be achieved.

Acquisition of diverse and plentiful training data will only get you part of the way to building an AI model with high performance. Almost as important is defining the clinically meaningful measurements, assessments, or other outputs which need to be automated. The automated evaluation of osteoarthritis (OA) in standing PA fixed-flexion knee X-rays offers insights into how expert annotations can help shape the performance of the AI models.

Knee OA is assessed using a number of radiographic indicators, some of which are anatomical measurements, in this case joint space width

(JSW), and some of which are based on consensus grading scales, namely, Kellgren-Lawrence grading (KL). JSW measurement involves identifying the minimum distance between the distal femur and proximal tibia, with the aim of estimating the knee cartilage thickness. Given that cartilage is not visible in CR images and that the image itself is a 2D projection of the knee, the JSW measurement itself is at best an estimation of a physical distance.

In this example, one strategy for building an AI model would be to acquire expert annotations from radiologists and orthopedic surgeons who are tasked with drawing their estimation of JSW in the medial and lateral compartments of both knees (four measurements in total per bilateral X-ray). The model could then be trained using the images as inputs and the JSW measurements as outputs.

However, given that the goal is to accurately measure a distance between two surfaces, another strategy would be to segment the individual bones, as well as the joint space, and then measure the distance in between.

Quality Control

MSK imaging targets specific areas of the skeleton with the aim of making diagnostic evaluations based on anatomical, morphological, or contrast assessment. The first step in making accurate diagnoses is to assess the quality of the imaging. Patient positioning is critical to ensuring a valid diagnostic result, and radiologists are often faced with the task of screening X-rays for positioning or other image acquisition errors.

With the implementation of AI, automation of quality control in MSK CR images could be accomplished at the point of imaging, when the patient is still available and corrected images could be acquired. For example, AP standing pelvic X-rays require specific positioning of the lower extremities and hips. Errors in positioning can lead the radiologist or orthopedic surgeon to order a new X-ray, which costs time and effort for the clinician and patient.

As we know, deep learning requires large amounts of annotated image data for training models to be robust. In the pelvic X-ray quality

control example, training data should encompass a range of potential positioning errors from a variety of patient groups. No amount of training data will be able to completely reproduce the scope of the problem, but the robustness of the solution will benefit from the diversity of pelvic representations in the training examples.

Anomaly Detection

Clinically relevant anomalous findings in MSK X-ray include fractures, tumors, lesions, and bone marrow edemas, to name a few. Anomaly detection is perhaps the most challenging task for AI because they may occur anywhere within the skeletal tissue and to varying degrees. In contrast, anatomy-specific findings such as hip dysplasia, knee osteoarthritis, or scoliosis can be more readily modeled using AI given a suitable amount and variety of training images.

Beyond the technical challenges of anomaly detection are the clinical implications for erroneous findings. False-positive detection of a bone tumor, for example, could lead to unnecessary follow-ups and highly invasive diagnostic procedures which affect the patient's well-being and cost the healthcare system time and resources.

False negative, or missed findings, pose even greater risks to both patients and practitioners. A missed spinal fracture diagnosis in an osteopenic elderly patient, or a missed tumor in a pediatric patient, could lead to diminished quality of life and untimely death, along with the legal ramifications for the clinicians and institutions, although we fully acknowledge that the risk to patients is the first concern in designing any diagnostic tool.

IB Lab KOALA: Assessment of the Gonarthrosis Stage

Knee osteoarthritis is a painful and immobilizing joint disease that can lead to joint replacement. Knee osteoarthritis has a lifetime risk of up to 45% [2], with risk determined based on two main risk factors: aging and obesity [2, 3]. Knee osteoarthritis affects over 200 million patients worldwide

[4], resulting in approximately 100 million knee radiographs in the EU alone in 2020. Consistent tracking of radiographic changes over time could aid in early detection and prevention of disease progression. Due to the semiquantitative nature of the score, the individual diagnosis in the Kellgren-Lawrence score shows very low inter- and intraindividual agreement and is thus unfavorable for standardized treatment decisions, as well as prerequisites for efficacy studies of osteoarthritis therapies. Radiologists read an average of ten knee radiographs per day, which corresponds to approximately 40 min of daily workload.

Deep learning algorithms were trained on over 35,000 individual knee radiographs containing data from a longitudinal study of centers in the United States. Each image was evaluated by board-certified radiologists using the OARSI criteria and the Kellgren-Lawrence consensus scales.

The AI-driven KOALA software evaluates the stage of osteoarthritis according to the Kellgren & Lawrence grading system, is validated on over 10,000 knees, and is available as a CE-marked or an FDA cleared version. KOALA also provides accurate and automated measurements of minimum joint space width along with assessment of severity of joint space narrowing, presence of osteophytes and sclerosis based on OARSI criteria. Results are summarized in visual output reports, attached to the original radiograph and automatically stored in the PACS system. KOALA facilitates monitoring of disease progression by allowing comparison of radiographic disease parameters over time. The results must be confirmed or rejected by the assessing physician and is thus an assistance system for improving the efficiency and standardization of radiographs in knee osteoarthritis (Fig. 2).

IB Lab PANDA: Determination of Pediatric Bone Age

PANDA is used to assess bone age for predicting height in children. PANDA uses an ensemble of decision models to determine bone age based on the Greulich and Pyle atlas. The standard

Fig. 2 KOALA knee osteoarthritis report and analysis results displayed on the screen

derivation for a given chronological age is determined by rounding down to the nearest age in the Brush table for the corresponding sex [5].

PANDA was trained on over 12,000 hand radiographs from two institutions in the United States (Lucile Packard Children's Hospital of Stanford University and Children's Hospital Colorado) [6]. Validation was performed using the RSNA 2017 Bone Age Challenge test set. Each image in this test set was reviewed by three radiologists trained in pediatrics. IB Lab's diagnostic support tool, PANDA, uses deep learning technology to report bone age based on the Greulich and Pyle scale, saving time by presenting results within 5 s. PANDA's automated measurement of bone age is accurate to the mean absolute deviation of 4.3 months as measured on the test set from [7]. PANDA provides accurate data for decision-making in growth-associated disorders, and standardized measurements and reporting schemes facilitate monitoring of treatment progress. Manual estimation by comparing digital radiographs to reference images in the Greulich and Pyle atlas is tedious and has a high degree of variability between readers. PANDA provides a rapid automated method for estimating bone age and

monitoring growth and development in children (Fig. 3).

IB Lab HIPPO: Measurement of the Hip and Pelvis

HIPPO is used for measuring hip positioning and pelvic morphology by measuring the most common angles and distances on an X-ray of the pelvis. The HIPPO module is intended for adults between 18 and 90 years of age with hip pain, suspected congenital disease, femoral-acetabular impingement, or osteoarthritis of the hip.

HIPPO was developed using deep learning algorithms trained on over 4000 individual radiographs of the pelvis and hip. It reproducibly detects and localizes anatomically relevant landmarks on the hip and pelvis (e.g., tear figure) automatically. The AI follows the established radiological workflow: measurement of anatomical distances and angles, detection of disease morphologies, and standardized classification and reporting. There is a consensus assessment of each radiograph: Each detection step is performed by an ensemble of three

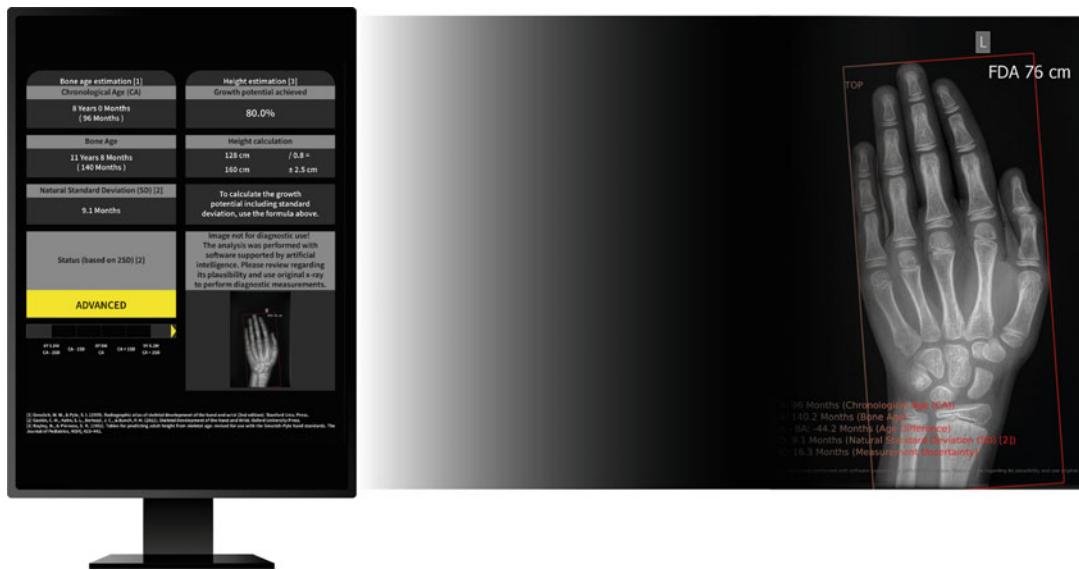

Fig. 3 PANDA bone age report and analysis results visible on the screen

AI models that vote for the best result and increased precision.

Using hip angle measurements, physicians can take appropriate action and therapy for early signs of hip disease, including arthritis and dysplasia. HIPPO performs objective, standardized measurements of key hip angles on digital radiographs. These include CCD and LCE angles, as well as Tönnis angle (acetabular index), Sharp's angle, and femoral extrusion index. In bilateral standing AP hip radiographs, HIPPO assists the medical expert in detecting the presence or absence of leg length discrepancies.

Femoroacetabular impingement and hip dysplasia are the two main causes of secondary hip degeneration, leading to hip replacement in the final stage. Hip arthroplasty is projected to increase from 1.8 million per year in 2015 to 2.8 million per year in 2050 in OECD countries [8], resulting in an increased workload for radiologists. Reading pelvis radiographs requires thorough knowledge of 3D pelvic morphology to correctly interpret the 2D projection; this is difficult, subjective, and prone to error. Unstructured reporting further leads to inconsistencies in the diagnostic process. Radiologists read an average of ten hip radiographs

per day, representing approximately 40 min of daily workload [9] (Fig. 4).

IB Lab LAMA: Measurement of the Whole Leg

LAMA is used to measure leg length discrepancies and detect deformities of the knee axes and can be used in the decision to perform an osteotomy.

LAMA is a fully automated radiological imaging software designed to help medical professionals to measure leg axis geometry. LAMA helps detect knee axis alignment deformities by performing the following measurements: mechanical Lateral Proximal Femoral Angle (mLPFA), mechanical Lateral Distal Femoral Angle (mLDFA), mechanical Medial Proximal Tibial Angle (mMPTA), mechanical Lateral Distal Tibial Angle (mLDTA), Mechanical Axis Deviation (MAD), Hip Knee Angle (HKA), and Anatomic Mechanical Angle (AMA) in standing AP radiographs of the whole leg. LAMA helps identify leg length discrepancies by providing the following measurements: femur, tibia, and full leg length, as

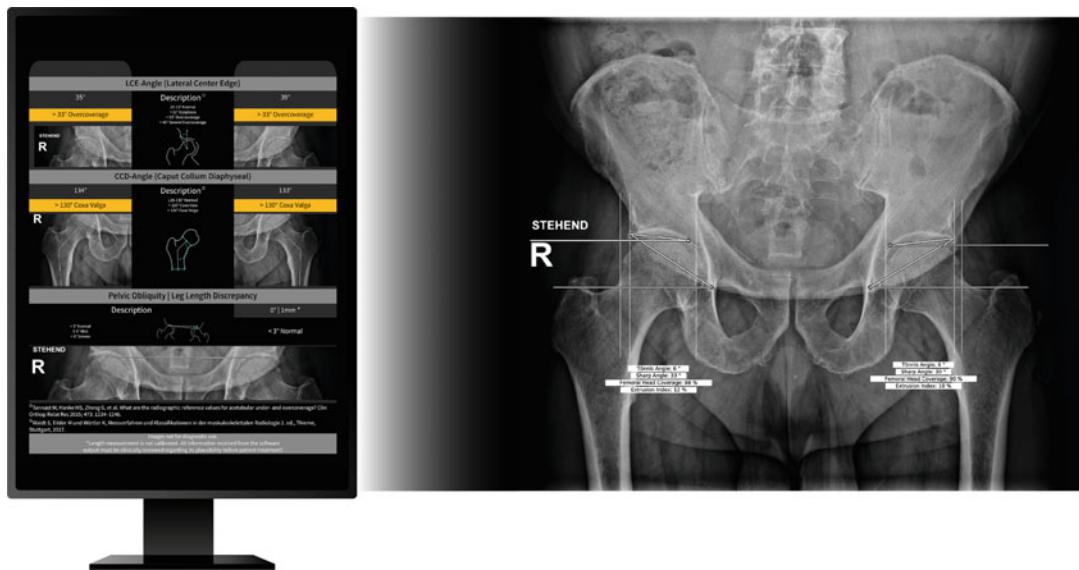

Fig. 4 HIPPO hip/pelvis report and analysis results visible on the screen

well as the difference between right and left legs on bilateral images. Lower limb leg or length discrepancies are common deformities that affect most adults and children; LAMA increases workflow efficiency by saving reading and reporting time.

Lower extremity leg or length discrepancies are common deformities affecting up to 70% of the adult and pediatric population [10]. When undetected or inaccurately measured, patients suffer functional and biomechanical limitations as well as cosmetic impairment. Even minor deviations can lead to imbalances and unilateral pain throughout the body and trigger passive structural and degenerative changes in the hip, spine, knee, and muscles. Accurate, reliable measurements of lower extremity geometry require expert training and specialized software in established protocols. Standardization through reproducible AI that automatically measures at the expert level can help avoid errors and train junior doctors. The diagnostic support tool LAMA uses deep learning technology to automatically and accurately measure leg geometry to evaluate lower extremity deformities. LAMA helps detect genu varum/valgum by measuring mechanical axis deviation (MAD) and detect leg length discrepancies by comparing the right and left legs on bilateral

images. AI facilitates monitoring of disease progression by facilitating comparison of radiological disease parameters over time (Fig. 5).

AI Disrupts Status Quo of Radiology Reporting

Status quo: nonstructured, manual workflows

Currently, the existing workflows for diagnostic and reporting of disease findings are non-structured and manual. Disease symptoms are often recognized at stages either too late to apply the appropriate treatment (e.g., OA), or the diagnostic results are based on nonstandardized radiological parameters (e.g., for pre-/postsurgery assessments). The agreement rate in terms of disease classification among physicians can be as low as 30%. We aim to change this by providing a continuous workflow to enhance the diagnostic and reporting workflow with standardized and accurate disease findings.

We change managements: augmenting the workflow with more precise and novel imaging biomarkers for new treatments and proactive intervention.

