Computer-based analysis of dermatoscopic images has the advantage that the images are usually acquired in a standardized fashion. This is different than when clinical, macroscopic images are acquired – especially when they are taken directly by the patients. Several applications (e.g., *SkinVision BV*) nowadays provide risk measures of pigmented and nonpigmented skin lesions based on macroscopic images taken by the patient. Some of these applications exhibit a high sensitivity in detecting skin cancer [11]. However, there is still room for improvement [12].

Additionally, to the analysis of dermoscopic and clinical images of melanoma, recent studies performed computer-based decision-making on dermatopathological images. For melanoma, the

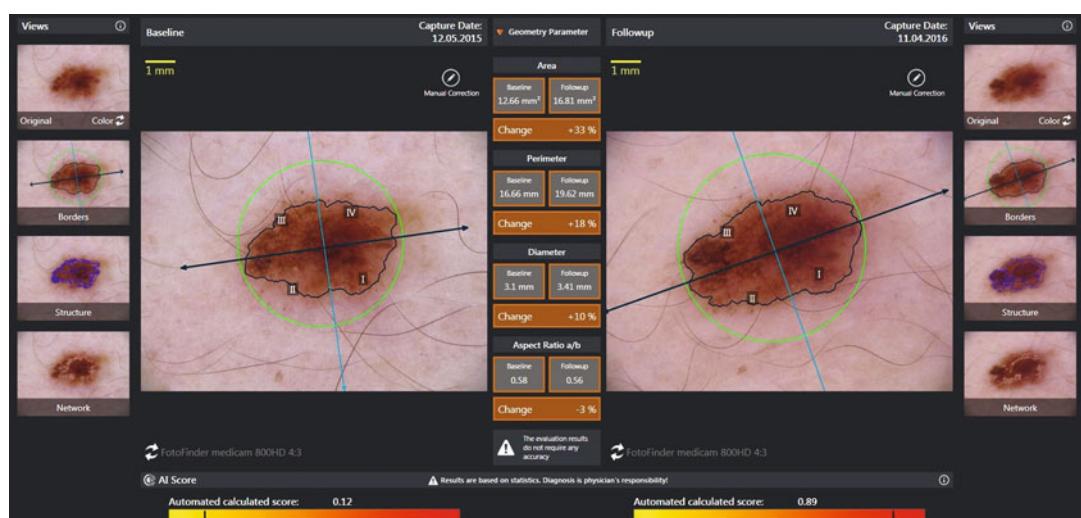

Fig. 1 Algorithm-based evaluation tool for melanocytic lesions. (© 2021 FotoFinder Systems GmbH)

literature reports 25–26% of discordance for classifying a benign nevus versus malignant melanoma between individual pathologists. Convolutional neural networks can thus be a valuable tool to assist human dermatopathological melanoma diagnoses [13].

Area of Application: Psoriasis

In addition to extensive studies on the detection of skin cancer using AI, the quantification as well as qualification of inflammatory dermatoses by computer-based decision-making has become a research topic with increasing popularity. With a prevalence of 2.5%, psoriasis is one of the most common inflammatory skin diseases among Caucasians.

The *Psoriasis Area and Severity Index* (PASI) and *body surface area* (BSA) criteria represent the gold standards for psoriasis severity assessments. A PASI and BSA of >10% or more indicate moderate to severe psoriasis, which is also the threshold for reimbursement of expensive systemic therapies in most countries.

Compared to examiner-dependent variability in PASI and BSA, AI-based algorithms have the potential for reproducible, standardized evaluations of these scores. Different studies show that

the assessment of erythema [14], as well as induration and scaling [15], is already technically possible through artificial intelligence. Computer-assisted programs for PASI can accurately calculate the proportion of psoriatic skin surface as well as the severity of erythema, induration, and desquamation by anatomic region. In pilot clinical validations, the technology showed a high reproducibility and high levels of agreement to results attained by PASI-trained physicians [16, 17] (Fig. 2).

Meanwhile, in addition to disease quantification, artificial intelligence can also help to provide a diagnosis of psoriasis. An algorithm that had to distinguish between 9 diagnoses based on 100 clinical pictures made fewer misdiagnoses of psoriasis and missed fewer diagnoses of psoriasis compared to 25 Chinese dermatologists [19].

After the diagnosis of psoriasis has been confirmed, artificial intelligence offers additional benefits in therapy planning. In a real-world setting, many patients with psoriasis need dose adjustments or changes to prescribed medication. One research project used the example of a biological therapy (IL-17A inhibitors) to show that machine learning can be used to determine which patients would benefit from modifications to the initial prescribed drug doses [20]. Another research team was able to predict the long-term

Fig. 2 Patient with psoriasis vulgaris. (a) Affected body surface area predicted by machine learning algorithm compared to manually marked area by experts. (b) Clinical findings with erythrosquamous plaques of the same patient

without markings [18]. (© Reprinted by permission from Springer, *Der Hautarzt*, Role of artificial intelligence in assessing the extent and progression of dermatoses, Maul et al. (2020))

responses of patients with psoriasis to biological therapies in general [21]. For the two biologics *tofacitinib* and *etanercept*, the long-term response to the drug treatment could be predicted by analyzing systemic inflammatory proteins measured before and several weeks after treatment initiation using a machine learning-based algorithm [22].

Overall, an improvement in diagnosis and treatment is expected in psoriasis patients, thanks to artificial intelligence.

Area of Application: Eczema

In contrast to the skin changes of psoriasis, which are mostly sharply defined and with a high contrast to unaffected skin, eczema phenotypes are often diffuse and vary depending on the disease stage and the cause of the eczema. For computer-assisted image diagnosis of eczema diseases, the challenge therefore is not only to discriminate correctly between healthy and affected skin but also to differentiate between different forms of eczema. In order to train algorithms to provide an AI-supported image analysis of these diverse assessment parameters, a large initial quantity of

image files is required. These might need to be further processed or enhanced.

Thus, current literature only contains sparse work on the use of artificial intelligence in the context of eczema. There are studies detecting eczema versus noneczema cases [23] or evaluating electronic patient data for phenotyping potential atopic patients, with predictive mechanistic models of progression and treatment response [24]. In studies with more clinical relevance, algorithms could identify various forms of eczema (e.g., seborrheic dermatitis, chronic eczema) [25] and were able to differentiate between eczematous and infectious conditions [26]. The latter distinction is particularly interesting, as it could be used to derive therapeutic suggestions.

Experimental studies have also investigated the detection of hand eczema from standardized images. However, clinical applicability in daily practice has not yet been achieved [27]. For example, jewelry or deep hand lines were misinterpreted as diseased skin. Also, the detection of less pronounced eczema is currently still problematic (Fig. 3).

Overall, algorithm-based analysis for an examiner-independent diagnosis of the spread

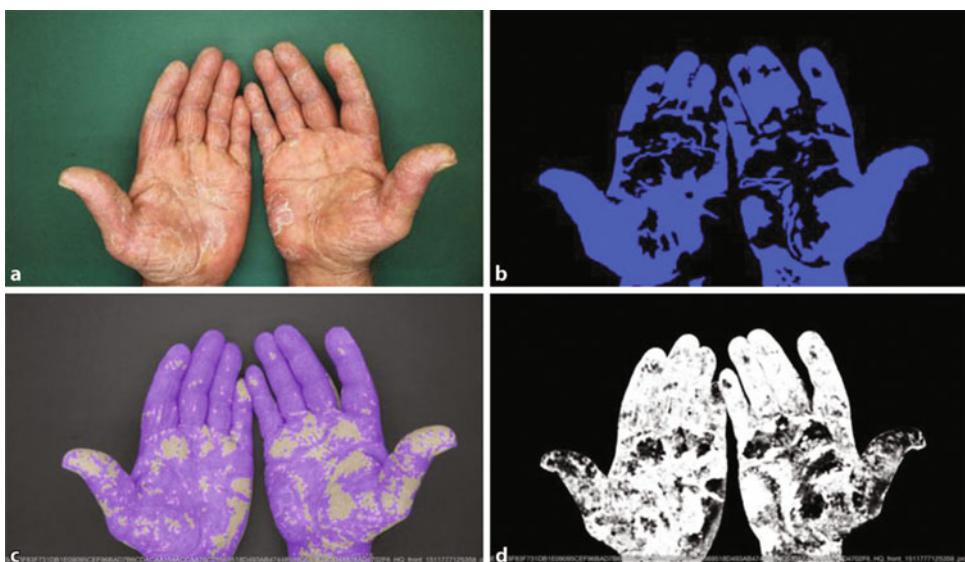

Fig. 3 Performance of the trained algorithm in a case with hand eczema. (a) Input image. (b) Extracted expert label. (c, d) Superposition of the computed images [18]. (©

and severity of eczema disease that is comparable to diagnoses existing for psoriasis is not yet available.

Area of Application: Other Skin Disorders

There is also preliminary experimental experience with the use of artificial intelligence in other dermatological diseases. In the diagnosis and quantification of vitiligo [18], acne vulgaris [28], onychomycosis [29], allergology [30], and dermatopathology [13], algorithm-based diagnostics performed similarly to comparison groups of dermatologists.

An early 2017 study demonstrated the possibility of diagnosing acne vulgaris using a neural network [31]. Recent publications on the application of computer-assisted systems to acne vulgaris are based on large data sets of cell phone photographs of affected patients. The data sets are used to develop AI-based algorithms to determine the severity of facial acne and identify different types of acne lesions or post-inflammatory hyperpigmentation [32]. Other applications monitor the disease progression and recommend a visit to the doctor if necessary. Especially in the case of acne vulgaris, such a procedure could prevent more severe consequences with permanent skin damage in the form of scars.

Recently, artificial intelligence has also been successfully applied to the diagnosis of onychomycosis. Based on almost 50,000 finger and toenail images, the computer-based image analysis was able to demonstrate a higher diagnostic accuracy than a group of dermatologists [29].

These new technologies have also found increasing application in the beauty industry. There are the so-called smart mirror analyzers on the Internet (e.g., *HAUT.AI*), which are AI-supported technologies with image recognition systems that analyze the skin and are supposed to recommend skin care products based on the appearance of the skin and the current weather forecast. It remains questionable to what extent such applications are misused for advertising purposes by cosmetic professionals and whether they

dissuade patients from consulting a doctor when necessary.

Dermatologist Attitude Toward Artificial Intelligence

Interestingly, although the number of studies is increasing, there are relatively few papers in which dermatologists are significantly involved in the conception, design, and interpretation of the studies. Most studies are led by computer scientists and engineers [33]. As a practicing dermatologist, one must become aware of the potential benefits, but also the possible disadvantages in daily clinical routine. Overall, dermatologists have an optimistic attitude toward artificial intelligence. Majority of dermatologists believe that artificial intelligence will improve dermatology and think that it should be a part of medical training. An increasing understanding of the application of artificial intelligence within dermatology was correlated with a positive attitude. Only a minority of dermatologists agree or strongly agree that the human dermatologist will be replaced by artificial intelligence in the foreseeable future [34]. Ultimately, it is wise to consider technological advances in a healthcare system while critically analyzing the drawbacks of such innovations.

Limitation of Artificial Intelligence in Dermatology

Time and again, technical systems surpass human performance under laboratory conditions and then fail in everyday clinical practice due to aspects as process integration, acceptance by users, inoperability in stressful situations, or the technical circumstances. High significance in research under experimental conditions does not correlate with the actual significance in practice.

Even though the use of AI in outpatient settings, such as for dermoscopic differentiation of malignant and benign skin tumors, seems to become increasingly realistic, there are several limitations to the usage of artificial intelligence

in daily dermatological practice. Available and relevant medical image data can be limited, due to rarely occurring conditions, privacy issues, and especially the lack of human experts available to annotate training data. Also, the quality of image data is often lacking due to overexposure or underexposure, reflection, or blurred pictures. Additional misdiagnoses often occur due to artifacts (e.g., tattoos, hairs, air bubbles, skin flakes, markings, coffee stains) [35]. The accuracy in differentiation that can be achieved by machine learning depends largely on the quantity as well as the quality of the available data.

Besides the technical challenges that limit the application of artificial intelligence in clinical practice, the lack of public acceptance also plays a decisive role. This is significantly lower in medicine than in other areas (e.g., smartphone facial recognition). In addition to data protection, a lack of patient understanding also seems to limit willingness to use AI-based services.

Better Applicability of AI Thanks to Teledermatology

National and international working groups support the establishment of teledermatological projects (e.g., *derma2go AG* [36], *e-derm-consult GmbH* [37]) and in recent years have increasingly been using AI-based technologies to support doctors on site. Previous efforts to establish AI in everyday dermatology have had limited success because of the lack of concrete use cases in clinical practice and the fact that algorithms had been developed using standardized images. Recent learning success in automated diagnosis of skin lesions using clinical smartphone images, some of which are low-resolution, suggests that these technologies are now ready to be tested in or made available to daily practice [38]. Thus, AI in telemedicine is becoming an achievable reality to expand dermatologic care options and further reduce costs and waiting times. For example, AI could serve as a clinical diagnostic support tool for dermatologists engaging in telemedicine or to direct ambiguous or malignant pathologies to an available physician. Solutions are needed which are also viable for a

large number of patients. These must focus on being able to treat the simple problems as automatically as possible, so that the expertise of the few human dermatologists can be reserved for the evaluation and treatment of complex problems. As an example, the *PASSION project* aims to use AI to identify five visually easily identifiable dermatoses in children and treat them according to a standardized procedure [39]. This will not lead to the elimination of in-person dermatology consultations, as not all dermatoses can be identified and treated using teledermatology. The best results were obtained when AI and physician were combined, especially when the physician was inexperienced. Because of a shortage of dermatologists, cases are often seen by general practitioners with less diagnostic experience (Fig. 4).

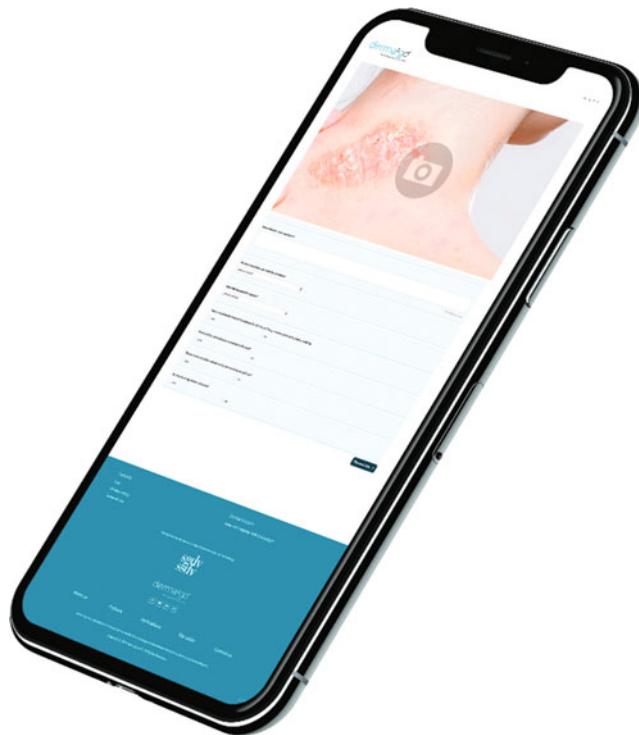

Ethnic Variations as a Challenge in the Development of Algorithms

Ethnic variations represent a challenge in the development of automated algorithms. Many algorithms developed so far were based on clinical images of Caucasians with skin types I–III according to Fitzpatrick. Conventional clinical experience shows that pathologies may present differently in their efflorescences (especially redness, scaling, lichenification) depending on the skin type. Also, dermatologic pathologies, such as the manifestations of atopic dermatitis, differ worldwide. In Africa, patients with atopic dermatitis have more follicular and lichenoid lesions; in Asia, lichenification and prurigo forms are more common; in India and Iran, flexural involvement is less frequent [40].

A pilot study in which an AI model was trained in an Asian population and subsequently validated in a Caucasian population found the procedure to be error-prone [41]. To further improve the accuracy of the systems in this regard and to be able to generalize to other ethnicities and skin types, it is important to increase the number of available clinical images of patients of different ages and ethnicities.

Several research groups worldwide have taken up this topic. *The Africa Teledermatology Project*,

Fig. 4 AI in telemedicine is becoming an achievable aim. (© derma2go AG)

supported by the *Commission for Development Studies of the Austrian Academy of Sciences* and the *American Academy of Dermatology*, has been building up a corresponding database for teaching and research purposes for years.

To further improve the accuracy of the systems and to be able to provide global solutions, it is important to increase the amount of available clinical data. This can only be achieved with the active participation of local healthcare providers as well as the dermatological community, always considering the interest of the individual patients.

Abstract

Acute kidney injury (AKI) is a disease defined as an abrupt decline in kidney function and is a common complication in

hospitalized patients with high clinical significance. Recently, a model for predicting the onset of AKI clinical data by machine learning using electronic medical record data has attracted researchers' attention. The state-of-the-art model has achieved high discrimination performance of area under the curve ≥ 0.9 . Accordingly, these models are expected to be used for appropriate clinical intervention and disease prevention. In this chapter, we review the studies on AKI onset prediction and discuss their major issues. Since the event definitions, prediction timepoints, and prediction target periods used in the models

Introduction

Kidneys play a central role in maintaining homeostasis in the human body. Their functions include the excretion of waste metabolites; regulation of fluid volume, electrolytes, and bone-mineral balance; and production of hematopoietic hormones. To measure overall kidney function, glomerular filtration rate (GFR) is accepted as the best indicator. In daily clinical practice, serum creatinine (SCr) levels are usually measured to estimate GFR. Using the SCr and estimated GFR values as indicators, diseases can be diagnosed. These include acute kidney injury (AKI), which is a rapid decrease in renal function, and chronic kidney disease (CKD), which is a chronic decrease in renal function. Predicting the onset and course of the disease is a clinically important challenge. Moreover, it is important to accurately predict the course of these clinical events and numerical values of their key indicators. The renal function and its temporal changes can be predicted numerically based on available clinical data. Thus, available models can be readily used to predict related transitions and events. Here, we review recent progress in these prediction models focusing on the onset of AKI as the most studied case.

AKI Overview

Acute kidney injury (AKI) is a common complication in hospitalized patients and is associated with high morbidity and mortality [1]. A recent meta-analysis has reported that one in five hospitalized patients develops AKI [2]. It is considered a major health issue, with 300,000 deaths annually in the United States, an average increase in hospital stays of 3.5 days, and a significant increase in medical expenses [3].

RIFLE (risk, injury, failure, loss of kidney function, and end-stage kidney disease) [4] and AKIN (Acute Kidney Injury Network) [5] criteria have been originally proposed and used for the diagnosis of AKI. More recently (in 2012), they have been replaced by KDIGO (Kidney Disease: Improving Global Outcomes) [6] criteria that are currently considered as a gold standard. According to the KDIGO criteria, AKI is diagnosed by meeting at least one of the following: (1) SCr increase by ≥ 0.3 mg/dL, (2) SCr increase to 1.5 times the baseline within 7 days, and (3) urine volume < 0.5 ml/kg/h for 6 h. AKI is also categorized into stages 1–3 by its severity [6].

Background for AKI Prediction

Early intervention of nephrologists, clinical specialists in this area, is crucial in AKI management, as discussed in the literature [7, 8]. More specifically, recent studies considered e-alert systems for automatic detection of AKI and accompanied intervention and demonstrated multiple clinical benefits, including shortening hospital stay [9]. On the other hand, it has been reported that simple, early detection alone does not reduce the mortality rate and subsequent renal function in randomized trials [10]. Thus, machine learning (ML) AKI models are considered a promising tool for early intervention and prevention.

Multivariate analysis has been widely used to assess risk factors of AKI. For instance, it has been efficient in several settings, including after cardiovascular surgery (patients with high risk of AKI [11–17]), after myocardial infarction [18], intensive care units (ICU) [19] sepsis patients in

ICU [20], pediatrics [21], pediatric ICU [22, 23], and general patients [24–27]. On the other hand, in recent years, there have been reports on machine learning models that comprehensively use available variables for more individual predictions with higher accuracy.

ML Model for AKI Onset Prediction

Multiple AKI onset prediction models for various situations have been reported using machine learning techniques. The appropriate parameters and performance of the models and their applications may vary depending on the situation. Common applications include general inpatients and ICU patients. Model parameters and performance may vary due to differences in pre-probability of AKI onset (patient condition severity) and in data acquisition intervals and content. Tables 1, 2, and 3 summarize previous studies on general inpatients, ICUs, and various other cases. Some important aspects of these models are discussed below.

Definition of AKI Event

As mentioned above, the KDIGO criteria are used as a standard for AKI diagnostics. Unfortunately, the urine volume data in general inpatients are difficult to collect and thus are rarely available. It results in a diagnosis of AKI based on the SCr values only in many studies. Some studies have adopted the AKIN classification or their own criteria. Also, there has been no consensus in definitions of baseline values for AKI diagnosis. Moreover, no studies have also examined the effect of different baseline definitions on the predictive performance of AKI models. Finally, the target AKI stage also differs depending on studies.