We disrupt the status quo by empowering physicians and scientists with powerful tools to

Fig. 5 Whole-leg report and analysis results visible on the screen

assess, track, and predict the disease. Our software offers an augmentation and standardization of the highly subjective (and time-consuming) assessment process of 2D/3D imaging in MSK radiology. The MSK platform analyzes data in near real time, whereas physicians need minutes to look through and assess and document the status of a scan. For this purpose, we build upon our existing know-how in image analysis and interpretation. In our case, the application of deep learning is recognition of MSK-relevant scoring and measuring tasks in radiological images. We enrich the findings with new bone health imaging biomarkers, such as insights into the bone micro architecture. Therefore, our objective is the detection and digital documentation of clinically relevant features in MSK imaging data beyond what can be performed by human readers in the course of a regular working time.

Take-Home Message: Artificial Intelligence (AI) in Musculoskeletal Radiology

- AI relies on deep learning to automatically detect and localize anatomically relevant landmarks at the hip, knee, and ankle.

- AI improves the diagnostic accuracy of knee osteoarthritis according to the latest clinical guidelines.
- AI facilitates (radiological) monitoring of the progression of various bone diseases such as osteoarthritis of the knee.
- AI enables early radiological signs to be detected and allows conclusions to be drawn about (possible) prognosis.
- AI increases patient throughput by automating the report generation process.
- AI reduces the impact of inter-rater variability in radiographic morphology assessment.

Abstract

Medical imaging and diagnostics have benefited from recent advances in machine learning in general and deep learning in particular. There are a large number of studies that report significant performance in a variety of medical image analysis tasks. At the same time, advances in time series analysis of electronic health records and physiological signals from a variety of sources (including clinical and nonclinical

wearable sensors) have enabled efficient clinical pipelines and diagnostic performance. While there are a large number of studies that report such advances and use cases, there is a certain level of resistance to clinical adaptability of such methods. We attribute one of the major reasons for this to be the black-box nature of such machine learning and data-driven models. While clinical decision-making, for example, using radiology, relies not only on radiographic information but also on clinical expertise (that could rely on clinical history of a patient as well as demographic information), such informed decision makes the backbone of clinical practice. Hence, machine learning should adapt to making such informed decisions for wider

S. M. Anwar (✉)

Engineering and Technology, Taxila, Pakistan

adaptability and finding more practical use cases. We argue that explainable methods, where a machine learning-based model provides supporting information for their decisions making them understandable, will be more representative of what is required in clinical practice. In turn, such methods would augment the current medical imaging and diagnosis pipeline and hence allow adaptation of artificial intelligence in clinical workflows. This would transform the healthcare industry with far-reaching benefits for both clinical practitioners and patients enabling precise and personalized medicine.

Introduction

In recent years, we have witnessed an explosive growth of applications utilizing artificial intelligence (AI) to solve a wide array of technological problems. This wave of recent success for AI-based methods is driven by the advancements in both hardware and software platforms. Thereby, AI and machine learning (ML) are adapted as technology of choice in areas which were not considered apt for such advancements a few years back. Among applications are included areas such as cybersecurity, social media, medical industry, and industry 4.0 transformation. The success of AI is fuelled by the availability of more compute power, large-scale datasets, and optimized computing libraries. In particular for medical industry, the revolution is just around the corner as we see more and more clinical tasks being affected by AI algorithms. A driving force has been the widespread digitization, resulting in the availability of big data. We now have hospitals having large-scale electronic health records storing patient information, radiographs, lab exams, and all sorts of information. A machine

learning algorithm will take these numbers as variables and attempts to learn a model that can predict patterns within the data.

There are certain challenges in this field: i) the amount of data for particular scenarios which could be limited, ii) the quality of the labels assigned to data, and iii) the ability of clinical experts to understand what the machine learning algorithm is predicting. While large-scale digitization in clinical settings means that big data is available, privacy and security concerns do not allow this data to be freely used and hence introduce certain boundaries. One of the reasons for these security concerns arises from the fact that it is not exactly clear how machine learning models are going to use this data. The amount of research coming out in this field and the level of interest shown by industry to roll out ML-enabled products for clinical pipelines are a clear indication of the fact that clinical practice in the twenty-first-century is going to change drastically. Herein, we present an overview of explainable artificial intelligence (XAI) which is believed to solve many problems associated with the adoption of AI in clinical pipelines. Since it is a developing field, we aim to identify the terminologies used and discuss how XAI is important in medical imaging and diagnosis. We highlight some of the methods that are being successfully used and also comment on the future direction this field could take. Hence a comprehensive overview of existing methods and taxonomies is presented.

Medical Imaging in Clinical Diagnosis

Medical imaging is a technique used for noninvasively looking inside the human body. This is used for both diagnosis and treatment planning. Moreover, medical imaging aids in early detection of a clinical conditions. There are different modalities used in the field of medical imaging with a wide variety of clinical applications. The use of imaging in clinical diagnosis and intervention planning has been prevalent for some time now. However, the use of automated image analysis techniques in recent years has resulted in an increase in the importance and significance of imaging in clinical

diagnostics. In addition, these imaging methods allow advances in medical research and have resulted in discovery of new knowledge and understanding of working of various body organs. Moreover, the progression of certain medical conditions is now better understood due to studies involving medical images acquired during different stages of the disease [1]. Hence, we can safely conclude that medical imaging has benefited the field of diagnosis, prognosis, and clinical research.

Most commonly used radiographic imaging techniques include X-rays, magnetic resonance imaging (MRI), computed tomography (CT), positron-emission tomography (PET), ultrasound, and mammography. Among these modalities, X-rays have been widely used for a long time due to their large-scale availability and lower cost. In terms of safety, there are certain concerns with X-ray-based imaging modalities (including CT). This is where MRI has been largely successful in terms of both safety and image quality. Recent MR scanners are versatile in terms of the body organs and the level of contrast (for both hard and soft tissues) and hence result in capturing a major stake in radiographs currently generated. Similarly, ultrasound generates images using sound waves and hence is considered safe. Ultrasounds are used for diagnosis of a variety clinical conditions in situations including vascular diseases and pediatrics. Some areas of medical image analysis have seen far better advances with human-level performance, such as in areas related to lung diseases [2] and lesion detection in mammograms [3]. Although the predictive performance of these methods is significant, the clinical community still demands further investigation before these are adopted in practice. Moreover, certain areas are still struggling such as pancreatic tumor detection, and hence innovation in technology and methods is required for clinical-level performance.

Recent Advances in Technology Toward Medical Imaging

There are certain areas of technology that have seen significant advancements in terms of their utility in medical imaging and diagnostics. This

has enabled machines to perform very complex tasks with human-level performance in fields such as medicine. Among these areas, AI is leading the way toward working with radiologists and revamping the clinical pipelines for better outcomes for patients and clinical diagnosis. Hence, AI-enabled technology will provide a holistic approach to medical systems. This would include AI-enabled guidelines for doctors to select a particular test, instead of performing different tests before coming up with the right one. In terms of acquiring a radiograph, AI would enable better image reconstruction strategies and help in identifying acquisition parameters that are better suited to the task at hand. Further, AI could help in dose optimization for generating medical images as well as image quality enhancements post acquisition (allowing to capture images with a lower level of dose). For reporting, AI and ML is already starting to augment radiologist to ensure attention to details and better and faster reporting (using segmentation and detection algorithms). AI is also leading the way in developing solutions for personalized treatment with precision medicine and allowing better optimization in utilizing the currently available healthcare facilities. While the industry is on this path of realizing AI-enabled solutions in all aspects of healthcare systems, there are certain limitation to currently existing methods and algorithms. Among these, one of the major considerations is the development of explainable AI. It is required to ensure that the models used in critical applications, such as medicine, are better understood and hence allow making more informed decisions.

Other than AI, some of the leading technological advances that are impacting medicine include the development of augment reality-based (AR) systems, utilization of three-dimensional printing, and the digital twin technology. One of the major beneficiaries from the development of AR systems is how surgeries are performed. In particular, using 3D imaging services and AR-based systems, surgeons are being empowered to make better surgery planning and decisions. Using 3D printing also helps in explaining the surgical procedures to patients and could allow better understanding in clinical

research. Hence a combination of 3D printing and AR would enable improved surgical decisions and allow patients to better understand surgical options and make more informed choices. For these methods, explainability is again important when machine learning algorithms are used for designing such systems. AI is also empowering the digital twin technology which would also benefit from explainable systems. The digital twin technology would allow clinical experts to allow best therapy solutions by testing it on the digital twin before administering it to a patient and hence achieve best possible outcomes for patients.

Machine Learning-Based Methods

To put it in simple terms, machine learning is going to disrupt how medicine is practiced [4]. Current medical systems are rule-based system, governed by a set of defined rules. But in the coming days, clinicians are going to rely on rules that are learned by the data themselves. Hence for the machine learning models to perform in an acceptable manner, the quality and quantity of the data for these “data-hungry” models is the most important factor. Another challenge of these data-driven models is that they do not guarantee a causal inference. This is where explainable models play a key role.

Medical image analysis has been a major beneficiary of the current developments in artificial intelligence. While the predictive performance of the models is on the rise, there are certain limitations of these methods which remain as a bottleneck in clinical adaptation of these new techniques. The advancements have been supported by the availability of large-scale datasets for a wide variety of applications. Data are now available for various imaging modalities such as magnetic resonance imaging, computed tomography, and X-rays. For instance, multimodal brain tumor segmentation (BRATS) [5] data are a widely used benchmark for brain tumor segmentation using MRI images and machine learning methods. A large collection of data, fastMRI [6], are available for MR image reconstruction studies. In particular raw data from single- and multi-coil acquisition scenarios

are publicly available enabling the development of ML models for this important area. It should be noted the deep learning (DL) models continue to outperform linear models and shallow networks in all forms of medical image analysis tasks [7].

In [8], a convolutional network was used to develop a model for retrieving medical images. Since the size of databases containing radiological images continues to increase all over the world, such a method is important for retrieving the most relevant radiographs. This would enable better diagnosis and prognosis and allow clinicians to study relevant patients before making diagnosis for new patients. In [9], a deep learning model was presented to segment brain tumor with considerable accuracy using the BRATS dataset. Recently, the focus has been on survival prediction for tumor subjects, where a precise segmentation of tumor regions plays a critical role [10]. While for explainable decision-making, radiomics features are preferred [11], but with limited data the predictive performance of such models can be affected. In [12], deep learning is used for 3D input MR images and tumor regions are segmented. Further, radiomics features are extracted from the tumor regions for survival prediction task, where decision trees are used for making the prediction. Machine learning has also been widely successful in many other segmentations and diagnosis tasks such as Alzheimer disease detection [13, 14] and multi-tissue segmentation [15]. It is also shown that combining multimodal data can improve the performance in clinical diagnosis [16]. Data-driven approaches using machine learning are also contributing to the field of image reconstruction [6]. It has been shown that deep learning can be used to optimize the subsampling patterns for MRI acquisition [17].

Although for medical image analysis, deep learning has been found to be successful, there are certain clinical application where the application of such methods is limited. One of the biggest challenges has been to use DL in scenarios where the data is limited, e.g., in electroencephalography (EEG) [18] and electrocorticography (ECoG) [19]. It should be noted that such transparent methods are better in terms of understandability, but their predictive power is limited. In another line of research, such models have been used to

generate information by learning knowledge from another imaging modality [20]. Machine learning has also been used for predicting patient outcomes by learning from 1D and low-dimensional data [21, 22]. In summary, there is no question on the application and usability of ML-based models in medical imaging and clinical diagnosis when we consider their predictive power. But the challenges arise from the black-box nature of such models and in cases where the reasons for the model coming up with certain predictions are not understandable by the stakeholders involved. In the next section, we provide an overview of the field of explainable AI and how this is important for clinical practice.

Explainable Artificial Intelligence: XAI

For critical areas of application such as medicine, machine learning models face a significant challenge when opaque models are used. Explainable methods are the foundation of explainable artificial intelligence – XAI, also called responsible AI in some cases. A high-level difference between ML and XAI is presented in Fig. 1, where the major difference is the introduction of a black box that enables explanation for the end user in terms of why a model makes a certain prediction. There are a wide range of definitions prevalent in literature for XAI, but no single definition has been agreed upon by all stakeholders yet. Moreover,

there are different terminologies used in literature which directly or indirectly refer to explainable methods. Interpretability is one of the most common terms that is used interchangeably with explainability, but it needs to be understood that both these terms represent different phenomenon. In particular, interpretability is a passive property of a model and broadly represents how much a model makes sense to a human while using that particular model. This could mean how much the person understands in terms of how the model is set up and working. On the other hand, explainable methods have a property where the model demonstrates the characteristics of clarifying its internal functions. In general, a model is considered to be understandable, if humans can understand the function of that model without going into the details of the internal functions or algorithms used. Hence, incorporating interpretability to a model means using methods to provide a meaning for humans in certain humanly understandable terms. Those methods that are interpretable are considered to be transparent, since the decisions made by such methods are understandable by humans – the key stakeholders in high-risk applications.

There are two aspects of explainable models in terms of understanding including model understanding and human understanding. Thereby the role of the audience (end user) is very important and must be considered while developing such methods. The audience could be diverse and

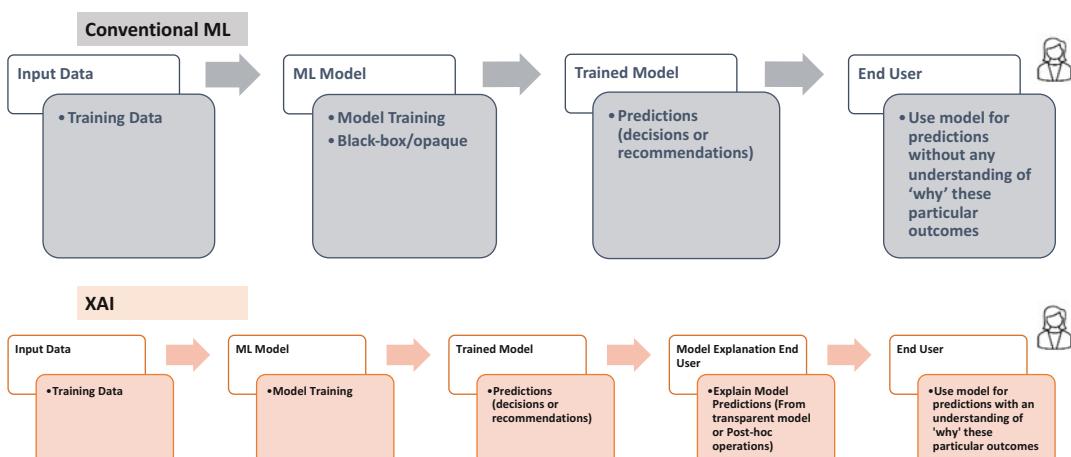

Fig. 1 Difference between conventional machine learning and explainable artificial intelligence pipelines

depends on the application including domain experts, data scientists and ML practitioners, regulatory bodies, executives, and end users. Hence the interpretations could vary depending on the type of audience. Moreover, this has also resulted in various goals that are being pursued in the field of XAI. One of the major goals of XAI is to achieve trustworthiness – a measure of confidence that the model will achieve the expected outcome in a certain situation. For medical applications, trustworthiness is critical, since both medical practitioners and end users are highly concerned on what AI would mean for them. A trustworthy model is critical in clinical decision-making. The goals of robustness and generalizability are also significant in medical domain. Hence explainable models need to have an associated level of confidence to the decision that these methods make. The models also need to be transferable and hence allow application in areas where data is limited. Transferability also accounts for the fact that a trained model can be successfully applied to the test (never before seen) data.

Another major concern in using AI in real-life application of critical nature is the ethical considerations. Explainable methods aim to achieve fairness and hence ensure that AI is used in an ethical and fair manner. For clinical applications, where human life could be at stake, it is important to achieve fairness in the decisions the AI-based models will make. To make models more interpretable and explainable, humans in the loop methods are being developed [23]. This ensures that humans are included in various stages of the AI-based decision-making. For example, interactive models are developed that learn from the human interaction with medical images, while radiologists make their readings in real time [24]. This data is used for training models that are expected to perform better than those models that involve no human interaction. Human in the loop also means that humans should be able to interact with ML models and the outcomes should be accessible.

Another important aspect in explainability is to define causability [25], which measures what the explainable model achieves in terms of causal understanding for a human being. Here causal relation defines the cause-and-effect relationship

[26]. It is imperative for explainable models, particularly in the medical imaging and diagnosis domain, to achieve a certain level of causability understanding. One way of achieving this is to fuse information from different modalities. In particular for use of AI in clinical practices, data is derived from diverse sources including imaging (MRI, PET, CT, etc.), clinical history, personal demographic information, lab tests, and physiological signals to name a few. Generating multi-modal embeddings in an explainable way could be the way forward to generate precise and personalized diagnosis. For generating such embedding arising from cross-modal data fusion, the semantic gap that exists between these varying data sources needs to be overcome. One way to achieve such interpretable representation is to use graph representation learning [25] which, although a promising direction, requires significant research.

Explainable methods are broadly categorized in two types: i) transparent models and ii) models that require post hoc operations. This categorization stems from the fact that some ML models are inherently simple and hence interpretable, in terms of both model understanding and human understanding, while complex models, such as deep neural networks which are not comprehensible for human, require post hoc operations that enable interpretability and explanations for the decisions the model makes.

Transparent Models

Such models are simple enough to be explainable by themselves and include classical machine learning algorithms such as logistic regression and K-nearest neighbors. While such models are simple and hence comprehensible for a human observer or domain expert, these models could be limited in terms of their predictive power. Moreover, the transparency of such models could be lost as soon as more data or complexity is added to such models. One of the reasons for success of more complex models, such as deep learning, has been their higher predictive capability even when large-scale data is involved. However, the added complexity is also the reason for

such model to be considered as opaque or black box, since they are no more interpretable by themselves. There are other ML methods that are considered to be transparent such as decision trees and simple rule-based learners. In particular, rule-based learners have a very intuitive nature and hence also led to the success of AI in a wide array of application before the advent of deep learning models. While such algorithms have some nice explainable properties, but for a lot of real-world application, defining a robust set of rules covering all seen and unseen scenarios has been a challenge. The models developed using probabilistic basis are also considered to be transparent, such as Bayesian models. Hence there has been a wide interest in developing such models even when deep learning is used for better interpretability and explainability. Inference from such models could lead toward identifying the causality as well as estimating the uncertainty associated with decisions allowing to build confidence in the decision taken by ML-based methods.

Post Hoc Interpretability

For ML models that are not transparent, methods are adopted that can explain how the output is produced by a trained model. The aim for these post hoc techniques is to communicate an understanding of the predictions generated by the ML model. These post hoc methods are further categorized based on the type of ML models these are used for. Model agnostic techniques are designed to be independent of the type of underlying model used. Such techniques include visualization methods, identification of feature-level importance, and model distillation to simplify models and hence understand the predictions. Moreover, for shallow ML models, such as support vector machines and ensemble techniques, feature relevance identification and visualization methods are used as post hoc operations. For deep learning, post hoc operations could involve model simplification, for which there are some standard methods presented in literature. Since a lot of advances in medical imaging and diagnosis are driven by adopting deep learning models and these models

are inherently opaque, we particularly look at some standard methods (performing post hoc explanations) for such models.

Explainable Models for Deep Neural Networks

Deep neural networks, by virtue of having a large parameter space and layers, have an inherently predictive performance when compared with linear and shallow ML models. There is a wide array of methods presented in literature for introducing post hoc explainability when using deep neural networks. We present a summary of four main areas here as reference.

In some methods, a simple transparent model (surrogate) is used at the output replacing the decision function. An example of such method is the local interpretable model agnostic explanation (LIME) algorithm [27]. The algorithm incorporates decision trees and introduces sparsity in an attempt to model surrogate linear explainable models. For analyzing feature-level importance, occlusion analysis can be performed [28]. In this method different patches or features are occluded, and the model output is analyzed. One way to analyze the output is to create heatmaps and hence identify which parts of the image or features are most affected. In Shapley (SHAP) analysis [29, 30], a larger set of features are occluded and hence have a global level of understanding. With deeper neural networks, the problem of shattered gradient arises, where the local gradient can look like noise and the changes in gradient over different layers are also significant. Explanations based on these gradients can look like noise and hence are not useful. SmoothGrad [31] is a technique used to overcome the shattered gradient phenomenon and hence can aid in model explanation for deeper neural networks. Generally, deep neural network follows a feed-forward cycle followed by back propagation while training. Inspired by this learning mechanism, layer-wise relevance propagation (LRP) [32, 33] mechanism is used to introduce explanations in the process. The LRP is a forward-backward loop where the relevance values are propagated through the neural

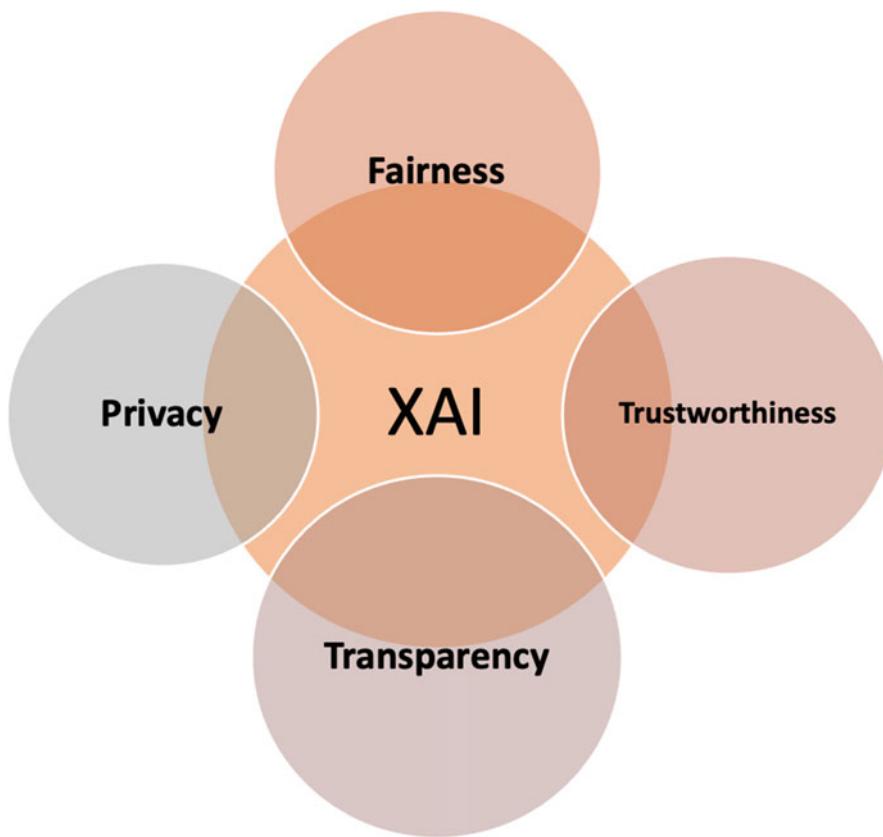

Fig. 2 The goals that explainable artificial intelligence aims to achieve with responsible AI

network from the input to the output and back and in the process generate explanations. There are other methods present in literature driven from these basic models to incorporate post hoc explanations in deep networks and can be found here [34]. In general, the kind of things expected from XAI is presented in Fig. 2. It is expected that XAI will enable trustworthiness, fairness, privacy, and transparency and lay the foundations for responsible AI.

Conclusions and Future Landscape for ML-Based Imaging and Diagnostic Methods

Over the last decade, we have seen a resurgence in the pace with which AI has been deployed in real-world application including medicine. The future lies in precision and personalized medicine, enabling better outcomes for all

stakeholders benefitting from the digitization and technological advancements. While this will be realized once the opaque (black-box) nature of currently used ML methods is transformed into more interpretable and explainable models, one emerging area which is closely related to explainability is the assessment of privacy while using ML and AI in clinical pipelines. Current data-driven models are known to memorize information, and with their black-box nature, it is not clearly understood what kind of information they could store. While the aim of current research is to develop models with high predictivity, with interpretation we cannot fully understand what kind of information these models hold and how this can be used by various stakeholders. Hence XAI would need to focus on privacy awareness to ensure that the critical information is secure, and it is better understood that in what ways the internal relations learned by a trained model

can be interpreted by those that have access to this information.

In conclusion, as the field of machine learning is progressing at a fast pace and in the process revolutionizing medical imaging and diagnosis, it is also creating new avenues and challenges. XAI is at the forefront of overcoming most of these challenges. With explainable AI, we can hope to achieve responsible AI, and this would enable a large-scale adaption of AI in clinical pipeline with more confident and satisfied stakeholders. The field is wide open and required significant research effort and innovation. One thing is for sure, that with XAI, medical practice will benefit in the coming days allowing improved diagnosis and better patient outcomes.

Abstract

COVID-19 has had a huge impact globally. This chapter examines the role that test set technologies coupled with artificial intelligence can transform clinical educational strategies. Using AI to streamline a methodology that has been around for decades enables education that is tailored to each clinician, acknowledges each individual's weaknesses,

and is available instantly wherever in the world the clinician is available. Cautionary notes are also provided.

Introduction

At the time of writing, COVID-19 has infected 62 million individuals, respectively, according to official reports [1]. The World Health Organization has stated that up to 35% of infected individuals can have long-term symptoms

Z. Gandomkar · P. C. Brennan (✉) · M. E. Suleiman

moe.suleiman@sydney.edu.au

(3 weeks post-testing) with 20% of 18- to 34-year-olds reporting prolonged symptoms [2]. The former amounts to up over 20 million individuals, which exceeds the incidence rates of all cancers combined [3]. In addition, it is important to emphasize that the US Centers for Disease Control and Prevention refer to the fact that there may be between 6x and 24x more actual cases than reported numbers, with the actual number fluctuating widely across locations [4].

High-resolution lung-computed tomography (CT) is the frontline tool facilitating accurate assessment of disease severity, progression, or treatment response [5–7]. However, recent research done by our group has shown that clinicians' sensitivity using HRCT for COVID-19 can be 50% or lower (discussed more below): We need better image interpretations [8]. Educational solutions with and without artificial intelligence (AI) to optimize COVID-19 diagnostic competency are required. One of the key approaches focuses on using test set technologies that are revolutionizing diagnoses in other domains such as breast cancer, lung cancer, and dust diseases, blending in an unusual way the latest in artificial intelligence, human expertise, and ergonomics.

Test Set Technologies

What is a test set technology? It is often a web-based program allowing clinicians and trainees ("readers") to diagnose sets of radiologic images wherever in the world they are located [9]. These clinically relevant test cases, which in the current context would be CT images of the chest to diagnose COVID-19, allows readers to look at real de-identified medical images the same way as they would in the clinic. A reader independently judges each image in a test set and whenever relevant identifies and locates COVID-19 lesions such as ground-glass opacities, mosaic patterns, or consolidations. The reader then decides using a confidence scale as to how sure they are that a COVID-19 infection exists. Readers can go back to any image or case and correct a previous decision prior to submitting their answers. Some cases contain disease while

others are COVID-19 free (Fig. 1). Instantly following such analyses, the most modern systems intelligently analyze the data and present a range of performance values including sensitivity and specificity to each clinician. In addition, using novel AI algorithms, reader-specific image files will be generated so that correct and incorrect decisions can be examined and education test sets can be built and delivered that are most appropriate to each individual radiologist. The result is a better way for radiologists to effectively improve their cancer detection skills.

There is good evidence that such intelligent educational platforms work. As reported in the world's leading journals such as Academic Radiology, this type of approach improves mean levels of disease detection by 34%, with individual clinicians achieving higher rates [10, 11]. This dramatic improvement occurs regardless of expertise and experience. In addition, these self-assessment approaches are popular and in terms of adoption, 90% of relevant clinicians in specific jurisdictions have been shown to voluntarily engage. For example, within 6 weeks of the launch of the CovED tool by the University of Sydney start-up company – DetectED-X, there were users in 145 countries. Partnering with major agencies such as GE and Amazon, to ensure the widest distribution, the highest levels of security and rapid access are critically important.