Prediction Timepoint and Target Period

When comparing existing studies, prediction timepoint (i.e., when to make the prediction or

the timepoint of instances to input into the model) and prediction target period are important. He J et al. [33] have examined how these conditions systematically affect model performance (details are given in Table 1). We have split the prediction timepoints into the following three categories: (I) case-control design, (II) at a certain point, and (III) continuous points. In addition, the prediction target period can be categorized into the following two categories: (i) within a certain window and (ii) by a certain event. The prediction framework of each model can be described by a combination of these categories (Fig. 1). (I) *Case-control design* is a retrospective design in which the onset of AKI is set as a positive label in advance, and then an instance of the negative label for the control is selected. Although this method can give a rough estimate of the contribution of features and prediction performance, it cannot be used in working models because the instance of the negative label cannot be set prospectively. (II) *At a certain point* is a standard design where data at a defined point, such as at the time of admission, is used as input to the model. In contrast, since the study of Koyner et al. [38], some researchers have used the design (III). This design continuously predicts multiple time series points for one patient, and these timepoints (e.g., on the day of admission, 1 day after, 2 days after) are collectively modeled. Since the models are trained and evaluated using all timepoints together, it is considered that the predictive ability and the contributing features are different from design (II). This continuous prediction design is specifically intended to predict the changes in a patient over time.

Input Features

Many models have used a large number of variables as input features, such as demographics, vital signs, laboratory results, medications, comorbidities, and admission and discharge records. The number of unique variables is very wide, ranging from about 100 to over 300,000. Since the structure of electronic medical record data differs depending on the system, it is difficult

Table 1 Reported models for general patients. In the algorithm column, the best performing algorithm is shown first. Abbreviations: AKI, acute kidney injury; BN, Bayesian network; CV, cross-validation; DT, decision tree; GBT, gradient boosted trees; k-NN, k-nearest neighbor; LASSO, least absolute shrinkage and selection operator;

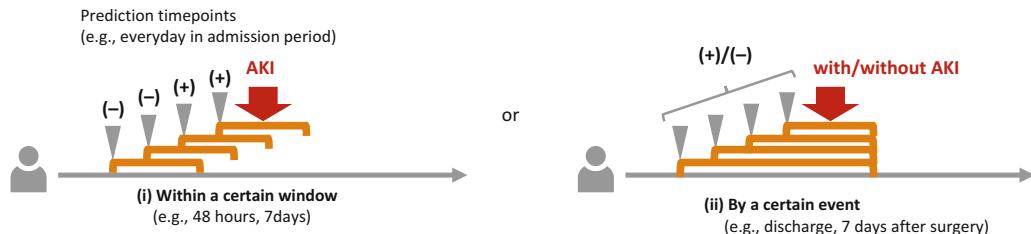

Fig. 1 Prediction timepoint and target period. Problem settings can be categorized using the combinations of prediction timepoint (arrowhead), (I) case-control design,

(II) at a certain point, and (III) continuous points, and target period (orange), (i) within a certain window and (ii) by a certain event

to unify the obtained feature set. Thus, it is practically necessary to make a feature set each time depending on the location where the model is built and operated. For example, in the postoperative AKI model, it is important to incorporate appropriate variables according to the settings, such as intraoperative time series features [61, 62]. As a factor analysis in an experimental setting, there has been a report in which proteomics data have been added as omics data to electronic medical record data [55]. When constructing the model, a feature selection process is sometimes required. Wu et al. [32] have compared several common feature selection methods and found that the performance of the model did not change significantly, but the importance ranking fluctuated significantly.

In most cases, electronic medical record data has irregular measurement intervals. Therefore,

when inputting a model, the representative values in some windows are often acquired in units of several hours to several days. If necessary, the interpolation with the feedforward method or median values is performed for missing data. Some models [42] of recurrent neural networks (RNNs) handle time series data in its original format. In other models, the derived features (mean, variance, maximum/minimum, or trends) are selectively or comprehensively calculated within a window and are used as input data. For instance, some researchers considered time series trend detection that improved the model performance [51] and a model taking into account time series changes in drug combinations [54]. In addition, recent studies (technical verification stage) have succeeded in creating features from unstructured data from clinical notes using natural language processing (NLP) [45]. Other researchers

attempted to verify performance changes using similar NLP-derived features added to the conventional feature set [48].

ML Algorithms

The most commonly used algorithms are tree-based ones, such as random forest (RF) and gradient boosted trees (GBT). These algorithms generally demonstrate high performance. Other common methods include logistic regression (LR), support vector machine (SVM), k-nearest neighbor (k-NN), naïve Bayes (NB), and deep neural networks (DNN). Tomašev et al. [42] have achieved the highest performance of all studies using multi-tasking RNNs. They have also provided the most comprehensive performance comparison of each method and concluded that their method demonstrated the best performance. On the other hand, in many studies, including later ones, other algorithms such as extreme gradient boosting (XGB) have shown the best performance, and the optimal method is still unclear. One of the factors may be that the optimal design of DNN is a complex process compared to other general machine learning models. In addition, the sample size for each study and the characteristics of the dataset may also influence method performance.

Model Performance

The area under the curve (AUC) of the receiver operating characteristic (ROC) curve is used as a common evaluation index in most studies. AUC value ranges from about 0.7 to 0.9, as shown in Tables 1, 2, and 3. Many studies show that the AUC value tends to be higher as the target AKI stage is higher or the prediction target period is shorter. Thus, for the model robustness, there has been a statement that it is desirable to predict AKI of stage ≥ 2 [68]. Taking the 48-h model as an example, the best performance was achieved by Tomašev N et al. in [42] and amounted to 0.921 for any stage AKI and 0.957 for stage ≥ 2 . Some

studies have also evaluated the precision, recall (sensitivity), or specificity of the model for some thresholds. In particular, Tomašev N et al. [42] have argued that a setting with a precision of 33% or 25% is realistic for practical applications. For example, in their 48-h model, about 55% of AKI patients could be picked up under the condition of precision 33%, i.e., there are two false-positive predictions for a true positive prediction.

The prediction performance is determined by multiple factors. In particular, precision value is particularly affected by prior probabilities. For example, although it has been reported that the difference in AUC value between general ward and ICU is small [39] since ICU patients have a higher prior probability of AKI, its effect on the precision and thresholds should still be considered. In another example, focusing on the age of patients, Wu et al. [28] have reported that the older they are, the lower the predictive performance and the greater the variation in the top factors contributing to prediction accuracy.

The External Validity of the Models

Few studies have used the models validated with external datasets. For example, the model by Koyner et al. [39] has been validated at multiple institutions, and stable results have been obtained [69]. Song et al. [44] have reported a model that predicts the transportability of AI between different locations and validated it for the AKI prediction. However, the stability of the external setting in many models is still unclear. MIMIC-III (Medical Information Mart for Intensive Care III) [70] data in ICU patients is the only common dataset that can be widely used, making it difficult to compare performance between studies. This issue is especially pressing when discussing model performance in general patients, for which no open data is available. Sharing anonymous data should help, but there are many barriers to its practical applications. Song et al. [43] have examined the model performance using the anonymous data for AKI prediction and found that the performance was maintained at a slightly reduced

level. However, due to the sparse nature of medical data, the risk of re-identification is still high.

Many studies have used years of data to train and validate models. As these are time-related data, it is an important issue whether the models can fit future data. For evaluation of the reported models, various methods are used. For instance, temporal validation splits the dataset by time, and the simple cross-validation method does not consider time at all. To address this issue, Davis et al. [37] have analyzed discrimination performance in a 9-year validation cohort. The AUC values were generally maintained in chronological order, but the magnitude of overprediction increased over time in regression models. Thus, the authors emphasized the importance of protocols for updating the models.

Explainability of Models

Multiple studies [38, 39, 41, 42, 50, 52, 63, 65] have discussed the explainability of the models. Feature importance values calculated from tree-based algorithms or permutation importance values have been used in the standard methods. SCr and its derivatives, including mean, change, and slope, were the most frequently used features. A wide variety of other variables are listed as top features, e.g., blood urea nitrogen, hemoglobin, bicarbonate, chloride, history of malignant neoplasm of the kidney, emergency department visits, and vancomycin use.

Recently there have been some studies utilizing Shapley additive explanations (SHAP) [71] for feature analysis. For instance, Song et al. [44] have illustrated partial dependence of top features by the method, and Tseng et al. [58] have shown that SHAP picked different top time series-related features compared to the conventional methods. In addition to those top global features mentioned, Gong et al. [49] have also provided an example of interpretation at the individual level using SHAP. However, the clinical interpretation of the model output (e.g., in which cases high output values are predicted and obtained) is

still insufficiently understood, thus hindering its practical applications.

Implementation Challenges

The prediction results provided by high-performance models are likely to generate unprecedented clinical processes. Interestingly, Rank et al. [59] have analyzed the performance of AKI prediction by clinicians. Even experienced clinicians showed an AUC of 0.745, which was lower than the result of many predictive models. Sutherland et al. [68] have illustrated “renal dashboard” as a screen sample to provide AKI risk scores and information about the potential intervention. However, only a few studies have implemented the prediction models as clinical tools. For instance, Ugwuowo et al. [72] have implemented and verified a model from [41] in a single-center electronic medical record system for 1.5 years. They have reported that 2856 patients at risk of 15% were extracted, and 18.9% of them actually developed AKI within 24 h. However, the impact of these models on the prevention of AKI has not been evaluated. In pediatric patients, Driest et al. [73] have conducted a randomized trial of the operation of another model [21]. The alerts increased the number of SCr tests in the ICU but did not change the incidence or severity of AKI. In addition, there was no difference in those indicators of patients in the ward. Future studies should consider the implementation of these models and their effects on the behavior and performance of clinicians, as well as the outcomes, including AKI onset prevention, renal function, and survival rate.

Conclusion

In this chapter, we have reviewed previous studies on AKI onset prediction and discussed their key issues. In particular, we have summarized technical issues, including algorithms, feature engineering, and explanations. We have demonstrated that further development of these technical elements

and their applications is required. Finally, we have emphasized the importance of implementation issues for future studies.

Abstract

The prevalence of end-stage renal disease is experiencing a relentless growth in modern societies, significantly reducing the quality of life of

the patients enduring it and imposing an increasingly unsustainable economic burden to global healthcare systems. Most patients with this condition undergo hemodialysis, with comorbidities such as anemia, cardiovascular risks, and mineral bone disorders being extremely common, hence imposing a further challenge for all involved actors. Artificial Intelligence has already shown an enormous potential at solving key problems in these areas. In particular, anemia management has received the greatest attention, due to the extremely high cost of the erythropoietin-stimulating agents that are employed to treat it, the serious complications of their misadministration, and the huge inter- and inter-patient variability of the treatment. As such, several AI-based systems for dose optimization have been proposed and even commercialized over the years. A thorough presentation of the

Supplementary Information: The online version of this chapter (https://doi.org/10.1007/978-3-030-64573-1_254) contains supplementary material, which is available to authorized users.

developments in this area will be tackled in this chapter, including a description of the Artificial Intelligence models empowering them, such as artificial neural networks – both feed-forward and recurrent ones – or Reinforcement Learning-based approaches. Additionally, further interesting applications of Artificial Intelligence to the field of hemodialysis will be discussed, such as patient clustering and comorbidity and mortality prediction, among others. AI is bound to revolutionize the field of hemodialysis, and the aim of this chapter is to present a snapshot of the most current developments, finishing with a projection of these trends into the future.

End-stage renal disease · Hemodialysis · Erythropoietin-stimulating agents · Anemia control · Hemoglobin prediction · Artificial Intelligence · Reinforcement Learning · Deep Learning · Recurrent neural network · Clustering

Introduction

The prevalence of renal diseases has experienced a continued growth in the last decades mainly due to generalized population aging and the global epidemic of the metabolic syndrome (abdominal obesity, insulin resistance, hypertension, and hyperlipidemia). Affecting 14.5% of patients aged 65+ years [1], chronic kidney disease (CKD) slowly deteriorates the kidneys until end-stage renal disease (ESRD) is reached, a condition which requires very expensive renal replacement therapies (RRTs), such as hemodialysis (HD) or transplant. Among patients undergoing HD (86.9% of ESRD patients), most of them (98%) do in-center HD, where they usually have 3–5 hour-long sessions three times a week.

Even if ESRD prevalence is just 0.2% of the total US population, it represents more than 10% of the total Medicare spending. In Europe, both ESRD prevalence and expenditures are slightly lower, yet the problem remains the same [2]. Nowadays, healthcare systems around the world are faced with the difficult challenge of optimizing

the expenditure in RRTs and ensuring its sustainability for an ever-increasing number of patients, and no easy solution is in sight.

Furthermore, HD replaces the blood filtration function of the kidney to some extent, but the renal endocrine role cannot be replaced, and hence multiple comorbidities appear, such as anemia, cardiovascular diseases, mineral bone disorders, etc. for which the patient has to take an average of 10–12 different tablets per day.

The rest of this chapter is organized as follows: in section “[Anemia, Hemoglobin Prediction, and ESA Dosage Optimization](#),” the problem of anemia secondary to HD is discussed. This is the most fruitful research topic regarding AI in HD, with several AI-based commercial systems for anemia management being currently employed in clinical practice. Section “[Comorbidities, Mortality Prediction, and Patient Clustering](#)” will discuss AI applications for analyzing comorbidities, predicting mortality, and clustering patients into groups in order to gain insights about their most usual profiles. Finally, section “[Other Miscellaneous Applications](#)” will introduce some miscellaneous topics of research in the field. All AI algorithms relevant to the field will be introduced progressively as they appear in the literature, so a sequential read of the chapter is recommended. The chapter ends in section “[Future Developments and Conclusions](#)” with some concluding remarks and the authors’ view about the future of the field.

Anemia, Hemoglobin Prediction, and ESA Dosage Optimization

Anemia, which is defined as a decrease in red blood cell (RBC) or hemoglobin (Hb) concentration, is one of the most common comorbidities in CKD, with a prevalence of around 50% in CKD patients at any stage, and around 75% in ESRD patients [3]. The lowered number of RBCs and/or Hb (which is the protein inside RBCs which carries the oxygen) leads to a reduction in the oxygen transport, which causes tiredness and weakness, and has a profound impact in the quality of life (QoL) of the patient. Furthermore, it increases morbidity and mortality from cardiovascular diseases (which, in turn, further deteriorate the renal function).

Even if CKD secondary anemia (CKD-anemia) arises from a variety of causes (iron deficiency, gastrointestinal bleeding, shortened RBC survival, etc.), the most significant and specific cause is the reduction in erythropoietin (EPO) synthesis. EPO is a glycoprotein secreted by the kidney that is crucial for the erythropoiesis process, by which hematopoietic stem cells produced in the bone marrow differentiate into mature RBCs ending in the bloodstream.

In the 1990s, the appearance of exogenous erythropoiesis-stimulating agents (ESAs) revolutionized the anemia treatment, improving the management of CKD-anemia along with the QoL of the patient, and replacing RBC transfusions almost completely. However, the response to ESAs has very strong inter- and intra-patient variability, combined with nonlinear, time-dependent dynamics, which are complex to model and not yet fully understood [4]. Furthermore, current guidelines agree that ESA treatment should only aim at a partial correction of Hb levels, as there is plenty of clinical evidence of higher mortality rates associated with higher ESA dosage [5]. As such, a target of 10–12 g/dL is currently recommended [6], even if normal Hb levels lie above 13 g/dL in men, and 12 g/dL in women for the average population. Finally, although multiple exogenous ESAs have been developed along the years (namely, epoetin alfa, darbepoetin beta, MPG-epoetin beta, etc.), their cost is still high, and their economic burden is significant.

Ideally, ESA administration protocols should be patient-specific and aim at achieving the Hb targets while keeping dosage as low as possible, thereby reducing both healthcare costs and patient risks. However, such task is extremely difficult to perform manually in clinical practice, and no universally accepted guidelines exist. This has led to the development of a huge variety of models to automatize the task, which can be divided in two main categories: model predictive control (MPC)-based approaches and direct ESA dose optimization.

MPC-Based Approaches: Hemoglobin Prediction

MPC-based approaches are the most common in the literature, and all currently available

commercial systems are based upon these. The core component of an MPC is the model, which should be able to accurately predict future Hb values based on an ESA dose proposal, patient characteristics, and current Hb values, among others. Then, the optimizer component takes a Hb reference to be achieved as input and uses the model to suggest the optimal treatment plan as an output. The Hb prediction model can be seen as a surrogate for the patient, with which a naïve optimizer could simply try several competing treatment plans in silico and choose the best one. Since the speed of the control is not an issue, such naïve controllers are commonly employed for this application, and the research focus is instead shifted toward finding the best possible Hb models. In practice, commercial systems for anemia control work as decision support systems, which suggest an ESA dose that the physician is then able to either follow or ignore. Figure 1 shows a schema of an MPC controller for Hb prediction.

There are two main groups of models for Hb prediction: physiologically based models and Artificial Intelligence (AI)-based models.

Physiologically Based Models

These models usually consist in a set of differential equations that describe the dynamics of erythropoiesis from first principles. The earliest of such models can be attributed to [7]. However, most current works are based upon [8], with subsequent modifications including further interactions within the erythropoiesis process, such as non-linear cell maturation and hormone decay rate [9] or neocytolysis [10].

The parameters of physiologically based models (e.g., RBC lifespan) are typically adjusted using the first months of a patient's history, *the descriptive phase*, after which the model can be employed for actual Hb prediction, *the prescriptive phase* [11]. The adjustment process is usually performed using direct search methods, e.g., trying random sets of parameters, and keeping the set for which the simulation best resembles the patient history during the descriptive phase. The physiologically based Mayo Clinic Anemia Management System (MCAMS) developed by [11, 12] and licensed to Physician Software

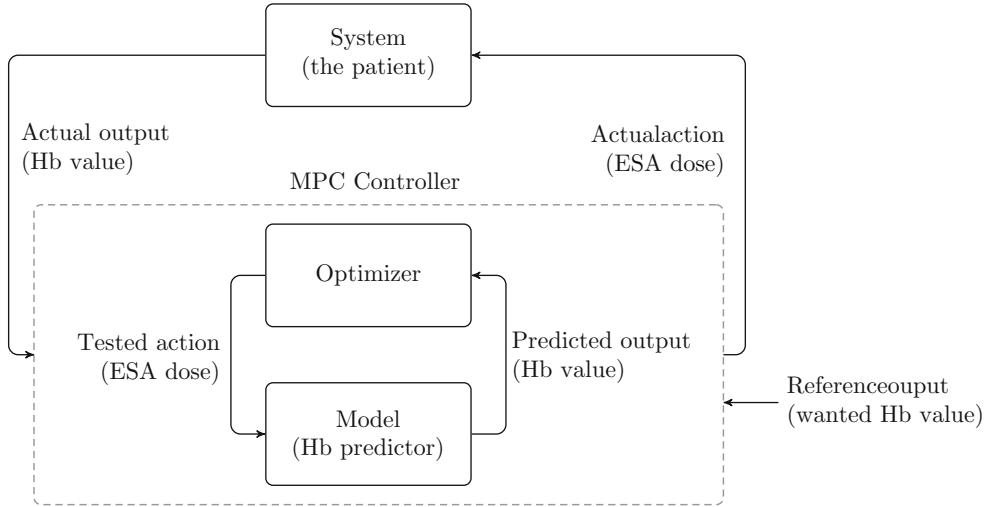

Fig. 1 MPC controller for Hb prediction: a naïve optimizer could use the model to test several possible actions (ESA doses), and simply choose the one which achieves a predicted Hb that is closest to the reference (the desired Hb value)

Systems has shown to achieve improvements in the percentage of patients within target Hb values.

AI-Based Models

AI-based models do not stem from an underlying erythropoiesis model; instead, they try to learn one purely from retrospective data in which the values of both the independent variable and the dependent variable (corresponding with the outcome of the model) are known. In AI research, such models are called supervised learning models, and they are based on the diagram presented in Fig. 2.

As it can be seen, the model itself is just a mathematical function $f_\theta(x)$, which takes an input x (e.g., ESA dose, patient characteristics, current Hb value, etc.) and produces an output \hat{y} (e.g., predicted Hb value in 30 days). The function $f_\theta(x)$ is parametric, which means that it can represent many different input-output relationships depending on its parameters θ , which are just numbers. During the learning phase, the model is shown many $\langle x, y \rangle$ pairs (where y is the ground truth for the output), and the model updates the value of its parameters in such a way that the predicted output \hat{y} and the ground truth y are as similar as possible for any given input x .