Artificial Intelligence in Medical Imaging and the Opportunity Provided by Test Sets

Artificial intelligence (AI), machine learning (ML), and deep learning (DL) are terms that are often used interchangeably. However, AI is a general term that can be interpreted as integrating human intelligence to machines, while ML is a subset of AI, which focuses on giving computers the ability to learn from a dataset (such as images within a test set), and DL is a technique used to accomplish ML. Nonetheless, to realize powerful AI systems that can accurately perform inferences from a large set of data, just as humans, AI systems need to learn from accurate and large enough

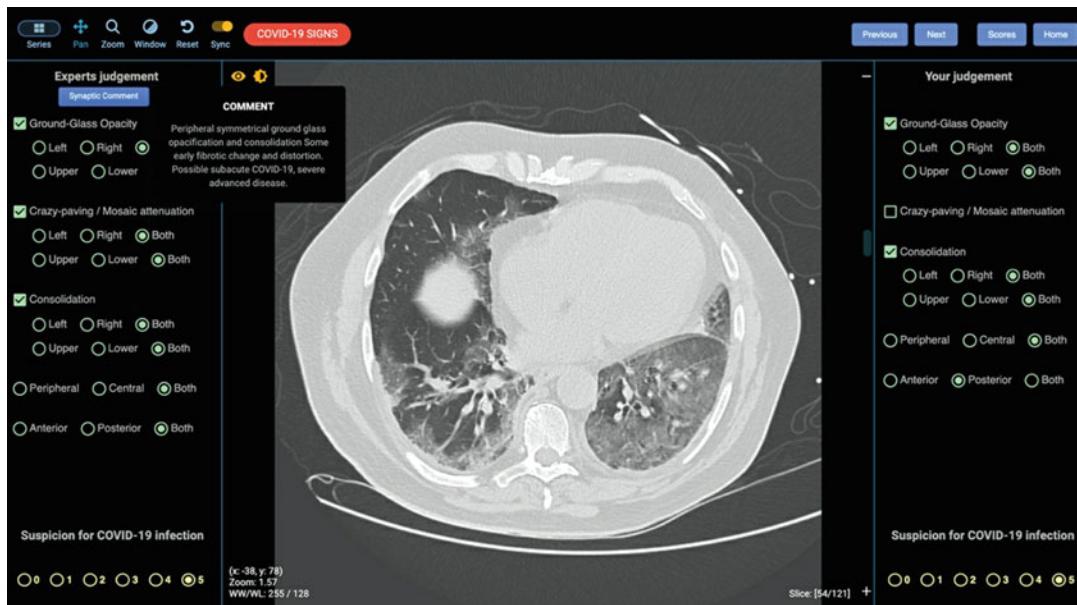

Fig. 1 An example of a test set image presented *after* the clinician has judged the image. On the right-hand side are the radiologists' classification of appearances and their location, on the left-hand side are the expert radiologists'

classification of appearances and their comments on the case. The disease appearances in this case were correctly identified. These images are from the recently developed CovED tool

training datasets. AI models are fed experiences through vast amounts of information with the aim of producing correct predictions for new unseen data, hence the training datasets need to be accessible, useable, valuable, and regularly validated.

Medical imaging providers generate huge amounts of data containing valuable information; such data however is often left in storage systems unutilized due to the regulatory restrictions around ethics and privacy. Furthermore, data extracted from the clinical world usually inherits the messiness of the real world reducing its usability and value. Nonetheless, increased usability and value can be accomplished by annotating and labeling the data to create large numbers of training samples; however, this would introduce yet another obstacle as expert annotators are expensive and mostly not available.

The test set technology introduced above provides radiologists with a more accessible and organized opportunity to utilize AI to improve their performance in detecting abnormalities in medical images. To be able to provide accurate test sets, medical images have to be anonymized,

annotated, and labeled with a summary of radiologists' reports; furthermore, this information is validated through further testing and diagnosis. Hence, if we take breast cancer diagnosis, for example, test sets containing cases on cancer will curate vast amounts of highly accurate information and data regarding the lesions' exact location (biopsy proven), appearance on the mammogram, and further information on past mammograms; this type of information along with the radiologists specifically recorded interactions with the images can help train AI systems to detect areas of interest on mammograms more accurately, giving radiologists much needed help on confirming a diagnosis.

Another example of the test set offering is around COVID-19 diagnosis. Although the appearances of COVID-19 are now known, they overlap with other pneumonitis diagnosis, making an accurate diagnosis harder. Through accurately diagnosed test sets, supported by high-quality pathology data, large number of cases with confirmed diagnosis of COVID-19 and accurate information on the locations of the main appearances of

the disease can be made available. This is like gold dust when attempting to train AI systems on the diagnosis of COVID-19. Furthermore, radiologists' interactions with the test set are also extensively recorded, which creates information on the difficulty of certain appearances, the presence of other diseases, and the effect of different technologies on the performance of radiologists on the diagnosis of COVID-19. This will help create AI systems that would customize educational tools to concentrate on radiologists' weaknesses, for example, allowing them to be faster and more confident in diagnosing COVID-19.

The remaining part of this chapter will further explain the need for such intelligent education and the methods used to ensure that artificial intelligence is the core technology to optimizing educational strategies when diagnosing COVID-19.

Why Does Education Need to Embrace AI to Enhance Detection of COVID-19?

Industry and researchers have looked at the extent of clinician efficacy when diagnosing COVID-19 from CT scans and a paper produced at the end of 2020 and currently in submission highlights the issue [8]. In brief the work showed for each of the three key COVID-19 CT features, many images were given a normal (no disease) rating, even though according to the experts, that appearance was there.

Two key findings were:

- Sensitivities as low as 65%, 25%, and 35% for ground-glass opacities, consolidation, and crazy paving appearances, respectively.
- Current levels of experience, education, fellowship expertise, specialization, and familiarity with COVID-19 had no impact on performance.

The conclusion from that work was that despite current methods of formal or informal education, clinicians are failing to recognize key radiologic features associated with COVID-19. Innovative educational solutions are required. In particular, it must be acknowledged that if we are to use test

set approaches as described above to enhance COVID-19 education, it must be acknowledged that educational modules must be tailored to suit the specific weakness of each user. It is not enough to simply make available the same modules for everyone since Dr. Brown's errors will be different from Dr. Li's. In this chapter, therefore, we describe a novel artificial intelligence solution to tailor the educational experience for each clinician or health care worker. The method allows specific algorithms for each individual to be built as they interact with the CovED images, resulting in solutions that can be available within a matter of minutes.

AI-Tailored Education Using Clinician Demographics and Image Features

Error making patterns of radiologists have been widely studied in the medical image perception sciences. It was shown that individual radiologist's error making patterns are consistent across cases [12, 13]. Therefore, a machine could be able to successfully learn clinicians' weakness and strengths and tailor educational materials for each individual. In the era of precision medicine, such strategy for precision medical education is highly desirable. Figure 2 shows possible approaches for using AI in order to customize the educational materials.

Considering the nature of the pandemic and clinicians' lack of time to spend on learning about the CT appearances of COVID-19, tailored educational platform is even more important than before. Previously, in other imaging modalities several attempts have been made by researchers to predict radiologists' errors to retrieve difficult cases for radiologists. As an example, in [14], an AI model relies on the previous interactions of the radiologist with mammograms and predicts if a new case is difficult for that radiologist. The model relies on a set of computer-extracted features from mammograms and trains two classifiers based on these features to classify the input images as false positives or true negatives (normal cases) as well false negative or true positives (cancer cases) [14]. The group extended these AI

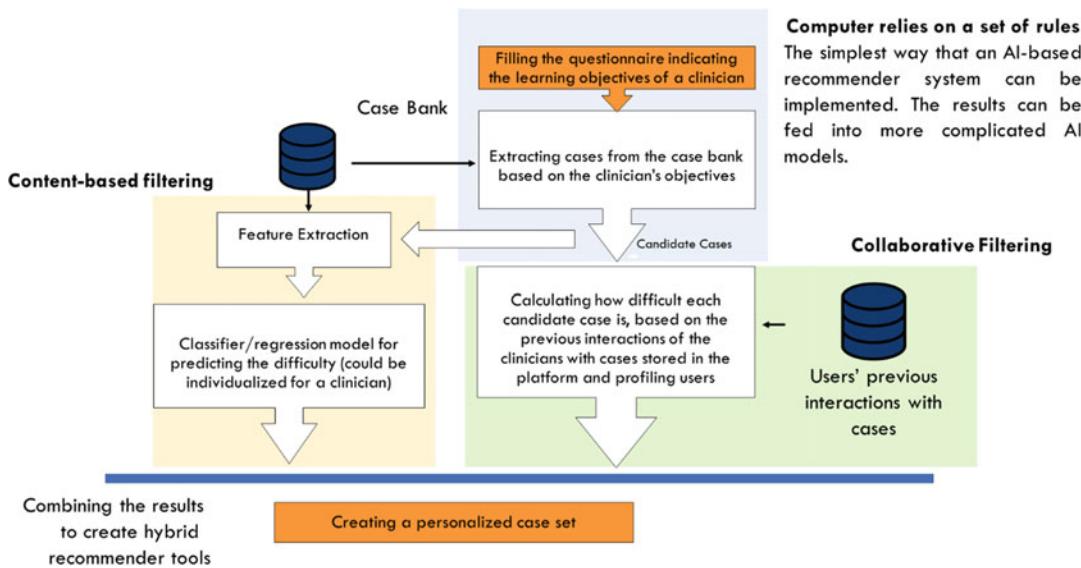

Fig. 2 Possible ways of leveraging the artificial intelligence (AI) algorithms for creating tailored educational materials

models to include other features in [15]. Another approach could be modeling the problem as a recommender system, which predicts user's rating to a case based on ratings of similar users to the same case or similar cases.

Collecting high-quality data is at the core of establishing such AI tools for personalized education. This requires platforms for recording radiologists' interactions with cases, so that the error-making patterns of observes can be modeled. As an example, using the large amount of data collected by the CovED platform [16], such an AI model has been built. In the platform, clinicians were asked to provide a score of 0 to 5, showing their confidence about the presence of COVID-19. The platform recorded all radiologists' interactions with the system. A solution, which predicts difficult positive and negative cases specific to each clinician, was developed based on a matrix factorization-based recommender system [17]. In summary, the clinician case rating matrix (\tilde{P}), where each row represented a radiologist and each column represented a case, was generated.

The clinician case rating matrix was decomposed into the product of two lower dimensionality matrices, i.e., $\tilde{P} = RC$, where R and C represent radiologist and case profiles in a new

space of latent factors. Intuitively, through the user and case profiles, the recommender system models similarities between cases and users. The predicted rating, $p_{i,j}^i$, from radiologist i to case j can be formulated as

$$p_j^i = \sum_{f=0}^{nfactors} R_{if} C_{fj}$$

where f is an iterator on the latent factors while $nfactors$ shows the number of factors. The number of latent factors is a hyper-parameter of our model, which should be set beforehand. It was shown that a matrix factorization with one latent factor is equivalent to the average score to the items without any personalization [17]. To improve the personalization, the number of latent factors should be increased. However, by increasing number of latent factors, models start to overfit to the training data and hence the quality of its prediction to a blinded test data will drop [17]. Therefore, a nice balance to avoid overfitting while reaching proper level of personalization is desirable. Usually, $nfactors$ should be set empirically. In these recommender systems, handling data sparsity is important as for each clinician assessments to a number of cases will be missing.

To handle the data sparsity, various methods have been proposed in the literature [17].

The matrix-factorization-based recommender system described above using the CovED platform achieved an AUC of 0.80 (CI:0.78–81) and 0.83 (CI:0.82–0.84) in detecting difficult positive and negative cases, respectively. Further analysis revealed that when ratings from 15 clinicians were available for a case, the mean absolute error for predicting the rating was, on average, ≤ 1 . Also, availability of a clinician's ratings for 15 cases guaranteed an average mean absolute error of approximately ≤ 1 in predicting the ratings of that clinician for new cases.

Therefore, adequate number of readings should be available for each user and each case and collecting interaction data is at the center of establishing such a model. Although the proposed methodology has been developed for COVID-19 cases, it can be extended to personalize other radiologic learning materials.

AI Companions to Help with COVID-19 Diagnosis

Various AI tools have been developed since beginning of the pandemic to aid clinicians to diagnose COVID-19 on chest CTs [18], segment the extent of infections [19], and classify COVID-19 severity [20]. The majority of these tools rely on deep learning models, whose main bottleneck is availability of high-quality datasets. Many clinicians from around the world attempted to make publicly available COVID-19 datasets, such as:

1 – “MosMedData: Chest CT Scans with COVID-19 Related Findings [21].” It includes 254 normal cases and various CT manifestation of COVID-19: ground-glass opacifications, where involvement of lung parenchyma is less than 25% (684 cases); ground-glass opacifications where involvement of lung parenchyma is between 25 and 50% (125 cases); ground-glass opacifications and regions of consolidation, where involvement of lung parenchyma is between 50 and 75% (45 cases); diffuse ground-glass opacifications and consolidation as well as reticular changes in lungs, where involvement of lung parenchyma exceeds 75% (2 cases). It also includes 50 cases,

where masks corresponding to the ground-glass opacifications and consolidations is provided.

2 – “China National Center for Bioinformation [22].” It includes 750 CT slices from 150 COVID-19 patients were manually segmented into background, lung field, ground-glass opacity, and consolidation.

3 – “UCSD dataset (confirmed by Tongji Hospital radiologist) [23].” It includes 350 CT slices from 216 COVID-19 patients with captions describing CT features and their extents. It also provides 396 CT slices from 170 non-COVID-19 patients.

4 – “COVID-19 CT segmentation dataset (<https://medicalsegmentation.com/covid19/>).”

It includes three sets of CT images with masks for ground-glass opacities, consolidations, and pleural effusion for 473 slices of 19 patients.

5 – “COVID-19 CT Lung and Infection Segmentation Dataset [24].” It includes lung and infection masks for 20 CT cases (left lung, right lung, and infections are labeled by two radiologists and verified by an experienced radiologist).

6 – “BIMCV COVID-19+ [25].” It includes 163 CT cases with image-level labels. It also provides 5 CT studies with semantic segmentation of radiographic findings.

Although many AI studies aimed at classifying images as COVID-19 or non-COVID-19 images, due to the similarity between COVID-19 CT manifestation and other viral pneumonia, radiology professional bodies recommend against using CT as the primary diagnostic tool [26]. The reverse transcriptase polymerase chain reaction (RT-PCR) assay of nasal and pharyngeal swab specimens is the gold standard for identifying SARS-CoV-2 patients [26]. However, lung CT images have been used for clinical triage of symptomatic patients who underwent chest CT following emergency room to speed up diagnostic workflow and establish isolation at admission. More importantly, assessing CT manifestation of COVID-19 independently predicted an adverse patient outcome associated with COVID-19 pneumonia [27]. It also can help for clinical staging of the disease and patients with milder symptoms and comorbidities [28]. Considering potential application of the CT to managing the COVID-19, deep learning-based segmented infectious areas as a

mask or heatmap could be the most useful “companions” for radiologists in COVID-19 pandemic.

Various tools for segmenting the areas infected by COVID-19 in CT have been proposed. As an example, Inf-Net [29] is a state-of-the-art deep learning model for segmenting the infection areas. Another example is COPLE-Net [30], which proposes a noise-robust dice loss function to address the challenges introduced by the noise in annotations. Deep learning models were also fine-tuned for multiclass segmentation to segment ground-glass opacities, consolidation, and pleural effusion.

Considering the paucity of fully annotated COVID-19 CT images, semi-supervised learning methods can also help in improving the performance of the deep learning models by leveraging availability of unannotated data [29, 31]. Usually in a semi-supervised approach, unannotated COVID-19 CT slices can be used to produce pseudo-annotated data [31]. To avoid overfitting, this can be done iteratively as follows:

- Inputs: Trained networks for segmenting COVID-19 on CT slices and unannotated COVID-19 data
- Repeat until no unannotated image is left
- Randomly select N CT images, annotate them using the network (pseudo-label set)
- Retrain the network using the union of original annotated images and this new set
- Omit the randomly selected images from the set containing unannotated data

For the images in the pseudo-annotation set, soft labels can be used. Soft labels provide a membership probability to a point rather than a binary number shows if the pixel is a member of the class or not. In the datasets, where a text is available for describing the CT features, the value of the soft label will be adjusted based on the image-level-provided labels.

Finally, Some Cautionary Notes

It should be noted that certain unintended consequences could occur as a result of introducing an AI companion tool to radiologists. For example, the perception of a “safety-net” could lead to a less

thorough visual search pattern as a result of over-trusting the AIs [32], an effect possibly more prominent among less-experienced radiologists. Also, introducing an AI might result in an extensive level of fatigue as readers might end up searching twice (or more), thus exhibiting prolonged fixations or multiple refixations on locations previously ruled out by their peripheral vision and potentially with a large proportion of these being normal aberrations [33]. The need therefore for clinicians to be educated thoroughly about the proper way to interact with AIs is required to establish and maintain the appropriate level of trust between the human and machine. Using heatmaps, for example, to explain AI decisions might facilitate such trust.

Conclusion

We have hit an important milestone regarding clinical education. Using the COVID-19 paradigm and novel AI algorithms, researchers and pedagogists can now develop systems of education that are tailored to the individual, rapidly accelerating learning activities. While the focus here is COVID-19 and radiology, the lessons learned can be applied across educational domains.

Abstract

Artificial intelligence is already impacting many areas of society, and there is much opportunity for future change and benefit to our lives. Surgical pathology is no exception to this technological shift. The growing availability of digital pathology is facilitating the development of algorithms to tackle challenging or laborious aspects of the pathologist's assessment and diagnosis. However, there are many issues to overcome before we see widespread, routine use of AI in clinical practice. In this chapter, we explore a brief history, clinical applications, technical aspects, standards of reporting, deployment, regulation, and education opportunities of AI in surgical pathology. We provide the reader with a general overview of the present position of surgical pathology in the world of AI.

Keywords

Surgical pathology · Histopathology · Pathology · Artificial intelligence · Machine learning · Deep learning · Digital pathology · Whole slide imaging · Virtual pathology · Image analysis

Introduction

Artificial intelligence (AI) and specifically deep learning (DL) are emerging technologies in surgical pathology, with much scope to impact clinical practice. There are 367,167 new cases of cancer per year in the UK [1], and

approximately 45% of cancer patients have surgery to remove their tumor [2]. Every one of these patient's biopsies or surgical specimens is examined and reported by pathologists. In addition to these figures, there are many more diagnostic and screening tests for cancer and specimens for nonmalignant diseases that are processed by pathology departments routinely. As such, a revolution in this field would significantly impact both patients and healthcare systems. While the concept of using computers to analyze images is not new to surgical pathology, the increasing availability of digital pathology scanning has created the ideal landscape for the development of AI.

In this chapter, we explore a brief history, clinical uses, technical considerations, standards of reporting, deployment, regulation, and educational potential of AI in surgical pathology. This chapter is intended for a scientific audience not familiar with AI, and its purpose is to be an overview of developments in this rapidly growing field, rather than an exhaustive review of all the literature.

Development and deployment of AI on a large scale has become a realistic possibility in recent years due to increasing computing power, capacity to store large images, and the expanding use of whole slide imaging to create digital images [3]. Whole slide imaging (Figs. 1 and 2) involves scanning of an entire glass slide and storing the image electronically at high resolution so that it is available for review on a computer [3]. The availability of these high-resolution medical images has created a platform for AI innovation.

Definitions

- Artificial intelligence – the development of computers able to engage in humanlike thought processes [5].
- Deep learning – a set of methods using the combination of multiple nonlinear transformations, aiming to create abstract, and potentially useful, representations. It is a branch of machine learning [6].
- Digital pathology a generic term for the use of electronic images in pathology, usually facilitated by whole slide imaging technology [7].
- Image analysis – process of inputting an image to an operator, and a measurement is produced as the output. Examples include automated detection and diagnosis of disease, identifying a specified region, size measurements, and calculation of risk [8].
- Machine learning – an area of artificial intelligence that involved creating applications that learn and improve their accuracy over time without specific programming that makes them perform this process [9].

- Telepathology – the projection of surgical pathology images electronically from one location to another for diagnosis and assessment by a pathologist [7].
- Virtual microscopy – the conversion of histological sections on glass microscope slides to high resolution digital images [10].
- Whole slide imaging – a technology that is used to digitize a glass slide in its entirety, making the slide available electronically for assessment by a pathologist as a digital image [7].

A Brief History

Artificial intelligence has created much excitement and interest in recent years, but the concept of intelligent machines is not a new one. Notably, Alan Turing published his groundbreaking paper “Computing Machinery and Intelligence” over 70 years ago, in 1950 [11], and such concepts even had their place in ancient mythology with humanlike, intelligent machines fashioned by the Greek god Hephaestus [12].

The origins of AI in pathology can be dated back as far as the mid-seventeenth century to Antoni van Leeuwenhoek who successfully created a system for measuring microscopic objects such as red blood cells, considered to be the early beginnings of image analysis [13]. However, it was not until there was significant advancement in computing technology in the mid-twentieth century that the path to modern digital pathology and AI truly started [14]. An early development in this period was the CELLSCAN system presented at a computing conference in 1961 that described the use of a television microscope and computer to perform analysis of white blood cells [15]. Another example from this era was the computer-aided image analysis of cells in a blood smear by Prewitt and Mendelsohn in 1966 [16]. They used the combination of a flying spot microscope, digital converter, and magnetic tape recorder to scan and record cell features. The magnetic tape was read by a computer to produce a grey scale image of the cell, reflecting cell borders and simple characteristics.

Telepathology was both the precursor to the development of digital pathology and remains a pathologist's tool in its own right. Ronald Weinstein, a pioneer of telepathology, wrote an editorial on its creation and uses in 1986 [17]. The technology allows assessment of tissue without the pathologist needing to be physically present with a glass microscope slide. It has two primary uses: first for frozen sections of a patients' tissue, requiring a diagnosis or decision to be made intraoperatively, and second to facilitate an expert second opinion on a case [18]. The first virtual microscope was developed in 1996 by the Saltz

group who applied technology to histology slides that was originally intended for photomicrographs [18, 19]. The first patents for whole slide imaging were filed in 1997 and 1998 by Bacus Research Laboratory [20]. Initially, the digitization of glass slides was limited by slow scanning capability, the need for focus stacking, and poor interoperability of the equipment for digitization [21]. Whole slide imaging has since evolved and overcome these issues with much improved scanning technology (Fig. 2) and can now rapidly produce high quality images, thus making the deployment of digital pathology more practical [20, 22]. The utility of deep learning algorithms in other fields, combined with the growing availability of digital pathology, has formed a natural progression toward applying AI to tasks in surgical pathology [3] (Fig. 3).

Clinical Applications

AI is predicted to spread across many healthcare settings; however, research in this area remains at the early stages [24]. In surgical pathology, universal clinical adoption of AI algorithms is reliant on routine digitization of histology slides, and this process has happened comparatively slowly when contrasted with digitization in other medical specialties such as radiology [24]. Despite both enthusiasm for this technology and concern that it may replace pathologists, current developments are narrow and task based and do not yet reflect the complexity of assessment and diagnosis by pathologists in the real world [25]. A statement by Prof. Geoffrey Hinton in 2016 is worth noting, "People should stop training radiologists now. It's

Fig. 3 Example set up of multiple whole slide imaging scanners [23]

just completely obvious that within 5 years, deep learning is going to do better than radiologists,” and yet, there is still a definite need for training radiologists at this time [26]. Recent data in the UK shows a declining workforce with only 3% of surgical pathology departments having enough staff to meet current clinical demand [27], and therefore, task-based AI could actually be used to assist busy pathologists in a range of ways. Presently, research focusses on more common cancers such as prostate cancer, breast cancer, and lung cancer, although interest in less common cancers and nonneoplastic disease is growing [28, 29]. We explore examples of algorithms applied to different task groups for digital pathology. We have divided these tasks into detecting and classifying disease, grading and scoring disease, finding rare events and small objects, and finding or outlining tumors, predictive tasks, and image quality improvement. Additionally, we will review the recent rise in grand challenges to solve diagnostic problems using AI in pathology.

Detecting and Classifying Disease

The pathologist’s role is important in the diagnosis of many diseases, but the process is not always simple. There are often multiple components, and this is only expanding with the evolving role of molecular pathology [30, 31]. An area targeted by researchers is the detection and classification of disease, and there are examples across multiple pathological specialties. Table 1 summarizes examples of papers reporting models that performed detection or classification tasks. Breast pathology is a subspecialty where deep learning algorithms have been successfully developed for such purposes in breast cancer [32–34]. For example, one algorithm was able to sort cases into nonmalignant or malignant with an AUC of 0.962 and three class accuracy of 81.3% for classification into normal/benign, DCIS, and invasive ductal carcinoma groups [33]. Similarly, AI has been applied to examples in uropathology, with research focusing primarily on prostate cancer [35–37]. One interesting study gathered a very

large dataset with a total of 44,732 whole slide images (WSIs) to perform classification and detection of prostate cancer, and also skin and breast cancers [35]. This group achieved an area under the curve (AUC) of 0.98 for the three cancer types. These same concepts can be applied to nonmalignant disease, and an example is a model developed for duodenal biopsies that distinguished between coeliac disease, nonspecific duodenitis, and normal tissue with >0.95 AUC for all cases [38]. Deployment of such tools could assist with prioritizing the most urgent or severe cases and potentially achieve faster turnaround times for those that are most critical.

Grading and Scoring Disease

The process of providing a diagnosis may involve providing a grade or score for aspects of a disease. This is usually an indication of severity and can impact the clinical management of the patient. Grading and scoring tasks can be laborious and susceptible to variability between pathologists [44, 45], and so this an area where AI may assist. Algorithms for Gleason grading in prostate cancer achieved a good performance in assessing prostate biopsies [46, 47]. One model with a dataset of over 1200 digital slides achieved a quadratic kappa score of 0.918 for Gleason grading of prostate cancer biopsies, indicating very good agreement. Furthermore, this concept may be applied to scoring of immunohistochemistry, and examples of this can be seen in breast pathology [48, 49]. One group achieved an overall accuracy of 83% when scoring HER2 immunohistochemistry in breast cancer [49]. Examples of models performing grading and scoring tasks are summarized in Table 2.

Finding or Outlining Tumors and Tissue

It may be useful to identify areas of malignant tumor in digital slides to highlight these features to the pathologist, and therefore assist in their diagnosis. Some examples of algorithms performing these tasks are summarized in Table 3.

Table 1 Examples of models performing detection and classification of disease

Reference	Disease/condition	Task	Performance measure	Dataset numbers	Staining
Araujo et al. [32]	Breast cancer	Classification of breast cancer	Carcinoma/noncarcinoma accuracy 83.3% and four class accuracy 77.8%	269 WSIs	H&E
Bejnordi et al. [33]	Breast cancer	Classification of breast cancer	AUC of 0.962 for classification of nonmalignant and malignant and three-class accuracy of 81.3%	221 WSIs	H&E
Bulten et al. [37]	Prostate cancer	Classification into malignant and nonmalignant	F1 score 0.62 discriminating tumor and nontumor	94 WSI pairs (H&E and IHC)	H&E, IHC
Campanella et al. [35]	Prostate cancer, basal cell carcinoma, and breast cancer metastases	Diagnosis of multiple cancers	AUC above 0.98 for all cancer types	44,732 WSIs: 24,859 prostate images, 9,962 skin images, and 9,894 breast images	H&E
Cruz-Roa et al. [34]	Breast cancer	Detection of invasive breast cancer	Dice coefficient of 75.86%, PPV 71.62%, and NPV 96.77% pixel-by-pixel evaluation compared to manually annotated invasive ductal carcinoma	605 cases	H&E
Halicek et al. [39]	Squamous cell carcinoma (SCC) of head and neck and thyroid cancer	Head and neck cancer detection	AUC of 0.916 for SCC group and AUC 0.954 for thyroid carcinoma group for detection of tumor	381 WSIs	H&E
Litjens et al. [36]	Prostate cancer and breast cancer sentinel nodes	Prostate cancer detection and metastatic breast cancer detection	AUC (median analysis) 0.99 for prostate cancer and 0.88 for sentinel node metastases	225 prostate WSIs +173 breast WSIs	H&E
Noorbaksh et al. [40]	Multiple cancers	Classification of 19 solid tumor types into malignant and benign	AUC 0.995(+/- 0.008)	27,815 WSIs	H&E
Sharma et al. [41]	Gastric cancer	Detecting cancer and detecting necrosis	Classification accuracy of 0.6990 for cancer and 0.8144 for necrosis	454 cases	H&E, IHC
Wei et al. [42]	Lung cancer	Classification of lung adenocarcinoma subtypes	AUC greater or equal to 0.97 for all classes	422 WSIs	H&E
Wei et al. [38]	Celiac disease	Classification of duodenal biopsies	Accuracies of 95.3% for coeliac disease, 91% for normal tissue, and 89.2% for nonspecific duodenitis. AUC>0.95 for all cases	1230 WSIs	H&E
Zhang et al. [43]	Bladder cancer	Bladder cancer diagnosis	AUC 97% and mean accuracy 94.6%	913 WSIs	H&E

Table 2 Examples of models grading and scoring disease

Reference	Disease/condition	Task	Performance measure	Dataset numbers	Staining
Bulten et al. [46]	Prostate cancer	Gleason grading of prostate cancer	Deep learning system agreement with reference standard – quadratic Cohen's kappa of 0.918, AUC 0.990 for benign versus malignant, AUC 0.978 grade group 2 or more, and 0.974 grade group 3 or more	1243 WSIs	H&E
Ertosun et al. [50]	Brain cancer	Glioma grading	Classification accuracy of 71% for identifying the grade of LGG into Grade II or Grade III	54 WSIs	H&E
Qaiser et al. [48]	Breast cancer	Immunohistochemical scoring of HER2 status	Mean scoring accuracy for four classes ranged 0.65–0.794	172 WSIs	H&E, IHC
Ström et al. [47]	Prostate cancer	Gleason grading of prostate cancer	Average pairwise kappa for assigning Gleason grades of 0.62	6953 WSIs for training. Test set of 1631 biopsies and external validation set of 330 biopsies	H&E
Vandenbergh et al. [49]	Breast cancer	Immunohistochemical scoring of HER2 status	Overall accuracy 83% between AI and pathologist	71 cases	IHC

Table 3 Examples of models finding or outlining tumors

Reference	Disease/condition	Task	Performance measure	Dataset numbers	Staining
Argarwalla et al. [51]	Breast cancer	Tumor segmentation	Best reported F1 score 0.83	270 WSIs	H&E
Liang et al. [52]	Gastric cancer	Tumor segmentation	Mean accuracy 91.09%	1900 images	H&E
Jia et al. [53]	Colon cancer	Tumor segmentation	Best reported F-measures of 0.836 and 0.835 for cancer images	910 images	H&E
Qaiser et al. [54]	Colon cancer	Tumor segmentation	Accurate tumor segmentation on two datasets – F1 scores 0.9243 and 0.8273, respectively	125 WSIs	H&E

Finding Rare Events and Small Objects

Finding and highlighting small objects or rare events may assist the pathologist with a diagnosis of a range of diseases. Table 4 summarizes examples of models that identified these features.