Linear Regression

Linear regression (LR) is one of the simplest supervised learning models. In [13], the authors

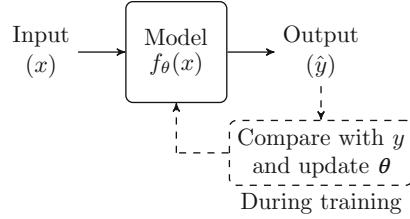

Fig. 2 General supervised learning model

use fuzzy sets to combine the output (predicted Hb) from three LR models, where each model corresponds to a prototypical patient according to their ESA sensitivity and average transferrin saturation (TSat) levels. The LR model used by [13] has been reproduced in Eq. 1:

$$\begin{aligned}
 Hb_{t+1} &= f_\theta(x) \\
 &= \theta_0 + \theta_1 \cdot EPO_{t-1} + \theta_2 \cdot EPO_t \\
 &\quad + \theta_3 \cdot EPO_{t+1} + \theta_4 \cdot Hb_{t-1} \\
 &\quad + \theta_5 \cdot Hb_t + \theta_6 \cdot TSat_t
 \end{aligned} \tag{1}$$

where t is the current time and $t-1, t, t+1$ denote that a value corresponds to the previous, current, or next month, respectively. Connecting with the general diagram in Fig. 2, the output $\hat{y} = Hb_{t+1}$, the input $x = [EPO_{t-1}, EPO_t, EPO_{t+1}, Hb_{t-1}, Hb_t, TSat_t]$, the parameters $\theta = [\theta_0, \theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6]$, and the model $f_\theta(x)$ correspond with the right-hand side of Eq. 1. Hence, the authors proposed to model the Hb

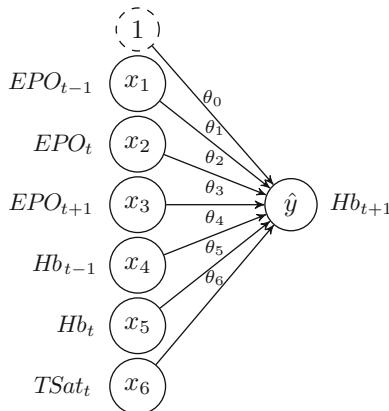

Fig. 3 Graphical representation of the linear regression model from [13]

in the next month (Hb_{t+1}) as a linear combination of previous (EPO_{t-1}), current (EPO_t), and future/proposed EPO doses (EPO_{t+1}), previous (Hb_{t-1}) and current Hb values (Hb_t), and current TSat ($TSat_t$). The parameters θ were learned automatically from medical records of 186 patients; this is a very powerful feature of AI algorithms, since no previous knowledge must be known about the problem (unlike with physiologically based models), they rather discover it by looking at the data. A graphical representation of the LR model from Eq. 1 is shown in Fig. 3.

It must be noted that, formally, the model in Eq. 1 is known an autoregressive model with exogenous inputs (ARX), since Hb_{t+1} depends on previous values of itself (autoregressive), and it includes other (exogenous) inputs.

Feed-Forward Neural Networks

The main disadvantage of LR is its very limited modeling power. Feed-forward neural networks (FFNNs) (also called multilayer perceptrons (MLPs)) are the most common kind of artificial neural network (ANN). Unlike LR, FFNNs are able to model very complex input-output relationships, including interactions among the inputs and arbitrary nonlinearities. For the task of Hb prediction, ANNs were used for the first time in [14, 15], where the authors demonstrated that they could yield more accurate results than ARX and radial basis function (RBF) networks. Since then, many more have appeared over the years, such as [16], where a significant jump in the number of patients (more than 10,000) and the number of inputs

(more than 20) was introduced; [17], where the prediction horizon was extended to 3 months into the future, instead of just one; or [18], which describes the model that is currently implemented in the commercial Anemia Control Module (ACM) developed by Fresenius Medical Care, which has shown to improve anemia target achievement while reducing EPO-dose administration [19]. A similar model [20] with similarly positive results was licensed by Dosis Inc. as Strategic Anemia Advisor (SAA).

FFNNs can be thought of as a stack of standard LRs with nonlinear activation functions in-between. To better illustrate this idea, Fig. 4 shows a representation of a FFNN very similar to the one used in [18]. A FFNN has an input layer and an output layer (exactly as in LR), but it adds hidden layers between them, each layer being comprised of several neurons (also called units). For instance, the FFNN in Fig. 4 has two hidden layers with six neurons each (plus a bias neuron, represented by a 1). The study of ANNs with many hidden layers makes up the field of Deep Learning (DL).

Each neuron in a FFNN behaves exactly as a LR plus a nonlinearity. For instance, the value at neuron z_1^1 can be calculated according to Eq. 2, where a LR over inputs $x_1, x_2, \dots, x_7, x_8$ has been performed and a *ReLU* nonlinear activation function ($ReLU(a) = \max(0, a)$) has been applied to the result, as denoted by the mirrored L symbol in some of the neurons of Fig. 4. Adding an activation function (such as *ReLU*, *sigmoid*, or *tanh*) to each neuron is crucial; otherwise, all the operations would remain linear, and the whole FFNN would be equivalent to a single LR over the inputs. Equations very similar to Eq. 2 can be defined for all neurons in the FFNN, hence defining the mathematical behavior of the whole network:

$$\begin{aligned} z_1^1 &= ReLU \\ (\theta_{01}^1 \cdot 1 + \theta_{11}^1 \cdot x_1 + \theta_{21}^1 \cdot x_2 + \dots + \theta_{71}^1 \cdot x_7 + \theta_{81}^1 \cdot x_8) \end{aligned} \quad (2)$$

In all kinds of ANNs (including LR, since it can be seen as the simplest kind of ANN), the parameters θ are usually obtained by a procedure

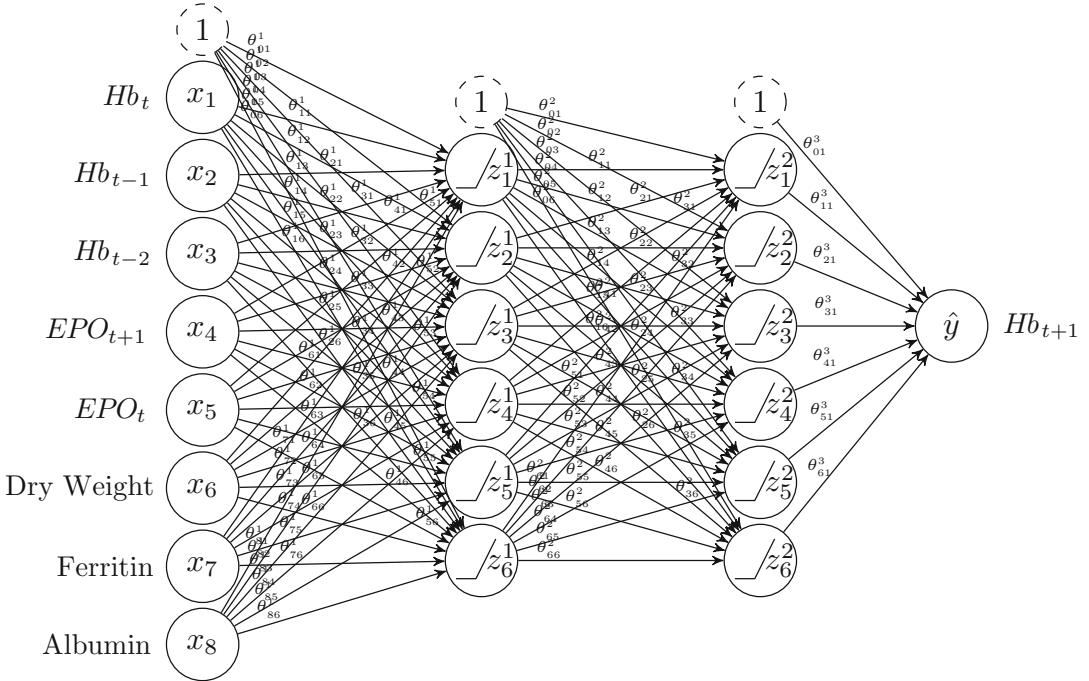

Fig. 4 FFNN for Hb prediction similar to the one in [18]

known as stochastic gradient descent (SGD). It starts by assigning random values to all parameters θ . First, a new sample $\langle x, y \rangle$ is taken, and the output \hat{y} of the ANN is calculated according to equations similar to Eq. 2. Second, the squared error between the ground truth y and the prediction \hat{y} is calculated as $(y - \hat{y})^2$. Third, the value of the parameters is updated in order to minimize that error. This process is repeated, iterating over the whole dataset multiple times, until the average error over all samples cannot be further improved.

Coming back to the Hb prediction model described in [18], the authors trained a FFNN on a dataset of 4,135 patients, with a total of 101,918 records from Italy, Spain, and Portugal. Moreover, they used a wide variety of inputs (also known as features), such as height, dry body weight, Hb, OcmKtV, ferritin, albumin, leucocytes, ESA dose (intravenous (IV) darbepoetin alpha), and iron dose (IV iron sucrose or IV iron gluconate), with some of them sampled at several points in the past (e.g., Hb_t , Hb_{t-1} , Hb_{t-2}). On one hand, using a high number of records from different countries exposes the ANN to a much more varied set of

data, making the trained ANN more general, and better able to deal with atypical, unseen situations. On the other hand, using many input features provides the ANN with more information about the patient, with which it can automatically learn better patient-dependent responses to ESA. Comparing with [13], where three LR models describing three prototypical patients were manually defined, FFNNs are able to learn the prototypes (in a sense) by themselves only by looking at the data.

ANNs are extremely powerful algorithms, able to learn very complex input-output relationships. In fact, a big FFNN could theoretically learn any dataset by heart, but then it would provide very poor predictions on data that it has not seen during training, which is a problem known as overfitting. To assess this issue, data is typically split into three sets: the training set contains around 70% of the data, and is used to train the ANN by updating its parameters with SGD; the validation set contains around 15% of the data, and is employed to assess the impact of changes to hyperparameters (such as number of hidden layers, number of neurons per

layer, etc.); finally, the test set is kept secret until the end, when the actual prediction performance of the ANN is eventually tested. For instance, in [18] the authors split the patients in proportions of 66%, 17%, and 17% for the training, validation, and test set, respectively, achieving similar performances in terms of mean absolute error (MAE) for all three sets, and hence proving that no overfitting occurred, a crucial issue to ensure a successful implementation of the model in daily clinical practice.

Recurrent Neural Networks

Despite the success of FFNNs in the task of Hb prediction, they are arguably not the best tool for the problem, since they have no notion of time despite the inputs (the patient history) being a time series. Fortunately, there is a kind of ANN known as recurrent neural network (RNN) that is specifically designed for time series modeling. The first instance where RNNs were applied to the problem of Hb prediction dates back to 2003 [14]; however, not much improvement was observed when compared with a simpler FFNN. It was not until 2020 when a sudden renewed interest in the topic appeared [21–23].

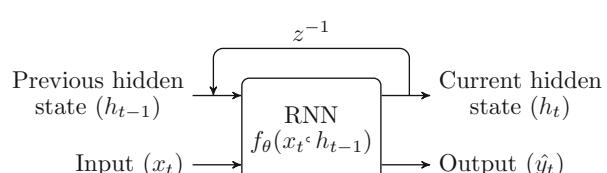

A high-level representation of a RNN can be found in Fig. 5. RNNs deal with sequential data (e.g., a medical history of a patient) by looking at one sample (one record: x_t) at a time. Then, they produce a prediction \hat{y}_t , and update their hidden state h_t , which is simply a vector of numbers that encodes information about all previous inputs $x_{t-1}, x_{t-2}, \dots, x_0$. When a new record from the same patient is input to the RNN, it can use the previous hidden state h_{t-1} along with the current information x_t to produce the Hb prediction \hat{y}_t . The hidden state can be understood as a memory of all the previous values and patterns of a patient's history that are useful for the RNN to predict the Hb.

Fig. 5 Overview of a recurrent neural network

In FFNNs, time is usually accounted for by adding the three last months of Hb values and ESA doses directly to the input (e.g., features Hb_t, Hb_{t-1}, Hb_{t-2} in Fig. 4). By contrast, RNNs encode time inherently by updating the hidden state. Hence, all previous information seen by the RNN could theoretically be remembered, including Hb values more than 3 months in the past (e.g., Hb_{t-3} , or even Hb_{t-20}), past values of other features (e.g., $Ferritin_{t-2}$), or, in general, any past information that could be useful for predicting Hb. Furthermore, since a prediction \hat{y} is provided at every time step t , RNNs can be used to predict Hb values from the very first month, without having to wait many months to adjust the parameters as with physiologically based models, or several months (usually three) to have all the required input data as with FFNN-based models.

RNNs can be comprised of different kinds of recurrent units (or neurons). The simplest recurrent unit is the Elman unit, which was used by [14]. However, Elman units are very limited, and are unable to keep long-term memories. These issues are solved by modern recurrent units, such as the long short-term memory (LSTM) units, employed by [21], and the gated recurrent units (GRUs), employed by [22, 23].

Perhaps, the most ambitious RNN model for Hb prediction to date is the one proposed by [23]. It was trained on more than 110,000 patients (around 3,000,000 total records) from clinics of 12 different countries, employing more than 30 different input features (including 3 kinds of ESA with both intravenous and subcutaneous administration). Despite (or maybe thanks to) the huge variability in the input data, it achieved a perceptible performance improvement when compared to previous state of the art while allowing to bring the benefits of algorithmic anemia control to virtually every patient without restriction (e.g.,

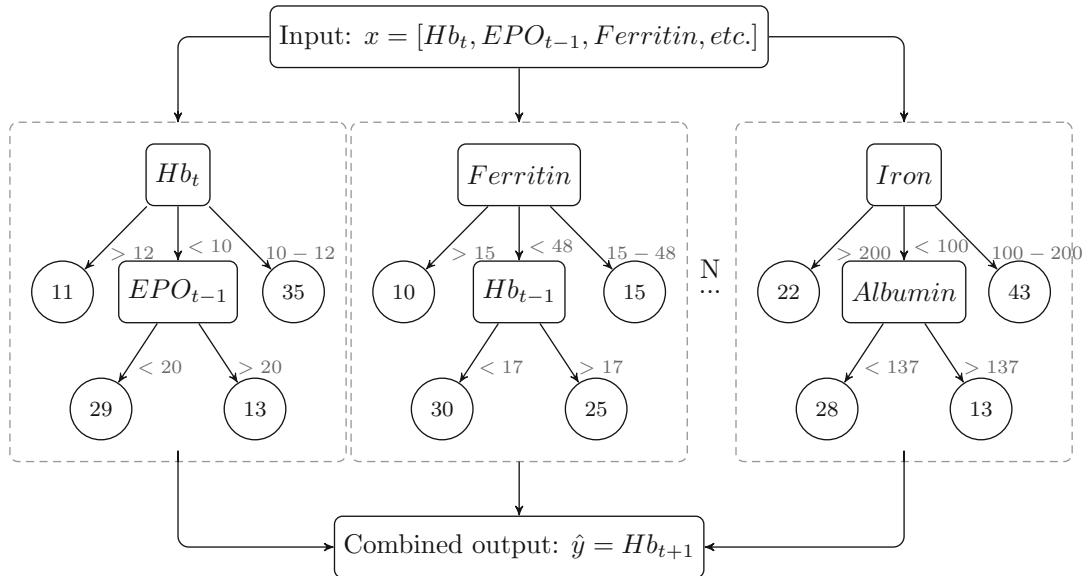

Fig. 6 Example of random forest for the problem of hemoglobin prediction

3 months of Hb history is no longer needed to obtain a prediction).

Other Supervised Learning Models

Despite FFNNs (and, more recently, RNNs) being the most popular for Hb prediction, many other models have also been explored over the years. In [15] the authors explore the use of radial basis function (RBF) networks, which are like FFNNs, but with parametric activation functions that compute a measure of the similarity between the inputs and a given prototypical input (patient). In [24] a modified version of support vector regression (SVR) with linear kernel is employed; this is similar to LR, but instead, SVR does not learn from points for which the prediction error is below a threshold. Finally, in [25], a model based on extremely randomized trees (ERTs) is used.

ERTs are a kind of random forest (RF), which is an ensemble method using decision trees (DTs). Ensemble methods combine the predictions from several individual models (e.g., by averaging), in order to improve the global performance. In a RF, DTs are trained independently on the same problem, but using a potentially different set of input features, tree architecture, or a different subset of the training samples. A toy example of a RF is

shown in Fig. 6, where the output of several DTs is combined to form the final output. As can be seen, when given an input, a trained DT takes a branch depending on the value of the input features, eventually arriving at a single final predicted value (represented as a circle).

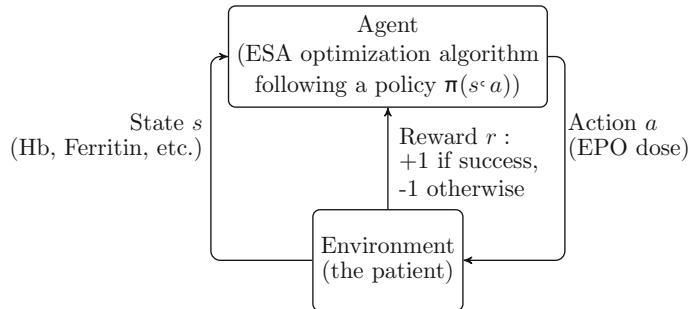

Direct Dose Optimization

Unlike MPC-based approaches, direct dose optimization systems are able to directly suggest the optimal ESA dose, without necessarily requiring an explicit model for Hb prediction. It must be noted that some of these methods do employ a Hb prediction model, but it is either extremely simple, or it is only used for the training of the dose optimizer, and not needed afterward.

Rule-Based Systems

Rule-based systems are derived from paper protocols designed by physicians that are expert in the topic. Authors in [26] proposed a rule-based system using the theory of fuzzy control, which was very popular in the 1990s, as it allowed to translate qualitative control rules into fuzzy sets that can be used to decide on the magnitude of a

Fig. 7 Typical Reinforcement Learning setup adapted to the problem of ESA optimization

control action; however, the model was not validated in real patients. In [27], the authors proposed a simple set of condition-action rules, which are guided mainly by the hematocrit (Hct) values (computed as three times the Hb value). For instance, one of such rules is: “If the calculated Hct is $\geq 39\%$, discontinue EPO and check the calculated Hct weekly. Resume EPO at 25% less than the previous dose as soon as the calculated Hct is $\leq 37.4\%$. ” The authors found no difference in Hb target achievement or ESA dosing when compared with manual control in real patients, although it is argued that the savings in terms of staff resources might be worth it. In [28], an analogous approach was followed, obtaining an improvement in Hb target achievement, which increased from 56% to 66% in 214 test patients.

Reinforcement Learning

Reinforcement Learning (RL) algorithms aim to learn a control policy $\pi(s, a)$ (an ESA dose optimization algorithm) that given a state s_t (e.g., $s_t = [EPO_t - 1, EPO_t, Hb_t - 1, Hb_t, TSat_t]$) chooses an action a_t (an ESA dose: $a_t = EPO_{t+1}$) that maximizes a long-term reward G_t (e.g., the longer that Hb levels stay within target range, the higher the value of G_t will be). G_t is usually defined as $G_t = r_t + \gamma \cdot r_{t+1} + \gamma^2 \cdot r_{t+2} + \dots$, where r_t is the reward that is obtained by choosing action a_t (e.g., $r_t = +1$ if Hb_{t+1} is in target range and $r_t = -1$ otherwise) and γ is a discount factor (e.g., $\gamma = 0.9$) that reduces the importance of future rewards (r_{t+1}, r_{t+2}, \dots). Finally, we can define the Q-function $Q_\pi(s, a)$ as the expected long-term reward G_t of choosing an action a at a given state s , and then following a policy π from there onward. An overview of the typical RL

setup adapted to the ESA optimization problem is shown in Fig. 7.

Instead of directly learning an optimal policy π^* , the objective of many RL algorithms is to approximate $Q_\pi(s, a)$ (with a table, a FFNN, an RBF, etc.) since, once it is known, the optimal policy π^* can always be found by taking the action a (from all possible actions in a state s) that maximizes $Q_\pi(s, a)$. This is

$$\pi^*(s) = \operatorname{argmax}_a Q(s, a) \quad (3)$$

There are two main groups of RL methods: on-policy (where the policy being learned is actually used to explore the environment) and off-policy (where the policy being learned does not coincide with the policy by which the environment is explored). In the context of ESA dose optimization, on-policy algorithms would require a patient (either real or simulated) to follow the policy that is proposed by the RL algorithm, which could be problematic in a real-life scenario; conversely, off-policy algorithms have the ability to learn an optimal policy from pre-acquired patient records (even if a sub-optimal ESA dosing policy was used). The most well-known on-policy RL algorithm is SARSA, which uses individual $\langle s_t, a_t, r_t, s_{t+1}, a_{t+1} \rangle$ tuples (hence its name) for learning the Q – function; and the most famous off – policy RL algorithm is Q – learning, which instead employs $\langle s_t, a_t, r_t, s_{t+1} \rangle$ tuples, where a_t might have been chosen following any policy. After learning an approximation to the Q-function, the optimal policy (the ESA dose optimizer) is trivial to obtain according to Eq. 3.