Predictive Tasks

A compelling use for some AI applications is the ability to perform tasks that may be challenging,

subjective, or impossible for humans. AI may be manipulated to make a range of predictions from digital slides, including predicting grade, subtype, survival, disease recurrence, and mutation status. One model was able to successfully predict cases of biochemical recurrence of prostate cancer within 1 year, performing with an AUC of 0.845 on external validation [59]. In another example, an algorithm used for breast cancer cases was able to predict tumor grade with 82% accuracy, ER status with 84% accuracy, and 75% for a risk of recurrence score [60]. Using AI to make

Table 4 Examples of models finding rare events or small objects

Reference	Disease/condition	Task	Performance measure	Dataset numbers	Staining
Kashif et al. [55]	Colon cancer	Cell detection	F1 score 0.748	15 images	H&E
Tellez et al. [56]	Breast cancer	Mitosis detection	F1score 0.480	832 WSIs	H&E, PHH3
Wang et al. [57]	Lung cancer	Cell detection	F1 score 0.8215	300 lung cancer tiles	H&E
Xing et al. [58]	Brain tumor, pancreatic cancer, and breast cancer	Nuclei segmentation	Mean F1 score for nuclei detection: 0.77 brain tumor 0.88 pancreatic NET 0.78 breast cancer	31 brain tumor images 22 pancreatic NET images 35 breast cancer images	H&E

predictions, especially the molecular profile of a disease from H&E slides, could in future save time and money that are spent on additional tests, in turn, potentially reaching a faster diagnosis and progressing the patient's management at an earlier stage. The model capable of predicting ER status is one illustration of this, and a further example is the paper that described successfully predicting six lung cancer mutations with H&E slides [61]. This was performed with an AUC of 0.733–0.856 for mutations STK11, EGFR, FAT1, SETBP1, KRAS, and TP53, therefore potentially reducing the need for additional testing of these in the future. Table 5 summarizes predictive artificial intelligence tools.

Image Quality Tools

AI has been applied to other aspects of the surgical pathology workflow. A convolutional neural network was constructed to identify and quantify out of focus areas created during the slide digitization process and could be used to trigger a rescan of the slide before review by a pathologist if needed [65]. A further example explored image quality and the impact of image artifacts on machine learning, for a clinical trial dataset, and found a minimal increase in accuracy when these cases were removed [66]. Image quality is a growing area of interest for the application of artificial intelligence.

Grand Challenges

One approach to speeding up the development of digital pathology AI algorithms has been to create publicly available datasets and to challenge international researchers to develop solutions [67]. Examples include the Camelyon dataset which has been successfully used to create AI tools capable of detecting metastatic breast cancer in lymph nodes (Fig. 4) [68]. Another challenge focused on distinguishing between glioblastoma multiforme and low-grade glioma brain tumors [69]. A recent challenge called the Prostate cANcer graDe Assessment (PANDA) challenge was in progress at the time of writing and consists of a dataset of 11,000 WSIs of H&E-stained prostate biopsies [70]. There is a growing number of similar challenges with publicly available datasets across multiple medical specialties [71] (Fig. 5).

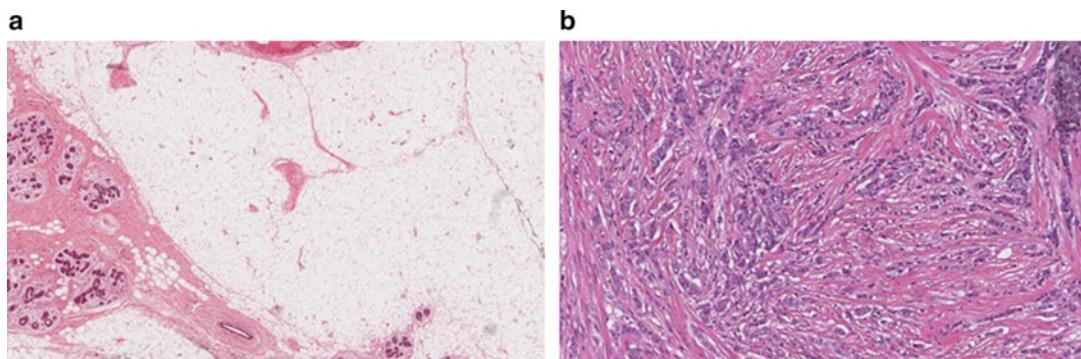

Technical Aspects of Digital Pathology

Digital pathology is the process of creating digital slides, and it involves four key stages:

1. Capturing the image
2. Storing the image
3. Manipulation and editing
4. Displaying and viewing the image [72]

Table 5 Examples of models performing predictive tasks

Reference	Disease/condition	Task	Performance measure	Dataset numbers	Staining
Coudray et al. [61]	Lung cancer	Genomics prediction from pathology images	AUC range 0.733–0.856 for six mutations	1634 WSIs +340 slides	H&E
Couture et al. [60]	Breast cancer	Prediction of cancer grade, ER status, subtypes, and recurrence risk	Accuracies were 82% for predicting grade, 84% for ER status, 77% for basal-like versus nonbasal like, 94% for ductal versus lobular, and 75% for high versus low-medium ROR-PT score	1203 cases	H&E, IHC
Kather et al. [62]	Colon cancer	Survival prediction of colorectal cancer	Demonstrated deep stroma score significantly prognostic of survival in all tumor stages HR 1.99 (1.27–3.12) whereas pathologist annotations were not in any stage	1382 WSIs	H&E
Tang et al. [63]	Brain cancer and lung cancer	Prediction of survival time of </= 1 year or >1 year	Best reported AUC for glioblastoma was 0.722 Best reported AUC for lung cancer was 0.702	424 WSIs of glioblastoma 305 WSIs of lung cancer	H&E
Veta et al. [64]	Breast cancer	Predict mitotic score and PAM50 proliferation score	Best reported mitotic score prediction: quadratic-weighted Cohen's kappa score $\kappa = 0.567$, 95% CI [0.464, 0.671] predicted scores versus ground truth Best proliferation score prediction: Spearman's correlation coefficient of $r = 0.617$, 95% CI [0.581 0.651] predictions versus ground truth	821 WSIs	H&E
Yamamoto et al. [59]	Prostate cancer	Predict prostate cancer recurrence	AUC 0.845 for predicting biochemical recurrence within 1 year on external validation	15,464 WSIs	H&E

**Fig. 4** (a) Digital slide of normal, benign breast tissue. (b) Digital slide of invasive breast cancer [4]

The availability of whole slide imaging technology that can rapidly perform these steps has made routine use of this a possibility in pathology laboratories [22].

Whole slide images (WSIs) are captured using digital slide scanners, typically using 20x or 40x objective lens which creates images of approximately 0.5 and 0.25 microns per pixel (MPP),

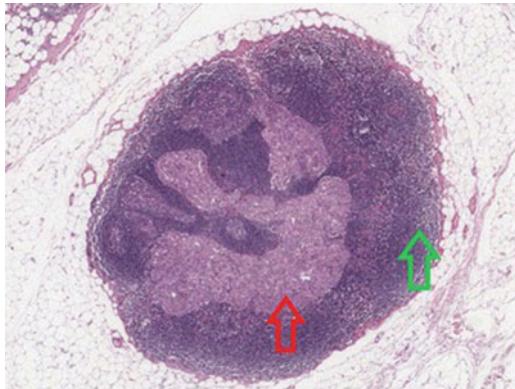

Fig. 5 Lymph node showing metastatic breast cancer (red arrow) and background normal lymph node tissue (green arrow) [4]

respectively [73, 74]. WSIs can vary significantly in size depending on the tissue scanned, the magnification used, and the image compression type [75]. As an example, a typical digital slide scanned at 20x (0.5 MPP) is approximately one gigapixel in size, and using JPEG2000 compression at image quality 70 requires between 200 and 400 megabytes of storage. Therefore, digital pathology imaging is highly demanding on image storage and archiving systems, and routine scanning can generate prohibitively large quantities of data, unless accounted for prior to deployment [76]. Currently, there is no common standard digital slide format [77], with each digital slide scanner vendor producing their own files, and often requiring their own software to view and analyze the images. However, collaborative work is being undertaken to extend the DICOM file format to incorporate digital slide images and pathology data [78]. Until this standard is achieved, many third party software solutions exist that can be used to view and analyze digital slides from multiple vendors [79].

The digitization of glass slides also introduces the possibility of image analysis and automated quantitation [77]. WSIs are stored as matrices containing red green blue (RGB) values describing the color of each pixel in the image, with three 8-bit values per pixel. It is these numeric values that form the basis of all subsequent automation and means that one digital slide can contain billions of values. The size of WSIs requires that

analysis must be done either at a lower power (zoomed out) or in parts – referred to as tiles, patches, or blocks – and aggregated in the final stages of processing [80]. Traditionally, image analysis in digital pathology used “low-level” techniques such as pixel-level thresholding and binary object morphology, to create hand-crafted image features that were fed into AI algorithms such as support vector machines (SVMs) and random forests, for predicting tissues classifications [80]. These methods have been rapidly phased out of digital pathology research due to the rising popularity of deep learning [29, 36].

Deep learning is a form of machine learning, which is in turn a subtype of AI, frequently used in digital pathology [28]. Deep learning is a form of artificial neural network (ANN) that uses auto-encoders to circumvent the traditional ANN issue known as the vanishing gradient problem [81]. This allows networks to be built using more layers (“deeper”), allowing more granular levels of representation, and subsequently higher prediction accuracy. Convolutional neural networks (CNNs) provide an additional framework prior to the ANN, whereby the pixel data from images are distilled into high level representations using three different processes: convolution, activation, and pooling [82]. The aim of these processes is to create an algorithm capable of interpreting raw input data (pixels in this case) by changing to more abstract representations of the data over multiple layers to make it more interpretable and identify important features [6, 83]. It uses a technique called back-propagation between layers of data to learn from looking at its past function and adjusts its internal parameters to minimize the error rate of each function’s prediction [84]. There are several phases to developing a deep learning algorithm [85] (Fig. 6):

- Data collection and formatting – deep learning algorithms require many training examples to ensure they are generalizable to real-world data [86]. Typically, networks are trained using labeled examples of images (supervised learning), and all images that pass through the network need a uniform size [87].
- Network architecture – the structure of the network should be designed according to the

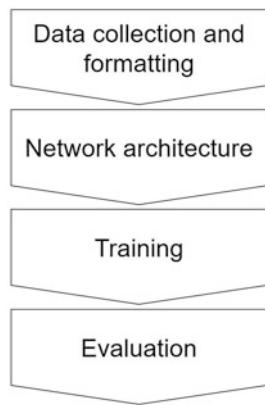

Fig. 6 Flowchart of key phases in developing a deep learning algorithm

visual task. This includes the arrangement of network layers, number of nodes per layer, and the convolution, activation, and pooling operations (if using a CNN). Alternatively, transfer learning is a popular method that takes existing network structures and retrains the algorithm on new training data [88].

- Training – the algorithm passes labeled examples through the network and adjusts its parameters based on their ability to correctly predict the image classification. Once every single image in the training set has passed through the network, the algorithm has processed one epoch. The number of epochs and other settings such as learning rate and batch size are known as hyperparameters, and these need to be optimized by the algorithm developer in order to maximize performance [89].
- Evaluation – deep learning algorithm design typically incorporates model evaluation or testing, which requires part of the dataset to be withheld from the training process [90]. The resulting model accuracy is then calculated from its predictive ability on the data that is not used for training. Cross validation is a popular evaluation strategy that iterates through the dataset in folds, so that each image is used in the testing process at least once [91].

Deep learning has seen a rapid rise in popularity due to the relative ease at which algorithms can be developed and deployed, as well as

outperforming traditional AI methodologies [92]. However, when deploying algorithms on real-world data, performance can be adversely affected by many factors:

- Overfitting – if the algorithm is not exposed to a training dataset that represents all the possible variations of images that it is likely to encounter, it will underperform on images that it has not seen before [93]. Algorithms need to be trained on a comprehensive dataset that has been carefully curated prior to processing.
- Variability in digital slides – image quality can affect algorithm performance by creating unnecessary variation to the appearance of digital slides [94]. Variation can occur as a digital or histological artifact and has the capacity to affect AI significantly [66]. Standardization of glass slide production and robust QC processes during scanning can help to mitigate this issue [95, 96], and color normalization is a popular tool for correcting stain variation after scanning [97].
- Human error in gold standard – due to the large volumes required, training examples that are hand-labeled inevitably contain human error [98]. These errors have less impact on algorithm performance in larger training datasets, but where it is infeasible to generate large numbers of training examples, it is considered good practice to double-score images.

Standards of Reporting of AI

A search of clinicaltrials.gov in December 2020 for terms “artificial intelligence,” “deep learning,” and “machine learning” revealed over 1000 registered clinical trials. In this growing research field, concern about the reporting and evaluation of AI technologies in healthcare is ongoing. To tackle this, Parikh et al. [99] proposed five criteria to consider in the evaluation of the quality of predictive algorithms in 2019. These were as follows:

1. Meaningful endpoints (e.g., patient survival, positive predictive value, or sensitivity)

2. Appropriate benchmarks (e.g., against “a clinician’s best judgment”)
3. Interoperable and generalizable (otherwise, these may be barriers to use by a clinician)
4. Specify interventions (e.g., the outcome of the algorithm links to an intervention to improve patient care)
5. Audit mechanisms (algorithms should be subject to ongoing audit after regulatory approval)

Following this, the provision of more extensive checklists was proposed to reflect the complexity and range of considerations for these technologies. The CONSORT-AI and SPIRIT-AI guidelines were released in 2020 as extensions of the existing Equator Network guidelines for clinical trials [100, 101]. These adaptations were developed in recognition of the differences in AI compared to other interventions, and as an attempt to standardize reporting of AI and improve transparency. The CONSORT-AI and SPIRIT-AI extensions contain 14 and 15 checklist items, respectively. These include the following:

- Stating the intended use of the AI intervention
- Giving the clinical context in which it should be used
- Details of the data inputs and expected outputs
- Details of the human-AI interaction
- How the outputs will impact decision-making or other aspects of clinical care
- How errors are handled

Additionally, further Equator network guideline extensions for AI were under development at the time of writing. The STARD-AI and TRIPOD-AI will be extensions of the current guidance for studies of diagnostic accuracy and multivariate prediction models, respectively [102, 103].

Deployment and Regulation

The widespread adoption of artificial intelligence in pathology is yet to happen, but a fully digitized workflow is generally considered a requirement to achieve this [104]. There are examples of many

centers who have already deployed digital pathology [105, 106], and there are recognized benefits to digitization in addition to its use for AI [76]. There are multiple considerations in the successful clinical adoption of AI. These may be broadly grouped into technical, infrastructure, or people-related issues, and some of these are listed below:

Technical

- To produce useful outputs, good quality input data is required, and even small changes in the input data when an algorithm is deployed can result in a reduction in performance [107].
- Current algorithms for surgical pathology are task orientated and rely on large amounts of training data. While there are no agreed optimal dataset sizes for training AI in digital pathology, the consensus is that to create robust algorithms that are transferable to routine pathology image data, algorithms should be trained on enough data to model such variation [67].

Infrastructure

- It is already difficult to manage large volumes of image data in digital pathology, but even more so additionally managing large numbers of extracted image features. This is a recognized challenge, along with having the systems able to cope with the data, algorithms, and their interaction [20].
- Digital pathology and AI may be expensive for laboratories to implement together at a good standard with systems that are adequately fast [67].
- AI tools for pathology will likely be introduced across multiple competing platforms, which will create issues around interoperability of the technology [108].
- Having the facilities for adequate visualization and visual analytics is vital in successfully interpreting imaging features of AI in digital pathology [20].

People

- There is much enthusiasm for AI in surgical pathology, but these systems are difficult to successfully deploy, and some may fail. It is important to maintain engagement from stakeholders when challenges are faced during the implementation of a new technology [67].
- Pathologists must have enough confidence in algorithms to sign out reports while using them, and there are new legal considerations associated with this [108].
- Involvement of members of the multi-disciplinary team in the development of AI could help in the practical implantation of algorithms into a pressured healthcare system [109].

Regulated clinical adoption of AI in healthcare is an area of growing importance, with an urgent need for a robust regulatory framework for tools that do not currently fit the measures in place [110]. Regulatory bodies are recognizing this need and starting to adapt to these technologies [111]. Despite the challenges, the first AI algorithms have received regulatory approval for use in clinical practice in pathology. Tools for supporting pathologists to detect prostate cancer [112] and PD-L1 positivity in lung cancer [113] are examples of algorithms with European CE-IVD approval. Similarly, there are examples with the US Food and Drug Administration (FDA) clearance for a breast cancer diagnosis algorithm [114] and algorithms for the diagnosis of multiple cancer subtypes [115]. Further guidance is likely to appear from regulatory bodies as more of these technologies are developed.

Education

Digital pathology and AI have created new ways of presenting surgical pathology education to medical students, specialty trainees, and for training and conferences in general [3, 116]. A practical use of the accumulation of the large

collections of cases for training and validating AI is that these could also be accessed for educational purposes [116]. The COVID-19 pandemic has highlighted the value of digital pathology use for training as it is very amenable to use remotely via secure videoconferencing software [117]. Some pathologists have created automated annotations and other interactive functions for trainees with this technology [3, 109]. Automated diagnostic aids could also support independent reporting of cases by surgical pathology trainees and biomedical scientists [109]. Finally, a general area for consideration is using education to build trust with pathologists, which could be achieved by adapting current training so that it provides a basic understanding of how these tools function and how to incorporate them into practice [108].

Conclusion

The landscape of AI in surgical pathology is changing continually, with new advancements appearing all the time. There has been significant progress in this field; however, there are still many barriers to overcome before AI becomes an established component of pathological diagnosis. Nevertheless, it is an exciting and dynamic area, and we are likely to see a transformation in the use of this technology in surgical pathology.

Abstract

Recent breakthroughs in the classification of thousands of images into defined categories by deep learning has led to the application of these algorithms and models to the field of medicine, particularly in histology and pathology. The evaluation of histological images obtained by a kidney biopsy is a key step in the diagnosis and assessment of disease status in the practice of clinical nephrology. Many studies have investigated how deep learning can be applied to nephropathology to evaluate complex structures present inside the kidneys. In this chapter,

we provide a brief discussion on nephropathology and introduce some of the most recent studies on artificial intelligence involving this field. Additionally, we also discuss about the implications of and challenges associated with the application of AI to nephropathology. The studies are divided into three subcategories based on the key objective of the presented study. These include (i) identifying the position of specific structures, especially the glomerulus (detection), (ii) segmentation and identification of various structures present in histological images (segmentation), and (iii) classification of specific images into clinically and pathologically defined categories (classification).

Keywords

Kidney pathology · Machine learning · Artificial intelligence · Glomerulus · Deep learning · Renal pathology · Nephropathology

Introduction

The evaluation of the histological images obtained through a kidney needle biopsy specimen is a key step in the diagnosis and assessment of disease status in clinical nephrology, combined with demographic and clinical information such as laboratory data. The histological evaluation includes various structural components including glomeruli, urinary tubules, renal arteries, and cellular components as well as their morphology. The evaluation must be performed across multiple stains that are used routinely, each of which has its advantages and disadvantages, including the commonly used hematoxylin and eosin (H&E), periodic acid-Schiff (PAS), periodic acid-methenamine silver (PAM), and Masson's trichrome (MT). Additionally, immunofluorescence (IF) staining performed to assess the deposition of immunoglobulins and other proteins (including complement and light chains), along with findings of electron microscopy such as identification of dense deposits, are combined. Moreover, in the experimental investigation, histological images of a resected nephrectomy

specimen obtained from rats or mice need to be evaluated. These include the investigation of nephrotoxicity of medications or disease condition and progression in gene knockout mice.

Computational evaluation of histological images offers automation, quantifiability, and reproducibility and has historically been well described. A recent breakthrough in the classification of large image datasets into defined categories using machine learning (ML), especially deep learning (DL) owing to increasing computational power, advances in scanning technology, and the storage of large datasets of virtual slides in medical institutions, has led to the application of these algorithms and models to medicine, including histology and pathology. DL algorithms, especially neural network architectures, have the potential to extract deep features from images by learning through multiple layers and subsequently can be combined directly with other data such as clinical variables and high-throughput sequencing data to perform an integrated analysis, which could pave the way for personalized medicine.

The importance of artificial intelligence (AI), including ML and DL in the evaluation of nephropathology, is gradually being recognized by the nephrology community. Several international consortiums have gathered and organized renal biopsy images and the associated clinical metadata into digital pathology repositories, and the application of DL to the data stored in such repositories has already been published [1]. Additionally, obstacles such as inter-pathologist disagreement regarding assessment, which leads to incorrect labeling in supervised learning, have been recognized [2], and a descriptor of kidney histological images has been proposed for standardization [3]. Moreover, the Banff 2019 Meeting discussed the potential use of AI in organ transplantation, such as for an automated evaluation of Banff classification and development of personalized medicine [4]. Here, supervised learning refers to ML that has a pair of input and labeled output, contrary to unsupervised learning, such as a clustering analysis, where labeled output is not available, and the algorithm finds patterns in data without previous knowledge.

Most notably, the number of studies investigating the applications of DL for performing complicated tasks involved in the assessment of complex structures and heterogenic pathological features of kidney histopathological images has been steadily increasing. These investigations are being carried out by those who are specialized in ML, nephrology, and pathology. Thus, in this chapter, the current studies involving AI in nephropathology, with specific focus on application, techniques, and algorithms, are introduced and summarized as a tertiary source for readers from other fields. For clarity, the studies were divided into three subcategories according to the study's major objective of application: detection, segmentation, and classification. Additionally, the subcategories were further divided based on the investigated tasks.

Detection

The computational evaluation of the histological findings of glomeruli in whole slide images (WSI) has been a central focus in the field. Urine is generated in the renal corpuscle, which is a small sphere approximately 200 μm in diameter, composed of the glomerulus and Bowman's capsule and is present in the renal cortex. The glomeruli reflect a variety of pathological conditions. To assess the glomeruli computationally, one must first annotate the position of the glomeruli in the WSI; however, manual detection and position annotation of thousands of WSI are labor-intensive for both needle biopsies and kidney sections. Thus, computational methods to detect the glomeruli in the WSI have gained interest. The difficulty of the task lies in the fact that the glomeruli present in all the different stains should be evaluated; however, the position of the glomeruli differs across stains, and sometimes a glomerulus present in one staining is not available in others. The studies usually evaluate the detection performance using precision (Eq. 1), recall (Eq. 2), and F1 score, which is a weighted average of precision and recall. When calculating precision and recall, true positives are usually defined by defined thresholds of intersection over union, calculated

by the area of overlap and area of union between manually annotated structures and predicted regions.

Detection Using Conventional Features

Samsi et al. proposed a method to identify glomeruli present in H&E-stained mouse kidney biopsy images by simple color segmentation, identification of regions corresponding to Bowman's space, and subsequent grouping of objects belonging to the same glomeruli [5]. The approach involving hand-crafted or traditional image features and ML algorithms, such as support vector machines (SVMs), has been historically performed in many studies. SVM is a popular supervised learning algorithm for classification and regression tasks; it finds maximum-margin hyperplanes using support vectors. Kakimoto et al. detected glomeruli in desmin-stained histological images from rats using a histogram of oriented gradients (HOG), a descriptor representing the shape features calculated using the histograms of gradient orientation and SVM [6]. From the same group, Kato et al. developed and used a customized HOG (named segmental HOG) combined with SVM to detect glomeruli in the slide images stained with desmin from rats and obtained an average F1 score of 0.866 [7]. Simon et al. used local binary patterns (LBP) combined with SVM and DL to successfully extract glomeruli from images of multiple stainings for mice, rats, and humans. LBP corresponds to the image features obtained by calculating the relative value of each pixel compared to that of the surrounding neighboring pixels. They applied the method on specimens of diabetic nephropathy (DN), a kidney-related serious comorbidity of diabetes mellitus with pathologies such as diffuse and nodular glomerulosclerosis [8]. Marée et al. proposed an approach for detecting glomeruli that first detected luminal regions by image thresholding and subsequently fit an ellipse using Fitzgibbon's fitting method in kidney needle biopsy samples. They applied the approach to MT-stained slide images [9].

Detection Using Deep Learning

DL algorithms can extract unsupervised features, rather than a calculation based on defined mathematical formulas, which makes it good for application to unstructured image data, particularly complex images such as histological images. Recent studies used DL algorithms and features derived from DL, especially convolutional neural networks (CNNs), to determine the position of the glomerulus. CNN is used most commonly with tasks involving images. CNN is composed of characteristic layers, including convolutional layers, which shift filters through images and extract feature maps to learn the patterns in the images, and pooling layers that reduce the dimensionality of the output of the previous layer. In nephropathology, Temerinac-Ott et al. used CNN to detect glomeruli from needle biopsy and nephrectomy slide images by performing a mutual comparison of the classification results of multiple stains, thus improving detection performance. The F1 score for a PAS-stained slide of a needle biopsy was 0.828 [10]. Bukowy et al. located glomeruli positions in MT-stained whole-kidney section images of rats using region-based CNN (R-CNN) and obtained an average precision and recall of 96.9% and 96.8%. Additionally, their proposed method could assess glomerular depth profiles [11]. R-CNN is an approach that is made specifically for the task of object detection, which combines selective search and CNN [12].

The proposed approaches worked well for detecting glomeruli in WSI, with single staining or different types of staining, judging from the performance. This may aid in the rapid and automatic identification of the glomerulus position, which is essential for generating the training dataset used in the supervised learning task. Glomeruli detection approach is gradually being replaced by the segmentation approaches discussed below, which are capable of concurrent identification of other structures in kidney histological images.

Segmentation

Image segmentation refers to the partitioning of images into multiple meaningful objects and has been one of the central focuses of DL studies involving images, which has led to the invention of networks for specific purposes like biomedical imaging and the broad application in medical images. The kidney pathology involves not only the glomeruli but also structures like the proximal and distal urinary tubules and renal arteries, which are evaluated for conditions like urinary tubulitis or arteriosclerosis. Accurate segmentation and identification of these structures in kidney biopsy images are also important along with concurrent detection of glomeruli. For this purpose, DL has been extensively used and has been successful in segmenting normal structures and pathologically changed structures in the kidney.

Segmentation of Glomeruli

Although the primary purpose is segmentation, some studies mainly investigate glomeruli identification in the slide images using the segmentation approach. Gadermayr et al. investigated multiple problems regarding the detection and segmentation of kidney biopsy images. They proposed an approach to classify glomeruli and non-glomeruli with a small amount of training data [13], segment PAS-stained renal WSI without training data [14], and proposed a method to segment sparse small objects in WSI [15]. Most recently, they proposed an approach that combined stain-independent supervised segmentation and unsupervised segmentation to segment kidney histological images. They performed image-to-image transition using generative adversarial networks to segment staining with unlabeled data, using staining for which labeling is available. They successfully applied the approach to PAS, acid fuchsin orange G, collagen III, and CD31 stained slide images, which would aid in keeping the manual labor required for annotation to a minimum [16]. Additionally, although the study may fall into the classification subcategory, Bueno et al.

used SegNet and U-Net to perform semantic segmentation and classification of the patches of WSI into non-glomerulus, glomerulus, and sclerotic glomerulus [17]. U-Net is a fully convolutional network (FCN), a network that is composed of only convolutional layers, developed specifically for biomedical image segmentation [18]. SegNet is also one of the FCNs with encoder-decoder architecture [19]. The study group made the corresponding glomerulus dataset available from the public repository, which would enhance the validation of the future development of AI-related nephropathology [20].

Segmentation of Multiple Structures

The mainstream of the segmentation task is to segment multiple structures, and some studies have already assessed the performance of DL in this task. Jayapandian et al. segmented biopsy images of patients with minimal change disease, which is a pathological condition that exhibits little or no abnormality in the glomerulus, using DL models. They evaluated the performance of the model by ground-truth annotation of the glomerular tuft, glomerular unit, proximal tubular segment, distal tubular segment, peritubular capillaries, and arteries. The annotation was performed by five nephropathologists, with four major stains. They achieved a high F1 score for the structures in multiple stains and found that PAS staining performed the best [1]. Most recently, Bouteldja et al. segmented PAS-stained images of the kidneys of various species under multiple conditions, including healthy and pathologic, into regions with renal tubules, glomerular tuft, glomerulus, artery, artery lumen, vein, and other remaining tissues using a modified U-Net. They revealed that the model could successfully segment and quantify the structure inside the images and confirmed that the approach could be applied to humans; it has the potential to serve as the general segmentation model of kidney biopsy images. Interestingly, the model performed well in the murine models, which have distinct pathologic characteristics of various causes, indicating

potential for applicability in pathological and normal conditions [21]. Additionally, a recent study by Ginley et al. proposed the use of CNN to segment normal glomeruli and glomeruli afflicted by pathological conditions of glomerulosclerosis, interstitial fibrosis, and tubular atrophy; they used circling annotation provided by pathologists for PAS-stained images. They also validated the model's performance in other institutions [22].

These studies provided premises that the digital quantitative evaluation for major structures evaluated routinely in kidney biopsies is possible, especially in pathological conditions where diverse structural changes occur, in addition to normal conditions. However, the problem of the identification of other structures not evaluated or annotated by the models, or segmentation in other complex pathological conditions, needs to be investigated in future studies.