There exist a variety of papers applying these RL principles to ESA optimization. In [13], an off-policy algorithm known as $Q(\lambda)$ (very similar to the Q-learning algorithm) was trained on “virtual” patients, which were simulated by following the set of linear equations introduced as an example in section “[Linear Regression](#).[“](#) An RBF network was used to approximate the Q-function. Similarly, in a follow-up paper [29], the authors applied the on-policy RL algorithm SARSA over a set of patients that were simulated by a FFNN.

On-policy algorithms require an environment that can be freely explored (i.e., they require a patient on which arbitrary EPO doses can be probed). However, since this would be dangerous, in the previous papers, the authors decided to instead develop a simulated patient by using a supervised learning model for Hb prediction. Nevertheless, by training on simulated data, the RL algorithm depends entirely on how good the original Hb prediction model is, and, hence, its applicability in a real-life scenario, with real patient data, may be jeopardized. Conversely, in [30], an off-policy Q-learning algorithm was trained on data from real patients. The Q-function was approximated by both a table and a FFNN, achieving slightly better results with the latter approach. Finally, in [25], the off-policy fitted Q iteration algorithm was trained on augmented patient data (the number of patients was artificially increased by interpolating among the real patients), using an RBF network for approximating the Q-function. To assess the performance of the model, ERTs were used to fit a Hb prediction model, and the behavior of the proposed controller was simulated, revealing an improvement over standard EPO dosage protocol.

Overall, RL methods are a very promising technology, since they allow the development of optimal policies that can be learned directly from data, without the need of an explicit Hb prediction model. In other words, the RL philosophy is the following: let us focus on learning a good ESA optimizer, which might be a much simpler task than learning the underlying patient dynamics that govern erythropoiesis. However, unlike with MPC-based approaches, the decisions taken by RL methods cannot be easily understood and might be potentially dangerous if tested directly on real patients.

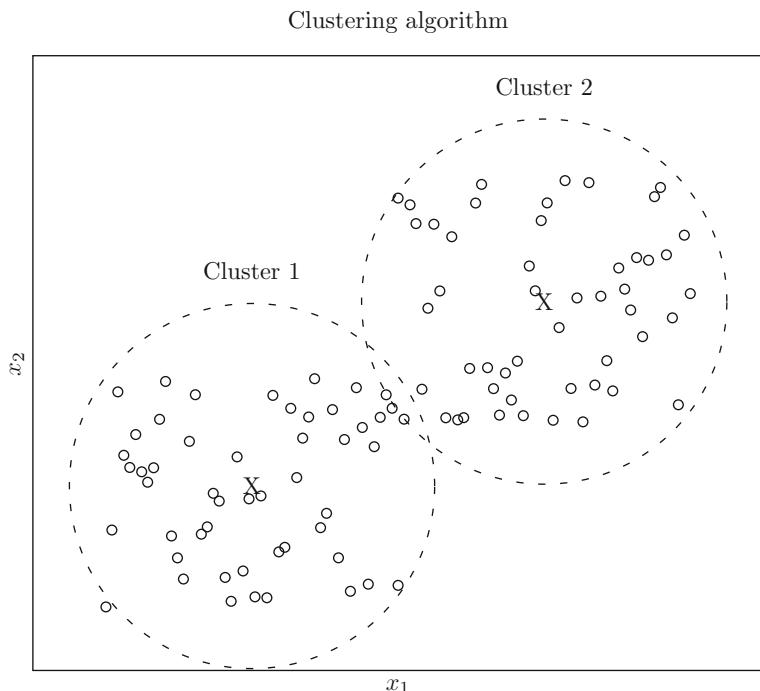

Comorbidities, Mortality Prediction, and Patient Clustering

Besides anemia control, the problem of early prediction of comorbidities associated with ESRD and HD, as well as patient (1-year, typically) mortality and patient clustering, has recently received some attention by the scientific community. Clustering algorithms are the most common form of unsupervised learning algorithms. Unlike supervised learning algorithms, these kinds of algorithms do not try to model an input-output relationship (see Fig. 2), but rather, they try to find relationships among the inputs themselves. A clustering algorithm, in particular, tries to find automatically groups of points (e.g., groups of patients), which are similar within their group, and different from others. Figure 8 shows a toy example of a clustering algorithm applied to two-dimensional data, where two clusters have been found.

Regarding patient clustering and mortality prediction, three articles have appeared in 2020. In [31], the authors trained a RF in 1,571 incident HD patients, achieving an area under the curve (AUC) of 0.728 for 1-year mortality prediction. AUC is a classification metric ranging from 0 to 1, with 1 meaning both perfect classification accuracy and absolute confidence by the model in the prediction. In [32], 101 incident HD patients were clustered by means of the hierarchical clustering algorithm, yielding 3 groups of patients (or clusters). The cluster where patients had (before HD) lower systolic blood pressures, lower serum creatinine, and urinary liver-type fatty acid-binding protein levels was associated with the highest 1-year mortality risk. Yet, the most ambitious study in this topic to date is [33], where almost 80,000 patients were clustered in 5 groups by the K-means algorithm. Then, a different support vector machine (SVM) classification model was trained for each of the clusters, achieving an AUC of 0.948 for 1-year mortality prediction. Furthermore, the characteristics of the patients inside each of the clusters revealed some interesting insights about the HD population and their prognosis.

In relation to comorbidities, a topic of great interest is the CKD-mineral bone disorder

Fig. 8 Example of clustering algorithm

(CKD-MBD), which is made patent by a drift from normal phosphate, calcium, or parathyroid hormone values, and is correlated with a significant mortality increase. Regulating all three parameters is extremely difficult due to their complex dynamics and interdependencies, and standard control protocols typically achieve variable degrees of success. In [34], an attempt was made at analyzing the associations among several of the variables that influence the problem by using RFs. This is still a very young field inside AI research, and publications on the topic are bound to appear in the coming years, due to the importance of the medical problem. Finally, in [35] a model for cardiovascular disease prediction in a 6-month window in incident HD patients was developed, achieving an AUC of 0.737 with a RF.

Other Miscellaneous Applications

There are several interesting AI applications in the HD field that do not belong to any specific category. For instance, [36] proposed a model for predicting arteriovenous fistula (AF) stenosis by processing AF sounds with a bidirectional LSTM convolutional neural network, which is a

supervised learning model designed specifically for processing signals (AF sounds) that are recorded over time (at several HD sessions). AF stenosis consists in the narrowing of the blood vessels used for the HD process. It is typically assessed by auscultation and assessed over time in a subjective manner. The system proposed by the authors aims at objectively assessing the stenosis (classifying it as either normal, hard, high, intermittent, or whistling), by processing the sound produced by the AF during HD. They achieved an AUC of 0.75–0.92 for the different classes, hence having the potential of becoming an objective measure of AF stenosis in clinical practice. Similarly, in [37], a FFNN-based model is used to predict session-specific Kt/V, fluid volume removal, heart rate, and blood pressure based on patient characteristics, historic hemodynamic responses, and dialysis-related prescriptions, achieving high success in predicting the first two values.

Regarding other topics, in [38], an assessment of performance trends in HD clinics was performed, by utilizing a kind of unsupervised learning algorithm known as self-organizing maps (SOMs) and Markov process theory. SOMs were also employed in [39] to identify the

characteristics of groups of patients according to their satisfaction with the HD treatment, hence allowing to explore areas of potential improvement. Finally, in [40], an exploration of the progress in wearable HD devices research is presented. The authors argue that AI will have a profound impact in such devices, which will have to be able to continually monitor the patient and respond to changes in homeostasis in an intelligent manner.

Future Developments and Conclusions

The relationship between HD and AI has been gaining momentum over the years, and it seems like this trend will continue into the foreseeable future, yielding results that will transcend the lab and revolutionize the clinical practice. As a clear example, several automatic ESA dose recommendation systems are already being used in real-life applications, and several others are likely on the way. These automated systems have the potential to bring personalized anemia management to a very large cohort of population, improving the QoL of the patients and reducing the costs of the increasingly unsustainable healthcare systems, especially in areas where resources are scarce and highly educated physicians are limited.

A classical (unfounded) concern with such systems is that they will replace doctors, but it is quite the opposite: AI will empower them. Just like any other medical device, AI systems are just tools that concentrate on doing one specific thing extremely well (e.g., ESA dose optimization), while the doctor is left with more time to focus on the patient as whole. In fact, if trained with enough data, AI systems will eventually outperform any human-based information-related process, since, unlike humans, AI models have the ability to easily extract and remember patterns from hundreds of thousands of patients. In that regard, the most limiting factor for AI development will be high-volume and high-quality data availability. Even if this is not a concern for a high-incidence condition such as CKD-anemia, it will definitely be for many other uncommon

diseases, and a global collaboration will likely be needed in such cases.

AI-based systems have a very promising journey ahead in helping HD patients live the best life possible, and it is expected that many more HD problems that still remain marginal in the field will be tackled very soon, including models for optimizing treatment and prediction of other CKD-associated comorbidities (such as CKD-MBD or cardiovascular diseases), systems to optimize the effectiveness and the experience of the patient during the HD process, or even the development of wearable artificial kidneys, which are still in very early stages, but are an extremely interesting technology nonetheless. AI has an unprecedented potential to revolutionize many medical fields for the better, and, as such, it should be understood and promoted by both scholars and physicians, with a shared objective of improving the life of the patients.

Abstract

The potential contribution of artificial intelligence to public health is made up, in a sense, of its many specific contributions to each of the medical disciplines, in that each individual contribution will help to improve the health of the population by making more efficient use of the resources of the healthcare system and improving individual health. There are, however, a few specific areas of public health and social medicine in which AI could bring about an evolution, or even a revolution. This may be the case for precision public health, which draws on data that is both more varied in nature, such as behavioral data from connected objects, and more precise in temporal and spatial resolution. Public health uses aggregate, often macroscopic, data to make health policy decisions. Such indicators are imperfect; they can be inconsistent or misleading and are often most useful in retrospect, rather than at the desired moment. Evidence-based policy would appear to be more legitimate and robust. AI could also change the way public health systems are organized at various levels. Learning healthcare systems, for example, are designed to adapt more or less autonomously to changing health needs. In any case, the challenges of effectively using AI will arise in public health as elsewhere, and they may even be exacerbated or intensified by the well-known and unresolved tension between individual preferences and collective preferences.

policy · Precision public health · Population health

Introduction

Public health can be a delicate matter, as it is a crosscutting and complementary discipline, rather than merely supplementary to other medical disciplines. Public health and the related field of social medicine serve somewhat as foils to the other medical disciplines, which are characterized by a biological and reductionist paradigm focused on the individual [1]: care is provided to people who may present with similar characteristics, but who are all unique. This makes it tempting to see public health and social medicine as somewhat of a supplement, adding context or a collective viewpoint to the footnotes of textbooks for other medical specialties. This can be seen in the many scientific articles that begin with: “This is a major public health issue because...” The collective dimension of public health means that it shares certain concepts and tools with epidemiology. Thus, at a time when artificial intelligence in medicine is often synonymous with P4 medicine (personalized, predictive, preventative, and participatory), there may be little specific overlap between public health and artificial intelligence. With this in mind, in this chapter we will discuss what is meant by public health more specifically: namely, all that which concerns the health of populations, the healthcare system, or, in other words, the collective and organizational dimensions of health [2]. We will look at the cases of social medicine and precision public health. The arrival of artificial intelligence in the field of public health, before it has even had the chance to bring about any evolutions or revolutions of note, has already

reactivated well-known and unresolved tensions between individual preferences and social preferences.

Defining Public Health and Social Medicine: Toward Greater Precision, or a Regression from the Collective to the Individual?

Public Health Versus Individual Health, Social Medicine Versus Personalized Medicine

Here, we use public health to mean the field concerned with population health, acting as a complement to medicine, which focuses on individual health [2]. Public health is primarily interested in prevention and how healthcare is organized. Population health is tied to the health of the individuals within that population, but the public health approach is intrinsically collective. Good examples might include infectious diseases and vaccination [3]. Infectious diseases that can be transmitted from human to human are a concern for both the individual and the group: there may be a need to create new institutions and networks, to mobilize certain techniques (vaccines), and to adopt policies to attempt to control or eradicate an epidemic at the population level, without a clear direct individual interest for each person. Infected people can pass on a virus without experiencing any ill effects, or with only minor symptoms. Yet, they could spread the disease to others who might develop symptoms or suffer more serious consequences. Public health looks at the organization of the healthcare system and healthcare professionals, at how public health policy is developed, and at the resources made available to implement these policies. It also studies the people involved at these different levels, based on the fundamental principle of health democracy that all citizens should be able to contribute to and give their opinion on public health decisions [4].

In the context of public health, social medicine can be understood as the application of public health principles to individual medical practice

[5]. Health practitioners must, of course, consider the unique and individual situation of each patient they see, but the patient's requests, needs, and resources should be understood in the context of the specific collective dimension of public health. In particular, this means considering the patient's environment, in the broadest possible sense, as well as their interactions with this environment, be they professional, socioeconomic, health, cultural, etc. Social medicine takes social determinants into account in its approach [6].

Medical and clinical practice primarily focuses on the direct relationship between the patient and the healthcare professional. The dominant paradigm today is biomedical and individual. Until now, the use of artificial intelligence in medicine has reflected the underlying principles of this paradigm and can be summarized under what is called P4 medicine: personalized, predictive, preventative, and participatory [7]. While "participatory" medicine may seem to have a collective dimension, this is quickly reduced to encouraging individuals to adopt responsible, informed, and autonomous behavior with regard to their own health. Thus, while it was not their original intention, most current and planned projects to use AI in medicine aim to augment doctors' usual capabilities in this patient-professional context: diagnostic, prognostic, and therapeutic capabilities [8]. The overall goal seems to be a more personalized and individualized form of care, with custom diagnosis and targeted treatments based on the patient's pharmacogenetic profile [9].

Precision Versus Individualization. Precision Public Health

Precision would therefore appear to be a key benefit of the use of AI in health. But what exactly is this precision? And what forms can it take? As we have just seen, it is widely held to mean the greater personalization and individualization of clinical and surgical procedures. This personalization, however, remains largely virtual, or at least similar to the use of classic risk factor analysis, applied to an individual: it says something about the patient, insofar as they are a member of a group

of people, large or small, that share a certain number of characteristics. AI can have a double benefit in this context, helping to reveal risk factors that are unknown or difficult to determine using traditional methods [8], and more precisely defining risk strata, thereby increasing patient group granularity. The collective aspect must therefore be taken into account upstream, during the statistical identification of characteristics of interest. However, it is less useful, and can even cause problems, when applying results derived from homogeneous groups to individual situations [10]. In public health, there is another kind of precision that may be applied.

Since the 2010s, the concept of precision public health has been discussed in important scientific and medical journals [11]. Precision can be assessed across all areas of public health: the precision of estimates and forecasts (number of cases, of deaths), spatial precision (indicators at the country level vs the kilometric or individual level), the precision of prevention information and messaging (undifferentiated advertising in the public space vs individual information, adjusted based on personal characteristics), precision in service provision (basing treatment costs on individual behaviors), and precision in decision-making and policy measures. For example, in Africa, recent estimates have indicated an overall decrease in infant mortality. However, an analysis with a 5 km resolution reveals sharply contrasting spatial inequalities, with infant mortality falling in some areas but actually rising in others [12].

Public Health, a Practice Based on Data, on Information, or on Evidence?

It cannot be said enough: there is no AI without data, whether that data is used to train algorithms or to apply them to real-world situations. Public health stands at the intersection between health and policy, and public health decision-making can reveal a lot about the state's prerogatives. Individual medicine is based on what is called "evidence-based medicine" [13], so the public health equivalent is "evidence-based policy," or EBP [14]. This emphasis on evidence is part of a

wider methodological framework. As big data and AI have taken off, the lines between data, information, and evidence in EBP have become blurred. Data is simply whatever is recorded or captured by some measuring device. Information can be based on data, when it is qualified and considered in a particular context that gives it value. Finally, evidence is information that comes from a process ensuring its soundness, over a long enough timescale to be relevant and after testing for any scientific errors, for example [15]. It remains difficult today to determine the added value of AI in its use of data, whether to produce information or evidence. The most fervent data supporters have called for data and AI to be used to guide decision-making without any theoretical or explanatory framework, or even without any human intervention [16]. This would lead us into what is called data-driven policy [17]. At the other extreme, traditional EBP models are situated downstream, with a focus on (human) expertise. There is also a third path, one that blends AI and expertise, a kind of evolution of older "expert systems."

We will now review several subfields of public health where AI may be used.

Where Is Artificial Intelligence Used in Public Health?

There Is No Artificial Intelligence Without Data: Data Federation and "New" Types of Data

The widespread and large-scale development of AI algorithms is predicated on increased access to relevant data. This is required to develop the algorithms, and then to move them into production, and finally to adapt them to working environments, interfacing them with other information systems. AI would seem to be a useful tool for organizing and federating all of this data, as well as processing and analyzing it. The diverse array of data sources presents an opportunity for public health, especially because we are so often lacking sufficient data: (i) real-life, repeated data, (ii) environmental data, (iii) behavioral data, and,

more specifically, (iv) data on exposure (which can be included under environmental data). AI in public health could therefore benefit from data from geographic information systems and more broadly from geospatial/geolocation data [18], data on digital footprints and individual activity, data from social networks and online forums [19], and data from connected objects, with a focus on passive data collection. These connected objects can include medical devices (implanted devices), as well as nonmedical devices, in particular smartphones.

The Citizen and the Patient: Producer, Actor, and Manager of Their Own Health

One of the best data sources for AI in public health, therefore, will be people themselves, whether they are patients or not, and whether they are sick or well. People are of interest whether or not they are presenting with a pathology, since the goal is to find associations between a certain exposure and a given health event. This exposure may be biological, or it may be social, cultural, economic, behavioral, etc. Every person therefore becomes a potential data “producer,” either actively or passively, while also becoming a “producer” and promoter of their own health. There is a loop that begins with the individual generating data, which is added to a pool of data collected from other individuals. This data pool is then processed using AI, and the original data “producer” may then be contacted with information or instructions about their health. A classic example would be the use of this model to improve therapeutic education [20].

Of course, AI can operate on a level well above that of the individual.

AI and Health Surveillance Systems

In the past, AI has been used in public health to monitor various potential threats, such as epidemics and the improper use of pharmaceuticals or medical devices [21]. The classic example is

Google Flu Trends, although it is no longer active and had certain clear limitations. Google Flu Trends claimed that it could predict flu outbreaks faster and more reliably than the CDC (Centers for Disease Control) by analyzing search terms entered into the Google search engine [22]. Various studies of the advantages and disadvantages showed that Google Flu Trends was not very precise and pointed out weaknesses in the algorithm, or rather algorithms, since the algorithm was replaced several times, although we do not know exactly how it was changed. Monitoring the use of medicines and medical devices after they have been approved and put on the market, in ever greater numbers each year, is an important public health issue. Monitoring each product systematically, by hand and on a case-by-case basis, does not seem to be a sustainable solution. Without completely replacing humans, AI can help to sort signals to determine which should be followed up on. Nevertheless, more recent events have shown us that currently, and probably for a long time yet, the best early warnings are based on the discernment of humans who are in the right place at the right time. It was not data-monitoring signals that raised the alarm about the COVID-19 pandemic, but a human doctor.

Learning Healthcare Systems (LHSs)

At the healthcare system level, for example, when there are one or more healthcare establishments involved, AI can be used to create a learning healthcare system, among other things [23]. This concept was developed in 2007 and has evolved since, with a focus on continuously improving the quality, organization, and suitability of care provided by a healthcare establishment. It involves collecting data about medical and paramedical practices (practice-based evidence), notably by using and processing electronic health records and utilizing flexible and continuous search abilities. Because an existing data warehouse or data pool is needed for an LHS to function, we see once again that AI can be used at various points throughout the system: from the collection of data to its specialized processing, federation, and

formatting. The AIs used in an LHS can vary in their autonomy: from very high (total) autonomy in the data extraction layers to much less autonomy (supervised) in the higher layers, where decisions are made. The prospects offered by LHSs require human involvement, both technical and organizational, with the promise of a system that is more reactive and less fixed. While the idea is interesting in principle, we lack sufficient information to accurately assess the realities and effectiveness of LHSs.

Risk and Insurance

Health is a special kind of economic good, as its capital can only ever diminish over time. Health costs are significant, and risk pooling and prevention mechanisms are often necessary, so that the individual whose risk materializes is not indebted for life or financially ruined because they have to pay the full costs themselves. We therefore have insurance, where you pay a premium based on the nature and likelihood of the risk you are insuring yourself against [24].

The notion of risk is central to public health, since it is used to determine primary, secondary, and tertiary prevention measures. Knowing all the relevant risk factors makes it possible to suggest changes in health behavior or to begin treatment before a pathology manifests itself [25].

The Notion of Risk in the Era of AI

Risk factors are not necessarily the cause of an illness, but they are indicators. Discovering a risk factor involves establishing a statistical association between an exposure (e.g., to tobacco) and a pathology (lung cancer) and then estimating the strength of association (relative risk). This is a familiar tool used in epidemiology [25]. AI's potential advantages lie in its ability to identify associations using new methods (machine learning), as well as in its ability to simultaneously account for a greater number of individual and contextual characteristics when calculating risk, and therefore risk intensity, for a specific person. Deep learning and Bayesian networks are particularly promising here. Bayesian networks make it

possible to calculate the conditional probability of developing a pathology given a set of characteristics [26]. Uncertainty and imprecision are taken into account in the network's design. Another advantage of Bayesian networks is that unlike most other AI algorithms, they provide a clear graphic model of the interconnections between characteristics. This helps to develop explanatory models for the health event in question: the model is already easier for human beings to understand.

Approaches Adopted from Marketing and PR: Segmentation and Targeting

The stratification of populations into different risk groups, traditionally following a gradient (of increasing risk), is similar to strategies used in marketing and PR. The idea is to segment a population based on certain characteristics, so that each segment can be targeted with qualitatively or quantitatively differentiated actions. A familiar example might be the strategies used by Facebook, Google, and Amazon, which have a lot to teach us about different techniques that could be used in public health to identify more relevant and more specific population strata. This approach has some similarities with individualization, since more characteristics can be taken into account, refining the way people are characterized by dividing them into smaller, and therefore more numerous, groups than in traditional approaches. For example, Amazon customers are divided into 200,000 different groups, and each customer may move from one group to another based on their browsing and purchase history. Each group is associated with a set of likely recommendations: if you belong to a certain group, because you "resemble" the other people in that group, it is likely that a purchase made by someone else in the group may be relevant to you, even though you did not make the purchase yourself. The stratification, segmentation, and targeting strategies used in marketing and PR are no longer unheard-of in public health. In fact, efforts to make preventative messages and information campaigns more effective already take their target audiences and communication methods into account.

Insurance and collective and individual risks can be integrated into the objectives of precision

public health. For example, precision public health may help to reduce health inequalities, including social and economic health inequalities, bringing a new dimension to the old issue of proportionate universalism [27]: should we help people in proportion to their health needs, with the goal of attaining a desired average level of population health? Or should the same assistance be provided to all, no matter their needs or socio-economic situation, in the interests of equality? In other words, because AI can help to identify risk factors that tend to be more individualized and more actionable than previous methods thanks to the use of digital technology and connected objects, the debate between equality and equity has returned to the fore.

Organization and Governance

Capturing Data for Research and Governance

As we have already said, one of the unique features of public health is that it operates at the intersection of health and policy and of research and medical practice. In fact, data and AI can be used to pursue two substantially different goals. A recent example that serves to illustrate how data and AI can be used across the spectrum between research and political decision-making is the COVID-19 pandemic and the role of case tracking in different public health policies aimed at controlling the epidemic at the national level [28]. In a highly aggregated form and initially intended for research purposes, mobile network operators made phone data available (e.g., in Italy and France), which painted a better picture of the changes in population movement before and after the implementation of lockdown measures. This information, initially used to calibrate models to track the geographical and populational spread of the virus (most models are “compartmental,” meaning they represent fragments of the population, with no need for individual data [29]), was actually used to inform policy decisions based on how effective restrictive measures had been and how well they had been followed. At the other end of the spectrum, smartphones could be

used as passive or active data collection tools (users enter the data themselves, or the phone passes on certain information, such as geolocation data), as information and communication tools (alerts when there has been suspected contact with a confirmed case, instructions or orders to go into quarantine, etc.), as well as a means for monitoring individuals. In the last instance, the smartphone can be seen as a digital passport, displaying a color code calculated by an AI whose criteria remain unknown and which decides whether or not to allow someone to enter a certain area (as in China [30]). The transfer of data between different actors, the police, airports, hospitals, health ministries, and so on, has also helped to drive individualized actions, for example, when a certain person was identified to be breaking their quarantine [31]. The police could then be informed and take action (as in South Korea and Singapore). More generally, over the last few years, we have seen the rise of personal scores (social credit score in China), calculated based on algorithms whose code remains secret [32]. The consequences of these scores are all too real, as they may bar citizens from accessing public resources, including healthcare. This is one of the downsides of AI: like most systems based on data federation, the mechanisms behind these scores still require human intervention.

New Public Health Actors: The Role of Platforms and the Private Sector

Digital technology is at the heart of AI’s contribution to public health. Digital technology has produced several giants of the private sector – the GAFAM (Google, Apple, Facebook, Amazon, and Microsoft) – who control as many resources and wield perhaps as much influence as most countries. These companies concentrate material resources and dominate the use of digital technologies by offering apparently free services that have become an essential part of daily life, allowing the companies to capture data through these tools and services. Their services have also been supported by the growth of AI: mostly for segmenting populations and targeting advertisements and marketing campaigns, but also more generally for refining recommendation systems

[33]. While health data in most countries is protected under a special legal status, a person's health status or diagnosis can often be better determined by capturing and cross-referencing data that are not initially related to health, but that are diverse and massive enough for the AI to interpret, than by using their actual health data. A significant portion of a person's health risk is based on their behaviors. The rise of open data has made it possible to cross-reference the private individual data captured by these companies with contextual and environmental data, for example, about exposures. No matter how you approach the issue, it is clear that these platforms are often best positioned to estimate risk, to open communication channels, and to personalize actions taken, since, beyond their digital and AI resources, these companies also possess incredible and very material logistical resources: data centers, warehouses, customer/vendor contact platforms, distribution networks, transportation networks, and so on.

Future Challenges

Many of the current and future challenges of AI in public health are not limited to this field alone. Larger issues remain with the acceptance of data capture and coding, with citizens' and patients' digital literacy [34], with biased algorithms whose faults hinder the further use of AI [35], with the digital divide, and finally with building algorithms that are powerful enough and appropriate for the field of health. There are also some challenges specific to the field of public health. For example, what trade-offs should be made when setting algorithms' optimization criteria, which need to cover both individual and collective health? And how much overlap should there be between health and policy?

Challenges Shared with Other Health Fields

AI will only become a part of public health if certain conditions are met: the relevant information systems would need to be interoperable and truly accessible [36], and there would need to be

support for capturing data and for processing and documenting this data. It will be necessary to win the acceptance and approval of citizens and patients, but also of healthcare professionals and decision-makers, for algorithms and the recommendations, information, etc., they produce, regardless of the quality of the algorithms developed [37, 38]. History has shown that the adoption of new digital technologies is not directly related to the quality or reliability of the information they provide, but rather to the user experience: Is it pleasant? Easy to use? Does it meet some need that the user has felt or previously expressed?

Biases are an important problem [35]. Algorithms are constructed based on data. In the frequent case of the reuse of data – that is, the use of data that was not collected specifically for building the algorithm – various biases may be found, including those of the designers themselves. Foremost among these are selection biases, since the database may not contain all of the relevant information. Instances of biases based on gender, ethnicity, and geographical origin have been the best documented so far: the risk in applying an algorithm developed from health data about white men to women of African origin is that it may produce results that are irrelevant and possibly even dangerous. This bias is already present in clinical research, but it is exacerbated by the use of AI, especially in public health, which covers many diverse populations. The hidden danger of highly inclusive AI in public health is that it would tend toward a totalizing representation and utilization. This risk stems from the principles of public health itself, which could be used by the state to try to organize every aspect of individual life in order to protect public health (or security, etc.). More generally, problems of health and digital literacy still need to be considered [34]. Not everyone has the same resources for engaging with the digital world, and the use of AI in public health could widen existing inequalities, or create new ones. Beyond simple digital literacy, access to digital hardware is also a real problem. During the COVID-19 pandemic, the population most at risk of serious illness and death is the elderly. In most countries, however, this population also has the lowest level of digital literacy and is the least likely to own a smartphone. This means that strategies to control

the epidemic based on smartphones and AI might not be the most suitable.

More Specific Challenges

It is often difficult to predict whether new phenomena in healthcare will be useful, since there are so many standards to be met. While a marketing department might be happy with a conversion rate (how many people see an advertisement vs how many people make a purchase) of between 10 and 40 percent, these levels of absolute effectiveness and relative gain are well below what is necessary in healthcare. For certain very specific and well-defined medical fields and tasks, such as anatomical pathology, AI performance may be excellent, especially when the AI is designed to support humans. But this is not true across the board, and most specialities require some proof that it is worth adding another dimension of complexity, namely, the social and populational dimension.

The tension between individual preference and social preference is present from the very first stage of algorithm design, even if it is rarely discussed. Essentially, algorithm training follows an optimization function. Most of the time, the algorithm looks for the best possible optimum for a specific criterion. In terms of public health, what exactly should be optimized, potentially to the detriment of other criteria? Individual health? Collective health? Cost-effectiveness? A technical debate on multi-criteria optimization and a social debate are both needed on this issue.

Of course, all of the challenges that AI normally faces in terms of ethics, societal issues, and legal issues take on a special importance here, since it is not only a question of individual health, but also of health policy. Whether the line between the public and the private in these matters should be sharply drawn or somewhat blurred remains an important question. Until now, the private sector has dominated the industrial aspects of health: producing medicines and medical devices. This sector is subject to heavy regulation at the national and international levels. It is therefore difficult for AI and digital technology to gain a foothold, since incredibly powerful private actors are already present upstream. These private

actors may seek to outflank newcomers by influencing new regulations.

Conclusion and Outlook

Artificial intelligence is used in public health at at least two points in the process of turning data into decision-making: upstream, in the capture, federation, and formatting of data, and downstream, in supporting decision-making. Until now, AI has developed rather quietly, focusing intently on data and only drawing the attention of those with a technical interest. If AI is to be used in decision-making, including any important contributions to the creation and implementation of health policy, certain issues must be resolved: namely, the dual tension between optimizing individual criteria or collective criteria and between public prerogatives and private ambitions.

Abstract

Artificial intelligence (AI) and machine learning in healthcare are growing at an unprecedented rate. Myriad uses of medical AI, ranging from tumor identification on imaging to workforce management, make use of a wealth of available healthcare data. These models are becoming increasingly commercially available. However, much of the utility of medical AI depends on the quality of the data models trained on, and critically, the contexts and biases within which these models are created. In this chapter, we first describe a business-informed framework that influences product development and commercialization of these technologies. We describe the consumer side that includes purchasers, end users, and patients. Subsequently, we underscore the pitfalls of the assumption that models trained in one context can be applied to another, that is, the myth of generalizability. We propose solutions to these problems and describe the importance of co-creation and multi-stakeholder engagement in designing medical AI. We highlight the need to define value metrics that consider equity and the mitigation of healthcare disparities. Lastly, we draw attention to open ethical, legal, and policy questions that must be answered as the role of AI in medicine progresses and grows.

Introduction

Paul Gauguin's magnum opus "Where Do We Come From? What Are We? Where Are We Going?" appears to outline the human life cycle. Read from right to left, the painting poses existential questions about what happens beyond. It is an apt analogy for current times of rapid transformation within healthcare, an industry that accounts for about one-fifth of the US economy. Specifically, artificial intelligence (AI) and machine learning (ML) in healthcare are projected

to grow from \$4.9 billion in 2020 to \$45.2 billion by 2026 [1]. Examples of medical AI abound; recent studies make use of AI to identify tumors on imaging [2, 3], direct aspects of clinical evaluation [4], and workforce management [5].

Evidence-based and data-driven medicine is considered the gold standard of high-quality, safe healthcare. Additionally, the healthcare industry is increasingly shifting toward value-based care models of payment [6]. This creates incentives to rely increasingly on big data [7]. A commonly used phrase applied to big data analytics is "garbage in, garbage out." If we are to deliver on the promise of AI with effective implementation, that requires specific frameworks and intentional harm mitigation to protect from unintended consequences.

In this chapter, we present a business perspective of medical AI and identify limits of ready-to-use off-the-shelf medical AI algorithms that are increasingly common. We offer an alternative approach with which to create and incorporate AI-based medical tools with strategies for high value purchasing decisions and implementation. Lastly, we will discuss the key considerations around AI-enabled healthcare technologies that incorporate quality, value, accuracy, effectiveness, and equity.

The Business Perspective: Product Development and Sales

It is important to consider the process of product development from the business and innovation point of view. To "know your customer," in the complexity of healthcare, we must define who "the customer" is. We must differentiate the end user from the economic buyer from the patient or consumer of care. Specifically, the former may be a clinician who is using hospital-purchased AI to diagnose and treat patients. The economic buyer would be a director or c-suite executive making the purchasing decision at an institutional level. In contrast, the healthcare consumer is the patient

whose health outcomes may depend on the quality of AI used but often has no say or knowledge of AI use or purchase. Thus, the target customer for a company developing AI for healthcare may be removed from the experience of the end user or the patient. This may result in misaligned incentives or gaps.

Also, whereas many clinicians consider healthcare to be a social good and ideally do not differentiate between one patient and another, for product developers and business, there is often a deliberate approach to market segmentation. That means intentionally selecting a particular segment of the market based on disease type, geography, population density, ability or willingness to pay, cost of customer acquisition (CoCA), etc. As medical AI falls into business-to-business (B2B) category, innovation firms seek customers with efficient sales processes. Some customers may have different size and complexity of the decision-making unit (DMU), which in turn affects CoCA.

These factors can influence initial access to healthcare technology as well as which data are used for initial algorithm development. It is plausible that the least discerning customer with fewer internal safeguards is the first purchaser. On the other hand, it may be that the savviest early adopter may influence the product by being part of the beachhead market. Later adopters, who believe by waiting they are getting a “proven” product, are actually purchasing something not necessarily equally effective in their own population.

Once a product is developed, its use may be broadened to populations and settings for which it was not originally designed or in which it was not tested. The “myth of generalizability” – the oftentimes incorrect assumption that conclusions drawn from one population apply to another – affects healthcare AI as it has affected much more established realms of healthcare [8–10]. Although many medical journals require that articles presenting healthcare AI validate results on external cohorts, this may not be a consideration for all potential purchasers and users of healthcare AI [11, 12]. Many early evaluations of medical AI have demonstrated that strong performance at a single site may not translate to strong performance at many other sites; there seems to be an inherent trade-off between improving systems locally and

creating generalizable systems [9, 13–15]. Therefore, marketing claims on accuracy, effectiveness, or predicted outcomes using data from other customers must be evaluated with a healthy degree of skepticism.

The Consumer Perspective: Purchaser, End User, and Patient

A key consideration is that accuracy of AI – much like the application of randomized controlled trials [16–18] – is bound by space and time. In particular, as a “learning” system, medical AI requires the relevant and most matched dataset not only for training but for continuous updates and ongoing improvements in order to serve the healthcare AI purchaser at a systems level, the end user of healthcare AI, as well as the patient or healthcare consumer. With regard to systems-level purchasers, examples include clinical systems, payers, accountable care organizations, or government entities. As these systems may have high complexity or large DMUs, they may be the last to be approached for sales and/or slowest to adopt technology.

Importantly, the populations that medical AI is meant to learn from – and the populations medical AI is meant to serve – are dynamic and diverse. In contrast, many algorithms are created and sold as “ready-made,” that is, trained and proprietary algorithms that are meant to be used as-is by the user. Furthermore, algorithms based on a finite set of data may not be able to adapt to different populations not captured by the data on which the algorithms are trained. If many of these algorithms do not correct for biases that are systemic in the data from which the algorithms are made to learn, then seemingly “novel” technology may perpetuate biases of the past.

An example of this would be that AI designed to detect radiologic lesions that is trained and tested in one ethnic or geographic population may not have the correct standards or benchmarks when applied to another population [19]. This is especially salient when considering existing racial and gender disparities that exist in data used in clinical trials that inform our current evidence-based medicine standards [20]. Data used for

current guidelines comes from studies with primarily white and male clinical subjects [20–22]. The majority of dermatology images, an area ripe for AI, use white subjects [23]. Facial recognition technology has been found to be more commonly inaccurate if users are female and/or black [24]. As we are starting with existing biases in our data, then we must be careful and resolute that AI design and implementation is suited to deliver quality outcomes across diverse populations. Another area of healthcare disparity is rural health. Use of AI has potential to close gaps especially on improving resource allocation, promoting supply chain integrity, and addressing workforce shortages [25]. This requires further study to evaluate.

Myth of Generalizability

Medical AI relies on the computer's ability to synthesize certain kinds of data almost infinitely faster than a human can and on the computer's ability to store vast amounts of information in its memory. In teaching computers to "see" (computer vision), "listen" (natural language processing), or "think" (CNNs), medical AI models are often built to sense patterns from quantities of information that are much larger than humans can. However, the assumptions made by AI may be predicated on biases inherent to the teams developing these tools [26].

Two examples are illustrative of the importance of multicenter data with local validation. The first, in ophthalmology [27], provides evidence for the validation of an AI-based model when comparing data from two ophthalmologic institutions in India within a field where there is known specialist variation. Another study of AI for chest X-rays in the United States demonstrates that even within a single country, models may not generalize across institutions.

The study by Gulshan et al. sought to validate the performance of an automated diabetic retinopathy (DR) diagnosis system across two sites in India. They found that, using data prospectively collected for two ophthalmologic institutions in India, an automated algorithm identified referable DR with performance equal to or exceeding the

retinal specialists and trained graders for a discrete outcome [27]. While the international retinal grading system is on a more granular five-point scale, it is common for clinical decision-making to focus on what is actionable or not. The gold standard used was labels agreed upon by a panel of retinal specialists. The need for a consensus DR classification has been noted in multiple studies to account for variation in specialist readings [28, 29]. Gulshan et al. caution that the use of different types of cameras may also impact the generalizability of their algorithm. Subsequent research on AI-powered DR evaluation by Google Health in Thailand across multiple centers found that clinical criteria alone were insufficient without data on socio-environmental factors [30]. For the healthcare administrator or government official seeking to apply this at the systems level, the takeaways are that such AI may be used as a screening tool, does not replace human specialists, and must take into account local context and data.

Another example is of Zech et al. [31], in which the authors employed convolutional neural networks (CNNs) to analyze medical imaging and generate computer-aided diagnoses. They assessed how well CNNs generalized across 3 hospital systems for a simulated pneumonia screening task, making use of a cohort of 158,323 chest radiographs drawn from 3 different institutions in the United States. Models trained on one institution's data did not always perform well when validated on another institution's data. For example, they found that the highest internal performance was achieved by combining training and test data from two of the three institutions (AUC 0.931, 95% CI 0.927–0.936); however, the model demonstrated significantly lower external performance at the third institution (AUC 0.815, 95% CI 0.745–0.885, $P = 0.001$). The authors advise: "Given the significant interest in using deep learning to analyze radiological imaging, our findings should give pause to those considering rapid deployment of such systems without first assessing their performance in a variety of real-world clinical settings." [31]

Taken together, these examples underscore the potential pitfalls in generalizability. Healthcare executives who seek to replace costly specialists

with medical AI are advised extreme caution; the evidence does not readily support that approach for consistent quality in patient-level or population-level outcomes. At the same time, in low resource settings with workforce shortages, as is found in rural health and global health, AI for screening may assist with prioritization or resource allocation decisions. Understanding strengths and limitations of any technology solution allows effective implementation.

Given these challenges, we offer the following approaches to increase value and mitigate risks:

Proposed Consideration 1: Co-creation

A best practice in product development involves co-creation, customization to the consumer, use of consumer data [32], short product life cycle, and agile approach with continuous releases. This is a change from traditional product development that employed a “one-size-fits-all approach” to development of a minimum viable product (MVP), longer timelines, and longer product life cycle. We believe it is critical for healthcare AI to utilize these industry best practices of ensuring that technology used is trained on local data from the AI purchaser rather than from a different dataset. The very nature of AI and ML allows the product to be customized to the customer if the ongoing learning is on customer-specific data.

Despite variation in context and patient population affecting the systemic and patient-level generalizability of many ready-made medical AI technologies [9, 13–15], the continuous learning nature of AI and ML could offer an advantage over standard use of “one-size-fits-all” clinical practice guidelines. By employing local data from which to draw inferences, clinician decisions can be more matched to the local population [33–36].

Diversification of training data is an important first step: as with clinical trial data, the more closely the study cohort mimics the clinical context in which AI solutions are being employed, the greater the accuracy [37, 38]. There is a false assumption that those informing AI development must be well versed in technology or innovation. In fact, local practitioners provide the requisite

insights into the particular clinical questions that AI solutions may help solve.

Proposed Consideration 2: Multi-Stakeholder Engagement

The public sector and nonprofits, whose mission is often to serve the needs of a wide array of groups, are a useful source of inclusive best practices for multi-stakeholder engagement throughout the stages of product development. For example, the Patient-Centered Outcomes Research Institute (PCORI) has developed a robust rubric used for patient-centered study design and widely accepted framework employed in the context of healthcare research and innovation that serves both large systems and smaller groups that face health disparities [39, 40]. Combining medical patient-engaged research design with innovative human-centered design is recommended for businesses in medical AI product development [41].