Classification

The glomerulus exhibits complex pathologies including mesangial hypercellularity, sclerosis caused by obstruction of the capillary space due to increased extracellular matrix, and crescent formation caused by extracapillary proliferation. In nephropathology, evaluation and classification of the findings present in an image of the glomerulus are crucial for evaluating slide images of patients with conditions such as suspected glomerulonephritis. This is because conditions such as crescent formation reflect high disease activity and poor prognosis. The classification and quantification of pathologies in structures other than the glomeruli have also been reported in the literature. Moreover, attempts to classify images according to clinical variables assessed in the clinical practice of nephrology have been described. Often combined with detection and segmentation discussed above, classification has been investigated extensively as these evaluations have potential clinical significance, such as for the automation of the staging of a specific disease. The classification performance of a defined label is often assessed by Cohen's kappa, which evaluates the inter-rater

agreement of categorical classification using the proportion of agreement and the expected proportion of agreement between raters.

Classification of Major Pathological Findings

The proposal for models or frameworks performing classification of having specific findings, often seen in clinical practice, has been well described in various stains. Barros et al. extracted features from glomeruli images using image processing and pattern recognition methods such as Otsu's thresholding, an automatic image thresholding method. They used the k-nearest neighbor algorithm, one of the ML algorithms that assign a label of the most general category near k objects in the feature space to classify the images as having proliferative glomerular lesions or not in H&E and PAS-stained slides. They obtained a precision and recall of 88% in the validation dataset [23]. Sheehan et al. proposed a framework for identifying glomeruli and scoring the mesangial matrix expansion in the PAS-stained slide images, using ML and some image processing methods. The scores obtained by the approach had a significant correlation with the manual scoring performed by renal pathologists [24]. Kannan et al. fine-tuned Inception V3 (the high-performance CNN architecture introduced in 2015 by Google regarding the classification of the images in ImageNet [25, 26]), to classify images obtained by the sliding window approach into the non-glomerulus, normal or partially sclerotic glomerulus, and globally sclerotic glomerulus categories within images stained with MT. They obtained a high accuracy of 92.7% in discriminating non-glomerulus images and images from other categories [27]. Fine-tuning here refers to making some of the layers including the last output layer of the pre-trained model and training the new model using its own datasets, thus transferring the knowledge learned in the other model. Marsh et al. proposed a method for the identification of globally sclerotic glomeruli from frozen section biopsies of kidney

transplantation donors using the fine-tuning of VGG16, a popular CNN architecture for ImageNet classification. The identification of the proportion of globally sclerotic glomeruli is important for assessing transplant outcomes, and the proposed approach yielded high performance [28]. For the evaluation taking multiple major stains into account, Wu et al. proposed a generator-to-classifier framework that classifies glomeruli into segmental, global sclerotic, and normal glomeruli. This approach considers features from the four major stains used routinely for evaluating kidney biopsy images generated by generative adversarial networks. They successfully classified sclerotic versus normal glomeruli and segmental and global sclerosis [29]. The studies mentioned above mainly investigated one or few of the findings evaluated in renal pathology. They succeeded in classifying important pathologies, especially global and segmental sclerosis; however, many other findings remained. For the simultaneous evaluation of models for multiple pathological findings, Uchino et al. developed classifiers of seven major pathological findings of a glomerulus, namely, global and segmental sclerosis, endocapillary proliferation, basement membrane structural change, mesangial matrix accumulation, mesangial cell proliferation, and crescent. By fine-tuning of Inception V3, they found that the classification performance of the models was close to that of nephrologists, although the performance was low to moderate, except for global sclerosis, in PAS and PAM staining [30]. Yamaguchi et al. evaluated the concordance of the annotation of 5 pathologists in 12 features and trained the CNN for features with high Cohen's kappa. The models discriminating the findings of capillary collapse and fibrous crescents yielded high performances, and the visualization results of the true positives showed that the CNN correctly pointed out the regions with respective features [31]. These studies proved that DL can be applied to discriminate between major pathological findings of glomeruli; however, more subtle findings have been poorly investigated or have low performance, possibly owing to a limited amount of available data.

Classification and Identification of Specific Components

The classification and identification of more specific and detailed components and pathologies have been investigated in several studies. These components have more inter-nephropathologist disagreements; therefore, the application of DL is considered necessary. Chagas et al. used CNN combined with SVM to classify glomeruli as having hypercellularity or not in H&E and PAS staining. They also further divided the hypercellularity into lesions of mesangial, endocapillary, and both regions and obtained an average accuracy of 82% [32]. Zeng et al. used CNN and image processing methods to locate glomeruli in the whole slide, identify glomerular lesions, and classify the glomeruli into segmental, global sclerotic, and crescentic in PAS-stained images of patients with IgA nephropathy (IgAN). Moreover, they divided the intrinsic cells into mesangial, endothelial, and podocyte types and compared the identification performance with that of junior pathologists, and the ground truth was given by senior pathologists. Additionally, network-calculated mesangial hypercellularity scores were compared with those provided by senior pathologists. The results indicated high Cohen's kappa values for the classification of segmental and global sclerotic and crescentic glomeruli and for mesangial score assessment. Additionally, the network identification of intrinsic cells inside glomeruli outperformed those of junior pathologists [33]. Chen et al. proposed a method to classify normal glomerulus and glomerulus having spike formation in membranous nephropathy (MN) in PAM-stained images using U-Net and multiple instance learning. Spike formation is one of the important changes induced by MN in the basement membrane [34]. Multiple instance learning is a weakly supervised learning method, applicable when a small amount of label is available [35]. These studies provided proof of concept that detailed features within glomeruli could be captured and quantified by DL.

Classification Based on Pathological Category

In some diseases, the pathological class or stage has been proposed and widely integrated into clinical guidelines used in daily practice. DL can carry out classification based on the annotated labels of these validated classes. For the classification of such classes and stages, Ginley et al. proposed a method to assess glomerular pathology in DN by combining CNN and recurrent neural networks (RNNs) in PAS staining. RNN is a neural network architecture that takes into account continuous information when learning, especially applicable in time series data or natural language processing. The classification of the DN stages determined by the approach had a moderate agreement with senior pathologists assessed by Cohen's kappa [36]. The same group proposed a method to automatically quantify glomerular lesions of lupus nephritis (LN) by a set of hand-crafted features and RNN. They classified biopsy images into class II to IV and additional V of LN and compared the results to pathologists. They achieved moderate Cohen's kappa [37]. Although these studies focused on DN and LN, other forms of glomerulonephritis that require staging, like the MEST-C score of IgAN, could be evaluated by the application of these models or other relevant DLs.

Classification of Images with Immunohistochemistry

In addition to stained light microscopic images, Ligabue et al. used CNN to classify images of IF staining. Assessment of IF staining is crucial in the diagnosis of conditions such as IgAN, and the classification of complex combinations of their appearance, distribution, location, and intensity requires expertise. They revealed that the performance of the models regarding classification was comparable with that of experienced pathologists, and the processing time of machines was faster than that of humans [38]. Choi et al. proposed a method combining Inception V3 and Faster R-CNN, a faster implementation of R-CNN, to

detect peritubular capillary (PTC) in the slide images and C4d immunohistological staining of PTC. This is an important histological feature of antibody-mediated rejection in kidney transplantation. The C4d score calculated by the proposed approach was in concordance with that of pathologists and had a significant relationship with clinical outcomes such as graft survival [39]. These applications in immunohistochemistry could be combined with other routine stains to achieve better classification of findings or prediction of renal outcome.

Classification Based on the Clinical Category and Genotype

One of the scarcely investigated tasks is the relationship between clinical variables and features derived from nephropathology images. One study investigated CNN performance on classification according to the clinical category. Kolachalama et al. assessed the relationship between histological images stained with MT and categorized clinical variables such as serum creatinine, proteinuria, and prognostic information corresponding to renal survival, by fine-tuning of Inception V3. The study revealed that for all the models of creatinine, proteinuria, and 1-, 3-, and 5-year renal survival, the CNN estimated better than the model based on the nephropathologist-estimated fibrosis score [40]. Additionally, combined with genetic information, Sheehan et al. used features derived from AlexNet, a popular CNN architecture, and SVM to detect glomeruli from WSI of PAS-stained mouse kidney histological images and classified the glomeruli based on the genotype. They successfully classified glomeruli into the genotype of Far2, which is related to mesangial matrix expansion and has been proved to increase in various clinical glomerulonephritis using features derived from glomerulus images. This study proved the potential of DL application to slide images to discriminate the genotype [41].

Summary and Future Implications

In this chapter, we summarized the current applications of DL in nephropathology, defining the subcategories of the investigated tasks. We introduced relevant studies and current perspectives for each subcategory. As summarized above, the segmentation of major components in kidney pathology has been performed in both pathological and normal slide images and successful. Additionally, many frameworks for classification across pathological findings and clinical variables have been described.

There are many other pathological conditions that are yet to be assessed, such as virus-associated kidney injury which is important in kidney transplantation; however, enough training data might not be available due to the rarity of these conditions. The performance of these domain-specific models is promising; however, the integration and implementation of the proposed frameworks in real-world clinical settings and the evaluation of the clinical significance of machine-derived classification and features, along with the interpretation of the rationale behind the prediction of DL models for human understanding, have not been satisfactorily described. This could be a future direction for the field. Additionally, the combination of features derived from established models of kidney pathology images, combined with transcriptomes, radiomics, or data from electronic health records for the prediction of outcomes or disease mechanisms, namely, multimodal learning, is still poorly investigated in the nephrology field compared to the fields like oncopathology. Most of the investigated tasks are performed by supervised learning, and extracting the features from kidney images in an unsupervised manner could extract novel features related to clinical outcomes.

DL application in nephropathology would aid in assisting nephrologists or pathologists clinically. The methods and algorithms of ML are still improving, and an in-depth understanding of the advantages and disadvantages of these newly invented methods is needed for

the implementation of these technologies in real clinical practice.

Abstract

In medicine, dermatology is a promising pioneer for the use of artificial intelligence (AI). In dermatological practice, the recognition of visual patterns (morphology) has always been fundamental for making a diagnosis, so artificial intelligence has great potential here. The collection of clinical data, especially image data, is playing an increasingly important role in the diagnosis and therapy of skin disease. Existing analog data archives are being digitized and restructured with great effort, and

new data sets are often captured and labeled directly in digital form. During the last years, a growing number of studies have demonstrated AI's benefits in research settings, and first applications are already used clinically. Particularly in the detection of skin cancer and for the quantification of chronic inflammatory skin diseases, artificial intelligence is supporting doctors as well as patients to find the right diagnosis and treatment. The purpose of this book chapter is to discuss the potential applications of artificial intelligence in various areas of dermatology.

Introduction

Up to two billion people worldwide are affected by skin conditions, prevalent across locations and age groups. Dermatology is a multifaceted discipline, ranging from aesthetic complaints to chronic inflammatory diseases and malignoma. Skin cancer is the most common cancer globally, with melanoma being the deadliest form.

Dermatology is a pioneer for the use of artificial intelligence (AI) in the field of medicine. The recognition of visual patterns (morphology) is fundamental for making a diagnosis in the dermatological practice, so artificial intelligence has great potential here. The collection of image data is playing an increasingly important role, focusing on diagnosis and treatment of skin disease. Existing analog data archives are digitized and structured with great effort, and new data sets are often captured and labeled directly in digital form. During the last years, a growing number of studies have demonstrated its benefits in research settings, and first applications are already in clinical usage. Particularly in the detection of skin cancer and for the quantification of chronic inflammatory skin diseases, artificial intelligence is supporting doctors as well as patients to find the right diagnose and establish sufficient treatment. The purpose of this chapter is to better understand the application possibilities of artificial intelligence in various fields of dermatology.

AIM in Dermatology

In the later part of the 2010s, artificial intelligence has gradually provided increasing clinical value in different areas of dermatology including skin cancer, psoriasis, eczema, and other skin diseases. In January 2017, a publication by Stanford

University in Nature attracted a great deal of media attention. A neural network achieved sensitivity and specificity comparable to 21 human dermatologists in distinguishing between keratinocyte carcinomas and benign seborrheic keratoses as well as between malignant melanomas and benign nevi on 130,000 histologically verified clinical test images [1]. Three years later, another study in Nature presented similar results for differential diagnosis across the 26 most common skin conditions in primary care, which for the first time analyzed images in combination with medical history data [2]. The basis for these studies is the so-called convolutional neural networks, which analyze image data in a manner inspired by biological processes of receptive fields. From the color values per pixel, simple structures called “features” are first extracted and combined into increasingly complex features, which should ultimately enable the recognition of an object category. Mathematical filter operations form the basis of this feature calculation. These processes can be used to highlight lines, edges, or other basic structures. These processes take place in an increasingly automated manner through pattern recognition and improve independently with an increasing amount of supplied image data.

Area of Application: Skin Cancer

Especially in image-based skin cancer diagnosis, computer-based image analysis has become increasingly important. Skin cancer in general is one of the most widespread cancers worldwide, with nonmelanoma skin cancer the most common cancer with a lifetime prevalence in Central and Northern Europe of 10–15% and increasing incidence [3]. Early detection of skin cancer has a major impact on prognosis. In the detection of skin cancer and especially in the differentiation of moles from melanoma, dermoscopy plays a central role, complementary to macroscopic assessment and medical history. Correct dermoscopic diagnosis is often a major challenge, as a broad spectrum of rarer differential diagnoses must first be excluded.

The analysis of dermoscopic images for the evaluation of moles and melanomas has been described in several research papers. In recent studies, convolutional neural networks outperformed dermatologists in distinguishing dermoscopic images of melanoma and nevi. A review from 2019 counted 1694 performed studies in this field, the majority in the field of computer science [4]. The widely cited study “Man against machine” from Heidelberg, Germany, investigated the diagnostic precision of a trained convolutional neural network compared to dermatologists and experts from all over the world and found that it was superior to most but not all dermatologists [5]. Based on this study, an algorithm-based evaluation tool for melanocytic lesions was approved for clinical use, which analyzes a dermoscopic image of a lesion and generates a numerical value that classifies the lesion as malignant or benign. In another study, the convolutional neural network also performed better than the dermatologists in most cases, in terms of the dermatopathological results of the lesions [6]. Nevertheless, it should be noted that these results were described under controlled conditions and cannot be replicated in clinical practice to date. Also, in the analysis of dermoscopic images of nonpigmented skin lesions, there are first publications comparing the diagnostic accuracy of

neural networks with that of dermatologists – with comparable results for both groups [7, 8]. With similar intention, a yearly event is conducted by the *International Skin Imaging Collaboration* (ISIC) [9]. Using a data set of over 25,000 dermoscopic images, international teams compete against each other with their algorithms. In all these projects and studies, dermatologists and artificial intelligence were considered as opponents. However, studies have found that the combination of human and artificial intelligence can achieve superior results to the independent results of either system [10] (Fig. 1).