An additional benefit of this approach is staying abreast of the evolving legal and policy landscape discussed later in the chapter. While business approaches sometimes can limit information sharing, in fact, open channels of communication can allow access to the most up-to-date knowledge through collaborators and engaged stakeholders. Engaged stakeholders can inform strategic growth, mitigate risks, and identify future avenues of dissemination.

Proposed Consideration 3: Metrics for Defining Value Delivered

Increasing penetration of value-based care models requires careful definition of quality. Value metrics for medications and machines exist, ranging from changes in biomarker levels, survival, and cost-effectiveness; however, these may be replete with biases or may not truly benefit the patient or end user. Biomarkers may not account for patient diversity. Survival outcomes may not account for adverse effects. Cost-effectiveness may not capture the extent of a patient’s experience. Fields are continuing to modify their metrics to adopt these dynamic values. For example, the oncology

community is growing in its focus on patient-centered outcomes rather than survival alone in its evaluation of treatment options [42]. Many fields are recognizing financial toxicity as another adverse effect of treatments [43, 44]. Importantly, for medical AI, we are at the position to define metrics for success with which we measure progress.

Reducing disparities has already been defined as value-based care quality metrics [45–47]. Some large payers institute payment withholdings if quality targets are not met [48]. We propose medical AI should be evaluated by matching metrics to those clinical systems already held accountable for payment. For example, it has been shown that women treated by female doctors have better myocardial infarction outcomes [49] and Black infants treated by Black pediatricians may have lower mortality [50, 51]. Medical AI trained to help predict risks and determine treatment should aim to close these gaps [52, 53].

It is critical to understand that conclusions from data of certain systems may imply causation related to individual factors that are, in fact, systems issues, as with the use of big data in health insurance [54]. Healthcare purchasers who do not ask discerning questions may find poorly validated medical AI harms both their patients and their bottom line. Business executives who are thoughtful can differentiate their medical AI products by comprehensive quality metrics. These cautions we offer highlight an opportunity to improve and represent a challenge to innovators.

Ethics, Law, and Policy

In forging the way forward, we must pause and ask “Where are we going?” We need to ensure that we aim to do more than convert existing data into technological solutions; we must aim to improve both data sources and outcomes. Within the field of ethics and bioethics for medical AI are many potential approaches defined by culture, values, philosophy, political affiliation, and national interest, all of which require careful thought.

Of note, Gauguin’s “Where Do We Come From? What Are We? Where Are We Going?” was painted at a time of personal crisis. It depicts the artist’s transition from centering on Judeo-Christian references to subjects interwoven with Tahitian mythology [55]. Similarly, in AI, we must be thoughtful in what use as a reference value or school of thought. The concept of “crisis” is particularly relevant during the COVID-19 pandemic, and simultaneously, at a time during which the American Medical Association labeled structural racism as a “public health threat” [56].

Additionally, there is a dynamic tension between industry controls for brand management and academic intellectual freedom. How these interfaces are handled can have significant consequences for trust in companies and industry for thought leadership, as was the case for Google’s handling of research ethics and equity [57]. Continued collaboration across sectors is essential to promote innovation and broad dissemination.

Legal liability of AI use in healthcare is an evolving field – who owns the risk when errors occur? From the example of electronic health record, even system failures can result in physician liability [58]. This is especially complicated in an industry where, per one study of US healthcare, error was already the third leading cause of death [59]. Of note, the critics of that study consider the large database analysis inadequate, which underscores the uncertainty inherent to use of big data to define baselines and benchmarks. As there will never be a single right answer, we advise developers and purchasers of medical AI to seek legal counsel with regard to enterprise risks. It is important to establish a clear rationale and documentation for potential future legal challenges.

Further, international law, particularly from the European Union [60], is shaping the opportunities and limits of this industry, with ongoing debates related to privacy, data sharing, competition, and even national security. The potential for a new technology “Cold War” has been suggested [61]. Specifically, there is a call for technology diplomacy, that is, ongoing efforts to bolster beneficence and equity in the dissemination and application of medical AI on a global scale

[62]. Evolving policy at institutional, local, state, national, and international level must be continually referenced and adapted to as we wrestle with complex and often contentious ethical dilemmas of medical AI.

Conclusion

In this chapter, we have asked the reader to consider how to ensure medical AI delivers value to customers. We offer cautious optimism for a technologically advanced future that serves both human needs and business objectives of revenue generation, market share, and return on investment. If innovation is opportunistic, fails to examine structural inequity, or does not engage stakeholders, there is the danger of merely encoding and perpetuating the past. On the other hand, with intentional human-centered design that accounts for the range of human variation across contexts, there is boundless opportunity. Therefore, there is urgent and deliberate need to be conscientious in our development and adoption of medical AI. In doing so, we may not need to ask “Where are we going?” but instead define and create the way forward.

in Africa has seen a few pilots and test cases in human resource planning, child health, diagnostics, and pharmaceuticals. Extant challenges around availability of informative data, legal and policy, costs of development, and lack of infrastructure have stymied progress in different parts of the continent. Despite these challenges, the prospects for AI in Africa to play active and significant roles in population health, individual care, health systems, and pharmaceuticals and medical technology are evident, and solving the highlighted challenges will help make its prospects possible. A major lesson from the experience of AI professionals working in resource-poor settings is that AI implementation should focus on incorporating products into existing systems and institutions rather than attempting to start from scratch or hoping to replace existing systems.

Africa · Low-resource · AIM · Primary health · Rwanda · Governance · SDGs · Developing countries

Introduction

Data drives scientific knowledge and advances in healthcare. Different approaches to human research – basic/preclinical research, observational studies, clinical trials, translational studies, and implementation research – have centered on collection, analysis, and interpretation of data that can improve individual and population health. In Africa, productive efforts have been seen with regard to the data revolution. For instance, health research output in Africa has consistently increased in number with some improved quality over the past two decades, especially in areas of infectious diseases and some non-communicable diseases. This increase is in spite of the continued emigration of clinicians and academic professionals away from Africa [1]. The improvement in health research effort is commendable although Africa contributes less than 1% of world research, there is an

opportunity for data analytics can change this low output [2].

The data source and data quality are important factors that determine whether an algorithm can recognize meaningful patterns, learn from experience, and make appropriate decisions given its perceptual and computational limitations. In African countries, most health information utilized for national planning are sourced from household surveys [3]. Some benefits of these surveys, especially those supported by multilateral organizations, include the high level of standardization, good quality control, adept interviewers, and careful data analysis. These surveys have been conducted more frequently in West Africa compared to other parts of the continent, while the central subregion has reported the least surveys over the past 25 years. Other sources of health information in Africa are population census, civil registration systems, disease surveillance, research studies, and health services statistics. These data sources are often fragmented. Generally, data with multiple sources are preferred to those with one source. However, in Africa, mechanisms for triangulation of available data are needed to minimize fragmentation and duplication while ensuring sound data is available in timely ways [4]. More so, computers can simulate more intelligent behaviors and make nuanced decisions with harmonized/pooled data rather than fragmented ones. Data actors including data managers, statisticians, and data analysts together with health departments will need to be involved at various stages of data collection so that developed algorithms can make the best use of data for Africa's population health.

Healthcare landscape in Africa has undergone significant changes, thanks to the recent technological advances such as access to the Internet, cloud computing, alternate energy source, and improved smartphone uptake. These technological innovations have improved the quantity and quality of health data available in the continent as well as the efficiency of data analysis, storage, and utilization as cloud computing continues to gain ground across the continent. In Africa, large volumes of health data are being generated – whether from rural health centers or from some of the

sophisticated genomic laboratories. Advances in information technology and data science have the potential to help resolve some complex developmental issues across the region. This has been recognized by multilateral organizations and research bodies including the World Health Organization (WHO), United Nations International Children's Emergency Fund (UNICEF), and National Institutes of Health (NIH) as well as corporate organizations [5, 6]. The ability to fully extract meaningful knowledge from Africa's health data will lead to rapid innovations that positively impact health of Africans and world at large.

Brief History of Artificial Intelligence for Medicine in Africa

Certain African folklores describe historical stories that bear semblance with modern-day computer science. One that is publicly available is about Ifa, the deity of wisdom, and intellectual development among Yoruba people in Nigeria, West Africa. The Ifa's divination system developed over 12,000 years ago, and still being practiced till date, utilizes binary codes and pattern recognition for communication between an Ifa priest and the gods. This divination system was also applied in solving health problems according to history [7].

Evidence-based application of artificial intelligence in medicine (AIM) was piloted in Africa in the mid-1980s. In 1986, a successful pilot test was initiated in Egypt to improve the detection of common and potentially blinding eye disorders before full-scale deployment in the USA [8]. A probabilistic decision-making system assisted rural health workers to identify life-threatening conditions in Gambian outpatient clinics. The system performed well in detecting 88% of cases among Gambians. In Kenya, AIM improved health worker-patient interaction quality with evidence of increased number of symptoms elicited [9]. Additionally, Computerized Aid To Treat (CATT) was also used in drug prescriptions in South Africa by nurses based on a cost-and-effectiveness algorithm [10].

Current Applications of AI for Medicine in Africa

The most significant applications of AI are happening in business and finance in Africa, but when it comes to AIM, more meaningful applications seem to be occurring in developed nations compared with what is obtained in Africa. Worldwide, it is anticipated that AI can help in saving over \$150 billion in costs by 2026, and different studies have documented the positive impact of AI in delivering benefits for different Sustainable Development Goals (SDGs) including health which is SDG 3 [11]. The prospects of AIM prompted the United Nations in different forums which brought different stakeholders together to discuss how AI can be used to deliver critical public services and help in the journey toward achieving the SDGs [12].

There has been a steady increase in the application of AI as a tool to solve health problems across the continent. Different pilots and test projects are being implemented in countries in the region for health challenges particularly around human resource, health education, diagnosis, consultation, and pharmaceuticals. Examples include a multinomial logistic classifier-based system that predicts the length of stay in public service among health workers and diagnosis of diabetic retinopathy in Zambia, algorithms for authentication of drugs in Nigeria, and chatbot for health education and consultation like the Ada Health and Swahili bot [13, 14].

A significant number of these projects are being led by private organizations and academic institutions which include Delft, IBM, Microsoft, Google, Babylon, etc. While early results from some of these pilots and tests have shown significant promise, there are numerous unanswered questions regarding how much impact these AIM tools have had or are having in terms of healthcare delivery in the continent.

In Africa, radiology seems to be the aspect seeing the most meaningful application of AIM, with the most advanced and integrated uses of AIM happening in that aspect of healthcare delivery. This includes the Delft Institute's software for tuberculosis diagnosis which has been deployed

in Mozambique, Malawi, and Eswatini [15]. Outside diagnostics, health education and information are other areas experiencing significant changes in Africa's AIM. Chatbots are gaining ground in delivering health information, triaging, and consultation to the public. Babylon Health is working with the Rwandan Government to roll out its artificial intelligence-powered triage and symptom checker to the whole country as part of a 10-year partnership [16].

Challenges with AIM Landscape in Africa

While implementation of AIM in Africa will have to face the extant challenges that affect health systems across the continent, there are specific issues that are peculiar to the successful deployment of AIM to meaningfully solve problems. These include economic, social, and institutional problems. These issues concern basic building blocks that are important to help ensure that AIM can be locally designed, developed, tested, and implemented at scale. These will be discussed under the following headings.

Digital Health Foundation

A digitized health system is a necessary foundation for the development and deployment of AIM. This digitalization will include widespread adoption of electronic health record (EHR), efficiency of interoperability, and creation of standards, registries, and infrastructures (e.g., storage).

Digital health has been gaining traction in the region over the past few years with more countries developing and adopting national digital strategies to drive growth in their health sector. However, most of the growth have occurred in the private sector and businesses, while the public sector lags behind due to inefficient governance, poor institutional capacity, and funding [17]. For example, adoption of EHR is limited across the continent where administrative use case is more prevalent than clinical application of EHR. Additionally, most of the clinical uses of EHR occurs in

donor-funded HIV treatment programs. The EHR of these HIV programs are often standalones and are often not integrated into a country's existing health system [18]. This results in difficulties with the creation and curation of health data, while problems with subsequent integration and adoption of AIM systems for health organizations and service providers across the region persist. Building a solid and integrated digital health foundation will pave the way for the smoother development and implementation of AIM.

Data Availability and Quality

Due to the low adoption of EHR systems and inadequate digital infrastructure across the healthcare delivery chain, there is inadequate data to locally train and develop AI systems in the region as most health records are still maintained in paper format [18].

Algorithms being designed for general use globally are trained with data that are not adequately representative of the African populace. This creates inherent bias in these systems that may be deployed to serve the Africans. For example, the International Skin Imaging Collaboration: Melanoma Project, which is one of the largest, open-source archives of pigmented lesions, has most of its data collected from Caucasian populations. Deploying any algorithm trained on this dataset may lead to underperformance among populations with darker skin tones [19]. A study conducted in Uganda using a dermatology AI software showed poor accuracy due to the training data predominantly originating from a Caucasian population [20]. Inadequate meaningful health data has slowed the progress of algorithms that will be more effective among African population. This has led to a reliance on foreign systems for application on the continent. These systems which will be affected by the bias, prejudices, and specific beliefs of the creators lead to unintended bias when applied to low-resource settings [21, 22]. Beyond clinical data, other health data such social determinants of health contribute to a robust AIM system. Some of these nonclinical health information is either still collected

traditionally with pen and paper or exists in inaccessible silos.

Infrastructure

AIM solutions will rely and be built on and integrated with existing digital health infrastructures which are often absent or inadequate in most African countries. African countries lag in Internet penetration and access to electricity (less than 30% of health facilities have electricity access) which has impeded the execution and sustainability of different solutions and technology in healthcare and other sectors [13]. These solutions will have to be deployed on digital devices either for use by health workers or individuals. While uptake of digital devices and adoption of ICT are rising on the continent (smartphone adoption stands at about 40%), most health systems and individuals on the continent still lack access to these devices which will hamper the scaling and adoption of these solutions going forward [23].

Costs and Funding

The healthcare system in the continent suffers from chronic underfunding and massively relies on donor funding. This challenge extends to digital health initiatives and is compounded by the existing unstructured market. Most of the funding for digital health projects including AIM systems come from outside the continent.

It is hard to ascertain how much the development of AIM might cost in developing countries. Considering the approach to development which will involve skills, data acquisition and preparation, and hardware and computing resources alongside system maintenance and upgrading, putting together these systems in Africa will be expensive. African countries are seeing a rise in the acquisition of skills required for development of AI systems as evidenced by the works of Data Science Nigeria and Zindi and the opening of hubs by Google, IBM, and Microsoft but still have a long way to go in getting the required

pool of expertise for local development of these systems [24, 25].

Governance, Regulations, and Ethics

African countries are at different stages in the development, adoption, and implementation of national digital health policies that will guide digital health. These policies and their implementation have been stymied by poor government engagement and political will, thereby negatively impacting the progress of digital health solutions [26].

The legal framework covering data use and protection is just being developed in most African countries. Only nine countries have passed data protection laws across the continent. Considering the repeated history of medical abuse of processes, research, and humans usually by outside actors, these laws are essential to ensuring that the data that will be used to develop AIM systems are ethically obtained and not misused. There is also a need for policies and guidelines that oversee the development and deployment of these AIM systems to ensure that these systems are just, fair, and aligned with Africa's values/heritage with clear lines of accountability. This will minimize the mistrust and hesitation associated with new technology in the region as some locals perceive that external actors are trying to impose their values [27].

Critical Areas of Attention for Improving AIM in Africa

African countries are seeing increasing development of AIM products and services; while the growth is encouraging and promising, the full potential of these will not be realized unless a few things are put in perspective and gotten right. These will be discussed under the following categories:

Data Ecosystem: As AIM will rely on significant volumes of data for training, and it is best that these data are locally generated, it will be important to work on creating systems that enable much easier data generation and curation; this will

involve the digitization of all process along the health delivery chain, widespread adoption of electronic health record, and creation of open data initiatives that increases access to national and government datasets. Rwanda is making progress in this regard as a significant hub for technology in Africa. It signed a deal with Inmarsat to lay the foundation for an Internet of Things (IoT) project to create an infrastructure that allows the easy generation, stability, and sharing of data for the required monitoring and development of solutions. Rwanda also has signed a deal with Babylon Health to create a nationwide digital health delivery system which covers significant digitization of health records. These ensure a foundation to help generate required data and foundation for development of AIM [28, 29].

Infrastructure: Africa has significant infrastructure gaps that cut across all sectors, especially in the aspect of electricity which is most significant to AIM and digital health [30]. While most consumer products might be deployed on smartphones that require less susceptibility to electricity limitations, integration into the health system will depend on access to electricity that will power the digital systems that the AIM will leverage and work on. The stability of electricity will affect the usability of such systems. Alternative power systems like solar electricity are gaining ground and being deployed to ensure power stability for health systems but ensuring good public electricity infrastructure will be more sustainable.

Development and Capacity Building: To enable development of more locally relevant and less bias products, it is important that local actors and stakeholders are fully integrated into the development process and are consulted at every stage. Development of AIM products as the next interesting thing in healthcare will only create tools that will not be useful, efficient, sustainable, and adopted by the stakeholders in the system; this is more important for products that are not directed primarily at consumers.

It is also important to work on capacity building for the respective governments, health workers, and individuals in the respective countries. This will also involve training and development of local talents and skills required to build and maintain these systems. Google has opened an AI

research center in Ghana, while IBM has two research centers, one in Nairobi, Kenya, and another in Johannesburg, South Africa; these research centers are meant to help develop talents in the region and ensure that solutions are developed and tested within the environment where they are needed [31].

Governance and Ethical Approaches

It is important that appropriate governance framework and foundations are laid before AIM gains traction as a regular tool for healthcare delivery across Africa. More countries need to ratify and implement data protection laws to protect against misuse and abuse of data. This also needs to extend to the creation of accountability for the systems that will be created. Carman and Rosman advised that existing principles and frameworks for developing good AI should not be adopted into the African context without holistic evaluation; they further advised that individuals and societies driving research in this area should ensure that values, culture, and contexts are put into consideration while ensuring that knowledgeable stakeholders are involved in all phases of development [27]. Much like everywhere else, it will be helpful for the African Union and her member states to create a committee to design ethical guidelines and frameworks for the implementation of AI in Africa as the European Union did.

Building for the Africa (How Best to Approach Solutions and Implementation)

- Availability of data being one of the major challenges for AIM, a continental network model for interconnecting nations in Africa through its data centers has been proposed. This will involve building world-class infrastructures connecting different medical facilities for collaboration and resource sharing, with the benefit of fast-tracking collaboration and speeding up data collection, storage, and processing in healthcare services [32]. Federated learning, a collaborative machine learning

without centralized training data, could be a viable solution to the problem of fragmented data [33]. Even though this technology was originally proposed mainly to ensure data safety and anonymity, it promises to also act as a method to build robust AI systems over decentralized data sources. This in effect cuts the cost of storing data in the cloud, in a single location. It leverages the diversity in data variation and preserves the integrity of each source, allowing for smarter models, lower latency, and lesser power consumption.

- Internet penetrations is rising in Africa, but a lot of places where these solutions might be relevant either have no access to the Internet or have bandwidth challenges. The solutions (especially ones targeted for use by frontline staff) developed need to make considerations and contingency plans for this challenge. This might involve the development of systems that can run offline and update when it has intermittent access to the Internet or low-end products that do not require large bandwidth to run appropriately.
- There are funding limitations, and it is best that solutions are targeted at relevant and high-impact challenges. These solutions should be funded and developed based on evidence and not as a “shiny new thing” concept. It is also important that health workers, targeted users, and all relevant stakeholders are involved in the design process to ensure that the solution is appropriately targeted at the problem. Most importantly, it is best that the development of these solutions is led by Africans.
- AIM is a tool and not an elixir; therefore, solutions should be built with the state of the health systems and governance in mind and with an understanding that they will be subject to the present challenges that are inherent in these targeted health systems.

Opportunities for AIM Impact in Africa

Considering the dominant health challenges on the continent and the state of the health sectors across different areas of the country, AIM will best be developed and deployed as solutions

under the categories based on a US Agency for International Development (USAID) report on the use of AI in global health which classified AI application in global health under four specific use case areas that are likely to have the highest potential for impact on global health. We will be expanding that to cover five areas by adding another significant use case that is important to healthcare delivery on the continent. These five areas are also relevant to primary healthcare which is very integral to improving health outcomes on the continent. These classes are:

AI-Enabled Population Health – This covers solutions that accept and analyze population health data and provide recommendations based on them. Examples include disease surveillance and warning systems, automated triaging solutions, etc.

Patient Virtual Health Assistance – This covers solution that assists patients on self-care, wellness, and health advice. Examples include health chatbots, screening tools, behavior change tools, etc.

Frontline Health Worker Virtual Health Assistance – This involves solutions that assist frontline healthcare workers’ expertise in co-ordinating patient care, education, advice, and required diagnosis. Examples include screening tools, AI-assisted diagnostics, and health record management.

Physician Clinical Decision Support – This covers the provision of specialist expertise to primary care physicians and generalists who are most involved in clinical care across the continent. Examples include AI-assisted diagnostics, clinical decision support, and quality assurance and training.

AI-Assisted Logistics – This class covers solutions that help to address and manage the supply chain of drugs and other essential health products [34].

Overview of Selected Applications of AI for Healthcare in Africa

Below are three selected cases of the application of AIM in Africa that are worthy of note. They

cover diagnosis, supply chain management, and health education, three of the most significant areas where AI will be strategic in making a difference in healthcare on the continent.

Kenya Medical Supplies Agency (KEMSA) with IBM's Watson

The Kenya Medical Supplies Authority (KEMSA) is a state-owned health logistics service company founded in the year 2000. This company has the authorization to procure, store or warehouse, and distribute medical commodities to public healthcare facilities and other public sector customers in Kenya. To improve on its service delivery, KEMSA partnered with IBM's Watson.

IBM's Watson is used by the Kenya Medical Supplies Authority (KEMSA) at its approximately 7000 facilities across the country. Pharmacists, patients, and doctors can interact with the AI through SMS, voice messages, and online messaging services. It can instantaneously access information and is being used to aid the medical supply chain. It can also act as an advisor that prevents supply shortages and finds new suppliers if needed. The health workers can find out if there is a medical supply available at their facility, when the next shipment will arrive, and if their hazardous wastes are disposed of. It is also used to maximize patient benefits as it allows them to find out which clinics have their required medications and how to properly dispose medical wastes at home. Users can interact with the AI through various platforms, including SMS, computer, and voice over mobile data [35].

Afya Pap in Zimbabwe

Afya Pap is a mobile app that serves as a personalized health education and coaching tool on chronic diseases especially diabetes and high blood pressure. It uses artificial intelligence and behavioral science to deliver personalized health advice and health insights to users. Afya Pap takes the medical conditions of the users and their lifestyle and culture into consideration, and based on these, the app can provide daily customized health

tips varying from easy exercise tips to medication reminders or eating healthier local foods. Also, users have an avatar that is a visual representation of their health status. The more they follow the provided health advice, the healthier their avatar looks.

Afya Pap is available for use in seven countries in Africa including Zimbabwe, Kenya, Uganda, Egypt, and others. It is a subscription-based app as users must pay a monthly subscription fee to use after the free 14-day trial period expires. Although Afya Pap was created to help patients suffering from diabetes and high blood pressure, it was extended at the beginning of the COVID-19 pandemic to provide live consultations with local physicians while also delivering COVID-19 prevention and care messaging to curb the spread of misinformation [36].

Delft Institute's CAD4TB Software

CAD4TB (Computer-Aided Detection for Tuberculosis) was designed to reduce costs and time involved in diagnosing tuberculosis. It was developed by Delft's Institute in the Netherlands; CAD4TB interprets digital x-rays using deep learning methods and remote expertise. It solves two critical problems in the diagnosis of tuberculosis.

- It delivers its results within a record time of 60 s to 1 min allowing patients to be diagnosed and treated within a day. Statistics have shown that early diagnosis and treatment of tuberculosis can not only save millions of lives but also curb its spread and reduce death rate from TB.
- The software beats other tests in cost-effectiveness. Aside from the fact that it is relatively cheap, it shows who is more likely to have tuberculosis and will need further testing, thus reducing the number of people that must spend a lot of money on the more expensive tests.

The CAD4TB can be used with or without an Internet connection. When a good Internet connection is available, the x-ray is processed by the CAD4TB server in the cloud. This allows it to be shared with other professional healthcare

providers who can provide expert advice remotely. In the absence of an Internet connection, the CAD4TB box which is connected to the x-ray system analyzes the image [37, 38].

There is a significant potential offered by AIM in improving healthcare in Africa. The existing use cases show that it is a feasible tool for tackling health challenges, reducing costs, and improving health access and quality. An evidence-based approach should be adopted in decision-making and implementation of AIM in Africa. African countries and institutions must also enact laws, guidelines, and policies that will ensure that users are protected and the products are developed for impact. A major lesson from the experience of AI professionals working in resource-poor settings is that AI implementation should focus on incorporating products into existing systems and institutions rather than attempting to start from scratch or hoping to replace existing systems.

Abstract

The sustainability of urban environments is an increasingly relevant problem. Air pollution plays a key role in the degradation of the environment as well as the health of the citizens exposed to it. In this chapter we provide a review of the methods available to model air pollution, focusing on the application of machine-learning methods. In fact, machine-learning methods have proved to importantly increase the accuracy of traditional air-pollution approaches while limiting the development cost of the models. Machine-learning tools have opened new approaches to study air pollution, such as flow-dynamics modeling or remote-sensing methodologies.

Introduction

Urban areas are at the center of the current climate-change debate. Starting at the end of the industrial revolution, urban areas have been growing at an accelerated rate. By 2050 the European Commission expects 70% of the global population to live in urban environments [4]. Thus, it is clear that cities play and will continue to play a major role in our society. Cities are responsible for a great share in the acceleration of climate change.

Mainly due to anthropogenic activity, cities act both as concentrators and diffusers of contaminants at the expense of not only the city itself but also of neighboring areas. In fact, ambient air pollution is responsible for 790,000 deaths in Europe [11], as shown in more detail in Fig. 1. Furthermore, the vast majority of cities tend to act as the so-called urban-heat-islands (UHI), modifying the natural thermal dynamics of neighboring areas. For those reasons among others, cities are expected to play a key role in the policies and endeavors aiming to reverse the effects of climate change within the next decade [18].

To deal with pollutant dispersion within the urban environment, one inevitably needs to consider the dynamics of urban flows. Environmental sciences tend to rely on the use of models to study and predict the behavior of atmospheric flows. Models can provide very useful

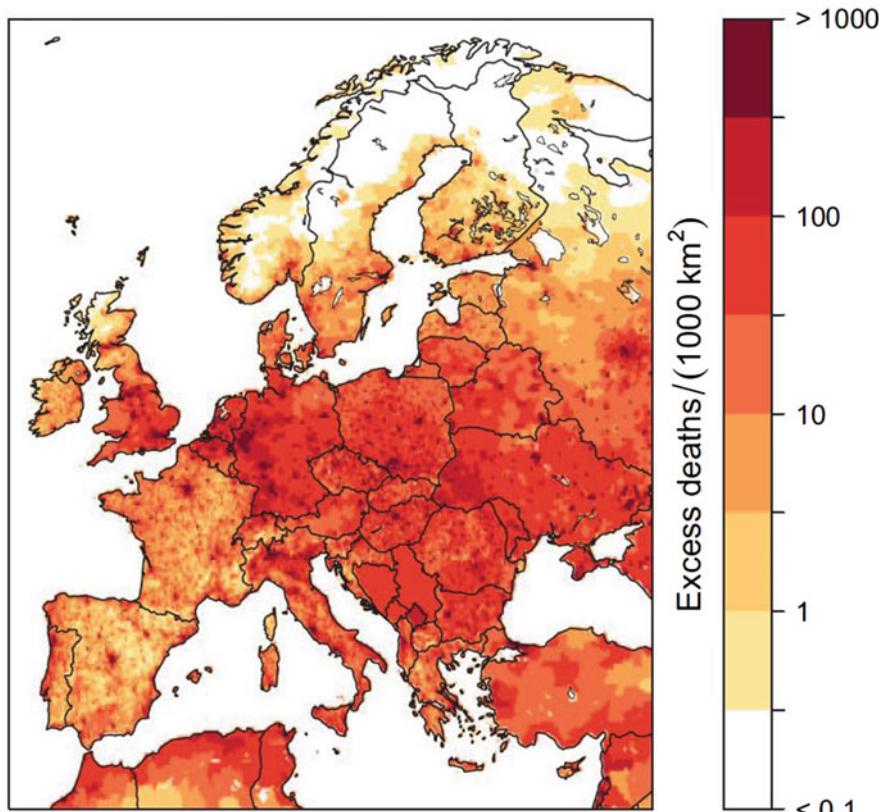

Fig. 1 Distribution of annual excess mortality from cardiovascular diseases due to air pollution in Europe. (Figure reproduced from Lelieveld et al., with permission from the publisher (Oxford University Press))

information when studying atmospheric phenomena at a very general level or when dealing with specific applications. However, to understand the flow within an urban environment as well as the inner relation to pollution mechanisms, modeling appears to be limited. In fact, urban flows are characterized by their complexity, thus severely difficulting the use of models to study the effects on pollutant dispersion or thermal problems. The experimental approach, although it can bring very useful insight into specific applications, typically does not provide information on the physical mechanisms driving urban flows [17]. Numerical simulations are also typically used in the study of turbulent flows and thus can be applied within the context of urban environments. Numerical approaches vary in terms of accuracy and complexity. The so-called Reynolds-averaged Navier-Stokes simulation (RANS) is widely used for its simplicity and reduced computational cost. Unfortunately, RANS methods exhibit important limitations when dealing with complex turbulent flows such as urban flows, thus limiting its use within the context of urban environments. In this way, urban flow simulations have to rely on more accurate approaches, such as direct numerical simulations (DNS) and large-eddy simulations, which have high computational cost. In addition, the domains considered in urban environments are typically large and complex, which again increase the computational cost.

The use of artificial intelligence (AI), and in particular of machine-learning methods, can improve the aforementioned limitations of the computational approach in the study of urban flows. In fact, using machine learning techniques one can produce turbulent models that are significantly more precise than the models historically used in computational fluid dynamics (CFD) without reaching the computational cost of DNS and LES methods. Those models would increase the forecasting capabilities of numerical methods in the study of urban flows. The next section will focus on explaining the state of the art of the aforementioned methods as well as the lines of study currently being explored.

Machine-Learning Methods in the Study of Urban Pollution

Machine-learning (ML) techniques have been widely used in many fields of physics and scientific research. In fact, ML has proved to be very effective in extracting underlying patterns and correlations within complex physical processes. The present section will focus on introducing the different ML approaches in the study of urban pollution. When dealing with urban environment pollution, two approaches are found. On the one hand, some studies focus on modeling pollutant dispersion as an independent physical phenomenon. Those models have been widely used and typically rely on empirical relations. Using ML methods, the aforementioned models can be significantly improved, as we will see later on. On the other hand, many studies rely on flow dynamics to characterize pollutant dispersion. This approach typically consists of solving the behavior of the flow in an urban environment in order to model the behavior of the pollutant. Several numerical methods have been widely used to solve urban flow dynamics (e.g., RANS and LES) but they are either too simplistic or too expensive in terms of computational cost. In this particular area, ML methods are being developed in order to reproduce flow dynamics without having to incur such computational costs.

ML Methods in Air-Pollutant Modeling

Air-pollution models have been widely used in order to analyze and control air quality in cities. Air quality is typically measured in terms of the particulate matter (PM) concentration, which basically measures the amount of particles found in the air. PMs are classified in terms of the size of the particulate. For instance, PM 10 refers to particles with diameters of 10 micrometers or smaller. In the present section we will focus on PM 2.5 as it is common to urban environments and it has been associated both with adverse health effects [21] and climate forcing [1]. Pollutant models have traditionally relied on linear regression techniques to capture the underlying mechanisms of

pollution. This approach is known to be limited, since urban-flow phenomena are characterized by their complexity, that is, the presence of nonlinearities and highly correlated effects. Complex phenomena are known to be challenging to linear methods as they tend to misrepresent important underlying relations [20]. ML arises as a solution to this problem and thus enhances air-pollution models. The fundamental idea behind ML pollutant models lies on using data, typically obtained with on-site measurements, to train the model such that it can predict a certain quantity. In the case of pollution models, the output of the model is normally pollutant concentration, that is, PM concentration. In the next lines we will present the most common ML algorithms applied to urban pollution models and compare them in terms of performance and accessibility.

The random-forest (RF) algorithm is a popular ML method to solve classification and regression problems. It is based on a classical decision-tree algorithm widely used in statistics and ML, but it builds each individual tree from random subsamples of the original data. In this way, each sub-sample of the original data produces a tree and thus produces a predicted response (or a predicted class if dealing with a classification problem). The final output of the model is determined by the average of each of the predictive responses (or classes) determined by each of the data subsamples. The use of a diverse database increases the probability of success [6], thus being very convenient to analyze complex phenomena which typically have important disparities within batches of data. In addition, thanks to the averaging process the algorithm can handle missing values in the dataset [3]. The accuracy of the method is dependent on the strength of each individual tree and the dependency of each subsample with one another [6].

Boosted regression algorithms are typically the result of modifying decision trees regression algorithms in order to enhance performance. For instance, the boosted regression tree (BRT) combines the well-known classification and regression trees (CART) with a large number of single models in order to improve the predictive performance of the model [6]. In fact, the averaging

process found in the RF model is replaced with a forward stagewise procedure in which existing trees are left untouched with new tree development using the residual information generated in the previous step of the process [6]. Alternatively, one can find gradient boosting regression methods such as XG Boost, which use gradient boosted decision trees in classification and regression problems, thus enhancing the speed and performance of the algorithm. In addition, XG Boost can be run using parallel trees as well as a cluster of computers during training time [3], which optimizes the method.

Multilayer perception (MLP) regression is part of the artificial neural network (ANN) family of methods. ANN methods are designed to mimic the behavior of the human brain during the learning process, that is, using interconnected synaptic neurons capable of learning and storing information about their environment [14]. The fundamental component of ANNs are neurons, which are described by a linear combination of weighted input signals and an activation function that limits the amplitude range of the output. ANN is built using at least three layers of neurons: the input, hidden, and output layers. The method processes information sequentially throughout the layers starting at the input layer and finishing at the output layer. The input of the system consists of the training data and a goal to fulfill. In this way, the system is trained on historical data to fulfill the predefined objective, learning during the process the underlying relations that lead to the fulfillment of the goal. Note that several training algorithms can be applied to a given network, for example, the back-propagation algorithm which combine forward and backward passes to train the network [14]. However, taking into account the motivation of the present chapter, we will neglect the training algorithm selection and focus exclusively on the performance of the models once trained. Other, more sophisticated types of ANN include recurrent neural networks (RNNs) and convolutional neural networks (CNNs), which have been used in the context of temporal predictions [13] and non-intrusive sensing [7] of turbulent flows. These strategies have high potential when it comes to developing robust air-pollution frameworks.

The aforementioned techniques are widely used in classification and regression problems and thus their application to air-pollution models – which are regression problems – is currently being studied. The present paragraph aims at discussing the performance of the different ML methods introduced early on. To do so, we will compare each model's performance with one another as well as with linear regression methods used in air-pollution models. To measure performance, four metrics are typically used in the related literature: the mean absolute error (MAE), the root mean square error (RMSE), and the mean square error (MSE). The MAE is defined as the sum of the absolute differences between the predicted values and the actual values scaled with the inverse of the number of observations. Similarly, the MSE is defined as the sum of the squares of the differences between the predicted and actual values scaled with the inverse of the number of observations. The RMSE is just the square root of the MSE. Wang et al. [20] used the aforementioned quantities to compare the performance of two ML methods, the ANN and the XG Boost, with the land use regression model (LUR). The authors developed a least-square LUR by fitting an intercept-only model and then adding explanatory variables (one at a time) based on the ranking of their correlation with the log-transformed of the PM 2.5. Some of the explanatory variables include: land uses, length of neighboring roads, distance to major aerial routes, traffic information, meteorology, etc. The models were developed using air-quality data (PM 2.5) collected over the course of 4 weeks between March and June 2019 in downtown Toronto (Canada). The samples were obtained on a non-rainy weekday between 7:00 AM and noon, covering 19 unique corridors in a 4-by-6 km area [20]. The authors explain that both LUR and ML methods present strengths and flaws. For instance, they found that LUR methods were highly dependent on the selection of the explanatory variables, which are directly dependent on the user's subjective judgment and a priori knowledge. In this way, a change in the selected explanatory variables, *ceteris paribus*, would have an important effect on the performance metrics (MAE, RME, RMSE, etc.). However, when

properly fit, the performance of LUR methods significantly improves – even surpassing ML methods – especially when the size of the dataset decreases [20]. In fact, the size of the dataset is a critical limitation of ML methods since large amounts of data need to be processed within the network's layers such that the model can produce accurate results. Nevertheless, the ANN superiority with respect to linear regression models is guaranteed by the universal approximation theorem of functions, which states that a fully-connected multilayer feedforward neural network with continuous, bounded and nonconstant activation function can act as a universal approximator for any smooth mapping to any accuracy [20]. The superiority of ANNs over traditional linear methods in the context of turbulent flows has also been thoroughly discussed by Guastoni et al. [7]. The authors conclude that ML methods provide opportunities to understand complex underlying relations in air-pollution dispersion processes as well as nonlinear relations between air quality and exogenous variables. Nevertheless, one cannot directly discard regression methods, since they may exhibit very good performance in the cases where local knowledge is available.

Doreswamy and Yogesh [3] presented a similar study where four ML models (RF, BRT, MLP, and CART) were compared in terms of performance. In addition, they also compared ML methods with classical statistical methods such as the linear regression. Once again, performance is analyzed using the error metrics (MAE, RME, RMSE, etc.) compared both in training and testing results. The dataset used in the process was taking hourly measurements of air pollution (PM_{2.5}) at 76 stations distributed over Newport (Taiwan) between 2012 and 2017. The obtained dataset was used to train the different ML algorithms and to compare the predicted air-pollution values with the actual measurements taken in the stations. The gradient-boosting regression – a type of boosting-regression algorithm – showed the best performance compared with both classical statistical methods and ML algorithms. In training, the gradient boosting regressor showed an MSE at one order of magnitude lower than the rest of

ML methods and more than two orders of magnitudes lower than the linear regression method. In the rest of the metrics, the obtained values were two to three times lower than the rest of methods. In tests, the difference between the methods was not as large, but the gradient-boosting regressor still obtained errors two times lower than the rest of the methods. In general, all the analyzed ML algorithms exhibited errors two times lower than the ones obtained with the linear regression [3], thus supporting the superiority of ML methods.

In conclusion, we have discussed different ML methods that can be used to develop air-pollution models. For the majority of the algorithms the performance was found to be better than that of classical statistical methods, such as the linear regression. In this way, the application of ML techniques to develop air-pollution models appears to be useful as the accuracy of the models is significantly improved. However, it is important to keep in mind that ML algorithms are limited by the amount of data needed during training, thus not being applicable when large batches of data are not available.

ML Methods to Model Flow Dynamics

The physics of the flow determines the dynamics of pollutant dispersion. In the previous paragraph we approached the study of air quality by modeling pollution, that is, using particulate matter. An alternative approach consists of studying the dynamics of the flow in order to determine the dispersion of pollutants. Numerical simulation such as LES and DNS can be very useful in order to study the dynamics of the flow. However, this kind of numerical technique has a very important computational cost which limits its use. In addition, the setup of the simulation is not a simple task, which again increases the development time. ML methods could significantly improve the current state of numerical simulations in urban flows by improving computational cost and by extension computational time. The main idea is to use the data obtained from a numerical simulation to predict the future behavior of the flow. Note that this approach is relatively new and

thus the available literature on the matter is limited. Nevertheless, the aforementioned approach is promising, as shown by Srinivasan et al. [13] in the context of recurrent neural networks. Non-intrusive sensing is another area with very high potential for ML-based methods, as shown by Guastoni et al. [8].

Xiao et al. [22] developed a fast-running non-intrusive reduced-order model (NIROM) to predict the behavior of the flow in urban environments. The authors gathered the data obtained from a high-fidelity numerical simulation (LES) in order to create the starting dataset. They used the data to generate snapshots of the flow fields such that it can be processed later on. A singular value decomposition (SVD) was applied simultaneously to all velocity components such that the natural correlation between the components is captured. The result of the process is a series of proper orthogonal decomposition functions, which are then used in a Gaussian process regression (GPR). The GPR consists of applying a linear combination of Gaussian-shape basis functions in order to obtain surface functions, which are one of the necessary inputs to build the network. Using the aforementioned elements, a neural network was trained in order to predict the behavior of the flow governing equations. The main idea is that one uses a dataset obtained using a high-fidelity simulation – which is computationally very costly – to obtain a model (NIROM) that will be able to predict the behavior of the flow, this time without the need of the dataset. The authors used the NIROM to predict the flow around the London South Bank University such that the prediction could be compared with actual measurements of the flow. They found that the NIROM was capable of making predictions beyond the range of the snapshots thus being able to accurately represent the vast majority of the dynamics represented in the high-fidelity model [22].

The main advantage of the NIROM over other ML-methods lies on the small amount of data required to make it function. Recall the gradient-boosting method presented in the previous paragraph, it required a huge amount of data to produce a reliable output. On the contrary, NIROMs are able to produce an accurate result with a

smaller database which can be obtained using a numerical simulation. Comparing the NIROM with high-fidelity numerical simulations, the main advantage of the NIROM lies on computational cost. Once the network is trained, the cost of producing new results is very small compared to the cost of running an additional high-fidelity numerical simulation such as a LES or a DNS. Nevertheless, the NIROM here presented, solves the behavior of the flow and thus needs to be adapted to study pollutant dispersion. This can be done either by including an additional equation in the NIROM (passive scalar) or by running an additional model that uses as input the solution of the governing equation of the flow.

Remote Sensing for Urban Air Observation

Impact of Remote-Sensing Sensors for Monitoring Urban Airflow

The value of remote-sensing data has been noticed in the early urban airflow and urban air-quality studies. Researchers have found opportunities to measure, visualize, and explain urban airflow and quality using remote-sensing images acquired from satellites. Early studies, however, have used the satellite images mostly as a background map in order to visualize the data which is collected from ground sensors. This is mainly because it took relatively longer time to develop higher resolution satellite sensors and to design new algorithms which can extract information about the urban airflow and air quality.

The newer satellite sensors have provided opportunities to researchers to develop algorithms to predict the airflow speed and direction, land surface temperature (LST), and atmospheric aerosol particles or in other words particulate matter (PM) which indicate the micrometer size of the particles that pollute air.

Accurate and real-time measurements of the airflow from satellite sensors still have limitations due to the available sensor specifications, visit frequencies (number of days needed for the satellite trip in the orbit before it returns back to the

same observation point again), spatial resolution, and accuracy of the information. On the other hand, measurement of LST and PM can be done more accurately and frequently with the existing satellite sensors. Therefore, in order to talk about the urban airflow and air qualities frequently LST measurements, PM measurements and the Urban-Heat-Island (UHI) effect are discussed. The UHI effect is the condition that describes higher temperatures in urban areas than surrounding areas of less development. An UHI occurs because of the extensive modification of the land surface. Remarkably higher temperatures are seen mainly in urban areas than in suburban and rural areas, because of the high number of the dense obstacles in urban areas.

Even though the existing remote-sensing satellite sensors cannot be used as high-precision urban airflow measurement tools, they can still provide a number of advantages. The most significant of them could be listed as follows:

- The ground sensors can be used for high-resolution airflow and air-quality measurements. However, the uneven distribution and limited installation possibilities create challenges to collect data which can fully represent the air measurements of the all urban area. On the other hand, using the ground measurements as control points, satellite measurements can be used to estimate the LST and PM for the areas where in situ measurements are not available.
- Satellite images can be used to find the optimal sensor positions in order to install the in situ sensors in urban areas.
- Remote-sensing images can help with monitoring very large areas and make it possible to do large-scale urban airflow research possible.
- Most of the time, it is possible to find digital maps of cities which bring information about the street tunnels, building boundaries, vegetation areas. However, satellite images can provide further information (low/high vegetation type, temperature changes of the lakes and other water reserves, building rooftop types, traffic density, etc.). These details which are acquired from the satellite images give chances to highly enhance the

information for doing detailed urban airflow and air quality analysis.

Remote-Sensing Data Resources and Analysis Methods

Satellite sensors can be classified as active and passive sensors. Active sensors (i.e., radar, LIDAR, etc.) first send a wave and generate an image by using the measurements of the waves which are scattered back. Passive sensors (i.e., multispectral, hyperspectral, thermal, etc.), however, generate images by using the light which is naturally received by the sensor. An active sensor, radar, can be used to measure wind vectors over the ocean through radar backscatter, which is also called scatterometry technique. The scatterometer on the SEASAT satellite makes it possible to resolve the wind direction within a 180-degree directional ambiguity, which is then resolved by knowledge of the overall atmospheric pressure pattern. The SEASAT scatterometer was an outstanding success, pointing the way toward future measurements of ocean wind speed and direction. Unfortunately this satellite had a massive power failure 6 months after it started operation. A replacement, stand-alone satellite, QuikSCAT, was launched quickly thereafter in 1999. The scatterometer on QuikSCAT is known as SeaWinds.

Passive sensors cannot measure the wind vectors straightforward like active sensors can measure. However, indirectly they allow researchers to estimate the airflow by measuring LST and PM. Therefore, they are frequently used in urban air flow studies. One of the most frequently used satellite sensors is the Terra satellite which was launched in December 1999. Terra is a highly valuable satellite which has been serving over 20 years for observing our earth. Terra satellite, which is approximately the size of a small school bus, carries five different sensors to observe different qualities of our earth. These sensors are: Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), Clouds and Earth's Radiant Energy System (CERES), Multi-angle Imaging Spectroradiometer (MISR),

Measurements of Pollution in the Troposphere (MOPITT), and Moderate Resolution Imaging Spectroradiometer (MODIS). ASTER is the only high spatial resolution instrument on the Terra platform. The Advanced Spaceborne Thermal Emission and Reflection Radiometer obtains high-resolution (15 to 90 square meters per pixel) images of the Earth in 14 different wavelengths of the electromagnetic spectrum, ranging from visible to thermal infrared light. Scientists use ASTER data to create detailed maps of land surface temperature, emissivity, reflectance, and elevation. ASTER provides high-resolution images in 14 different bands of the electromagnetic spectrum, ranging from visible to thermal infrared light. The resolution of images ranges between 15 and 90 meters. ASTER data are used to create detailed maps of surface temperature of land, emissivity, reflectance, and elevation [5]. Because the surface UHIs are typically characterized by (LST), it makes sense to measure LST from remotely sensed data to study UHI effects.

With its sweeping 2330-km-wide viewing swath, MODIS however sees every point on our world every 1–2 days in 36 discrete spectral bands. Consequently, MODIS tracks a wider array of the earth's vital signs than any other Terra sensor. For instance, the sensor measures the percent of the planet's surface that is covered by clouds almost every day. This wide spatial coverage enables MODIS, together with MISR and CERES, to help scientists determine the impact of clouds and aerosols on the Earth's energy budget. MODIS provides daily global coverage and the 10 km resolution of aerosol optical depth (AOD) for studying spatial variability of aerosols in urban areas. AOD is a reasonably good proxy for PM2.5 ground concentrations. Wang et al. [19] used this data to generate air quality maps and compared the information to the acute health needs of the residence in the test area. Téllez-Rojo et al. [16] used the same air-quality mapping approach for Mexico City and showed the direct relation of low air qualities to the acute respiratory symptoms of children.

The MOPITT sensor was designed to enhance our knowledge of the lower atmosphere and to

observe how it interacts with the land and ocean biospheres. The sensor measures emitted and reflected radiance from the Earth in three spectral bands. As this light enters the sensor, it passes along two different paths through onboard containers of carbon monoxide. The different paths absorb different amounts of energy, leading to small differences in the resulting signals that correlate with the presence of these gases in the atmosphere. MOPITT's spatial resolution is 22 km at nadir and it "sees" the Earth in swaths that are 640 km wide. Moreover, it can measure the concentrations of carbon monoxide in 5 km layers down a vertical column of atmosphere, to help scientists track the gas back to its sources.

Another highly used data source comes from the Landsat satellite (passive) sensors. Launched in 1982 on Landsat 4 and 1984 on Landsat 5, researchers found an opportunity to access the TM thermal bands. Landsat 4 operated successfully for over 10 years, with data collection terminated in 1993. The Landsat 5 TM acquired data for over 27 years until communication system failures essentially ended the TM data collections in November 2011. Landsat 6 never reached its operational orbit after launching in 1993. In 1999, Landsat 7 was launched with the ETM+ instrument. The newest Landsat mission, Landsat Data Continuity Mission (LDCM, or Landsat 8 after launch), was launched in February 2013 carrying the next-generation Landsat thermal-imaging sensor.

The Landsat TM data is one of the most widely used satellite images for LST retrieving because of its high resolution (120 m) and free download availability from the website of US Geological Survey (USGS), which has one thermal infrared (TIR) band. This makes retrieving LST from a single band more difficult than from multiple thermal bands. In comparison, ASTER data has five thermal bands with a higher resolution (90 m), which may provide more promising potential for LST retrieval studies, although very few studies of LST retrieval from ASTER data are available as yet. Therefore, in this study, we applied the mono-window algorithm to the Landsat TM and the split-window algorithm to ASTER data for the analysis of its effect of urban heat island in the

Table 1 Remote-Sensing Satellite Sensors for measuring LST and their spatial resolutions

Remote-sensing sensor	Spatial resolution (meter)
ASTER	90
Landsat 3 MSS	240
Landsat 4, 5 TM	120
Landsat 7 ETM+	60

case study of Hong Kong. Although satellite data (e.g., Landsat TM and ASTER thermal bands data) can be applied to examine the distribution of urban heat islands in places such as Hong Kong, the method still needs to be refined with in situ measurements of LST in future studies. Among others, Ho et al. [9] used Landsat ETM+ to map urban temperature and compared the results to the local weather station results. This comparison shows the high accuracy of the satellite based observations.

Table 1 compares the spatial resolutions of the most frequently used passive sensors. Higher resolution thermal images could also be obtained from airborne images. Even though the airborne images provide very high-resolution information, it requires a very expensive procedure to fly over a large area to collect information. If the observation needs to be repeated with a certain time frequency, this procedure opens technical and financial challenges. Therefore, satellite sensors are highly preferred both by researchers and other land-observation institutions.

Further Supportive Data that Satellite Remote Sensing Can Offer

Besides providing measurements about wind speed/direction, air quality, and the heat islands, satellite sensors can make more measurements about earth which could support detailed research in the field of urban airflow analysis. For instance, multispectral satellite images provide an opportunity to calculate normalized difference vegetation index (NDVI) which tells about the vegetation greenness in the area. Some researchers have used NDVI as a major indicator of the urban climate. Experiments showed that during summer-time NDVI is negatively correlated with

surface temperature. However, previous studies have also shown a causal relationship between NDVI and LST that is subject to seasonal variation. Furthermore, the response of LST to NDVI varies among different land cover types. Some studies have demonstrated that LST has a stronger correlation with other parameters which could be obtained by using multispectral satellite image bands. For instance, the normalized difference built-up index (NDBI) or vegetation fraction than with NDVI showed higher correlation to the urban LST.

Impervious surfaces are found in urban and suburban landscapes and can be related to population density and urbanization. It is shown that reliable quantification of UHI could be achieved by analyzing the relationship between LST and impervious surface areas, which are again calculated by using multispectral bands of the satellite images.

Besides providing vegetation and built-up area indicator parameters from the multispectral band ratios, satellite images also offer the opportunity of automatic mapping of detailed 2D or 3D structures and for observing the traffic density as well. In a previous study, Sirmacek et al. [12] have proposed a 3D building reconstruction method compared to the rooftop shape prediction accuracies when different satellite sensors are used. Huang et al. [10] have studied impacts of different building roof shapes on the urban airflow. Their study shows that automatic building detection and rooftop modeling methods might provide important information to enhance the urban air quality and airflow research. Taubenboeck et al. [15] have studied extracting patterns from satellite images which can indicate social groups and income distribution within urban areas. These studies might also provide more discussion points to the urban air quality analysis research. Last but not least, there is probably a significant correlation between road usage and air quality in urban areas. Zheng et al. [23] used AI to estimate urban air quality. They trained their models with features coming from satellite data, which indicate distances to the road network, length of the roads, and meteorological data. Their study showed the significant correlation of the urban air quality with the extracted road features. Therefore, both the passive

sensor based information and active sensor based information might be important satellite sensor based sources to study the urban air quality.

Challenges and Open Problems

In the previous sections, we have seen that the application of machine-learning methods can be helpful in the study of urban air pollution. Two approaches were covered, that is, air-pollution models – which consisted on directly modeling air pollution – and flow-dynamics models, which focused on inferring the behavior of pollutants from the dynamics of the flow. Nevertheless, both approaches exhibit limitations and areas of improvement. On the one hand, the application of machine-learning algorithms to air-pollution models requires large amounts of data to provide accurate predictions. On the other hand, modeling the dynamics of the flow, despite not needing such databases, requires running numerical simulations which have an important computational cost. Furthermore, the inference of pollutant dispersion from the dynamics of the flow is not direct and thus requires a proper validation.

Additionally, another challenge affecting both approaches is the training of networks. It is known that the network training and the employed data usually have an important influence on the outcome of the system. In fact, the matter of training biases and, by extension, the biases of the system are important questions in all the fields where artificial intelligence is applied. The assessment of this problematic is relevant both from a technical perspective – since it heavily affects the outcome of the predictions produced by the network – and from an ethical point of view, since the outcome of those networks will typically influence policy-making decisions.

On the other hand, active sensors can help with direct measurements of the wind speed and direction. However, due to their low resolutions, their application areas are limited with sea and ocean monitoring. Their resolutions cannot help with adding valuable information to study urban airflow. On the other hand, passive sensors of the satellites provide measurements which can indirectly help with the urban airflow studies. They

can measure air quality, local heat, vegetation density and greenness. They can even provide detailed 3D building models and information about the road network. Even though these parameters are highly correlated with urban airflow, for precise mapping, still it is important to calibrate and enhance the satellite based information with in situ sensors. Budde et al. [2] introduced SmartAQnet called study which aims to combine multiple data resources to study the urban air quality in detail. They have combined IoT data such as weather sensors, in-situ air quality sensors, dust measurement devices, satellite images, and high-resolution drone images. However, due to the scalability issue of such a complex sensor fusion challenge, they have limited their analysis only with the Augsburg city of Germany. This study shows the big data collection and analysis challenges which still exist.

Another challenge is the validation of the health impacts of the urban airflow analysis. Even though the earlier studies showed a correlation with respiratory diseases, further research is still needed to completely pinpoint the urban-airflow aspects responsible for it. This will allow to develop better residence health estimation models, for increased urban sustainability.

Abstract

Pharmaceutical products are researched and developed through many stages: target search, hit search, hit to lead, lead optimization, and preclinical and clinical trials, all of which have a complex, expensive, and time-

consuming process and a low overall success rate. Therefore, there is a need to reduce research and development costs by increasing the probability of success and improving process efficiency. One of the most promising approaches to this problem is the so-called *in silico* drug discovery, i.e., drug discovery using information technology such as artificial intelligence (AI) and molecular simulation. In this chapter, we describe the development and application of AI in drug discovery.

Introduction

Drug discovery and development processes can be broadly divided into three categories: basic research, nonclinical studies, and clinical studies. Basic research begins with the search for target molecules, followed by the identification of hit compounds from a vast compound library and optimization of the hit compounds. Nonclinical studies are conducted in animals to test drug pharmacodynamics, *in vivo* dynamics, and adverse effects. Clinical trials can then confirm the safety (side effects) and efficacy in humans. Since drugs are developed through many stages, drug discovery is complex, expensive, and time-consuming and has a low overall success rate. Therefore, various AI technologies are being developed worldwide, such as prediction of target proteins based on available studies and omics information; protein 3D structure prediction; screening of hit compounds; automatic generation of lead chemical structures and prediction of synthetic pathways; prediction of absorption, distribution, metabolism, and excretion (ADME) of drugs in the body; prediction of side effects; and decision support in clinical trials. The main purpose of AI technologies is to reduce the probability of failure by making accurate predictions before the actual experiments and tests are conducted, and it is expected to optimize costs and duration of development by reducing the number of experiments and tests.

In recent years, *in silico* drug discovery is an actively implemented approach that uses computational methods such as molecular simulation and machine learning to improve the efficiency of the drug discovery process. This is due to the progress in AI technology and big data. AI technologies range from conventional machine learning, such as support vector machine (SVM) and random forest (RF), to deep learning, including deep neural networks

(DNNs), convolutional neural networks (CNNs), and graph convolutional networks (GCNs). For big data, various databases are available, such as PubChem/Bioassay [1], the world's largest bioactivity database published by the National Institutes of Health's National Center for Biotechnology Information (NIH/NCBI) in the United States; ChEMBL [2] and DrugBank [3], which contain information on the activities of compounds and target proteins; SIDER [4] and Food and Drug Administration Adverse Events Reporting System (FDA FAERS), which contain information on compounds and side effects; and the Kyoto Encyclopedia of Genes and Genomes (KEGG) [5], which is a database that integrates information on diseases, drugs, and intermolecular networks such as metabolism and signal transduction.

Here, we focus on three topics that are important in the application of AI in drug discovery: (1) ligand screening and pharmacology; (2) absorption, distribution, metabolism, and excretion (ADME) in pharmacokinetics; and (3) data source for drug discovery.

Ligand Screening and Pharmacology

There are various difficulties in drug development, but one of the most challenging stages is the initial selection of compounds from the large pharmacological space. Theoretically, there are more than 10^{60} variations of molecular structures and more than 100,000 variations of target molecules to which a compound binds, even when limited to proteins, which are the most typical targets. Therefore, to efficiently search for the best compound-protein combination, advanced methods such as machine learning, especially deep learning, are necessary in addition to conventional ligand docking simulations. Various machine-learning methods have been applied to predict active compounds. Since Hinton's group won the state-of-the-art in the Kaggle competition held by Merck, a major pharmaceutical company, in 2012 for a deep learning method using a multitask deep neural network [6, 7], applications using deep learning have been rapidly advancing [8]. In this section, we will explain three computational approaches for the prediction of

compound-protein interactions in pharmacology: ligand-based, structure-based, and chemical genomics-based [9, 10].

Ligand-Based Approach

The ligand-based approach was developed based on the idea that compounds with similar chemical structures have similar pharmacological activities [11]. Therefore, the model inputs the chemical structure information of a candidate compound and then outputs the presence or absence of pharmacological activity such as bioactivity for disease cells and binding to target proteins. For example, in a quantitative structure-activity relationship-like (QSAR) approach, a machine-learning method is used to compare a candidate ligand with all known ligands and infer its binding ability. However, this approach has some drawbacks. Since protein information is not used for learning, the novel interactions that can be predicted are limited to the relationships between known ligands and protein families. In addition, this method requires the construction of a model for each target protein, and while it is possible to build an accurate model for proteins with abundantly known ligands, it becomes difficult to accurately predict binding active compounds conversely [12]. Multitask learning has been proposed as a technique to overcome this problem and has been recently used frequently [7]. Multitask learning is a technique for simultaneously learning pharmacological activity data for each of the multiple cell phenotypes and target proteins, which can be achieved with a network configuration that shares some of the hidden layers. Multitask learning is expected to improve the overall process accuracy because it can learn the features of active compounds that are common among multiple phenotypes/proteins; even when the scale of binding information for each phenotype/protein is small, they can be efficiently learned in a way that complements each other's data volume.

Structure-Based Approach

The structure-based approach uses the 3D structures of proteins and compounds to perform docking simulations on the pocket sites of target

proteins to predict whether they will bind or not. Unlike the ligand-based approach, it does not require known active compounds but allows the search for active compounds with new scaffolds [13]. However, this approach also has a crucial limitation. In fact, defining the 3D structure of a target protein is difficult as many target proteins have not been elucidated. In these cases, a structure-based approach cannot be applied.

Predicting the 3D structures of a protein from sequence information, although mainly observed for decades during the critical assessment of structure prediction (CASP) competition, is an extremely challenging issue. Recently, AlphaFold, a combination of deep learning and simulation techniques, has attracted much attention because of its superiority over existing methods [14]. In particular, in the CASP14 experiment, AlphaFold2 outperformed all its competitors and became a hot topic [15].

Various methods have been developed for the prediction of the 3D structure of proteins, including template-based methods and relaxation, using profiles and fragments. Many of the high-ranked systems used in the competition consist of modules to search in databases and contact map estimation and machine learning, including deep learning [16, 17]. In addition, it is often used in combination with a simulation module that uses an empirically based force field because it is difficult to perform a complete simulation based on the first principle [18, 19]. Although deep learning was used for the contact map estimation and multiple sequence alignment modules for 3D structure prediction before the appearance of AlphaFold, its first success was produced by expressing the uncertainty of contact map estimation and constructing a deep learning system with the simulation. Furthermore, a higher performance in AlphaFold2 was achieved by using the end-to-end architecture instead of using the intermediate step for the contact map estimation. In general, many deep learning applications have successfully replaced the traditional manual and sophisticated pipeline of multiple modules with a differentiable end-to-end architecture based on traditional processes. With the success of AlphaFold2, such an approach may become an important trend in other drug discovery issues.

Chemical Genomics-Based Approach and Polypharmacology

The chemical genomics-based approach predicts potential interactions by integrating the chemical space of drugs and the biological space of proteins, using both chemical structure similarity of compounds and sequence similarity of proteins as indicators [10]. This approach is expected to reveal complicated multiple interactions between compounds and proteins, that is, polypharmacology. Furthermore, the chemical genomics-based approach overcomes the disadvantages of ligand-based and structure-based approaches for various reasons. First, the fundamental advantage is the availability of a wide range of publicly available biological data. For example, the chemical structures and protein sequences of thousands of compounds have already been compiled in public databases [1, 2, 20]. This information can be used to predict the interactions [21]. Since the prediction is based on both chemical structure similarity of compounds and sequence similarity of proteins, it is more accurate than the ligand-based methods that use only compound information [22]. Second, the chemical genomics-based approach is more versatile than the ligand-based and structure-based approaches because it can be applied to target proteins for which there are many assay data or of which the 3D structure is not yet known, even if there is no known active compound information of the target protein itself. Third, the chemical genomics-based approach is the mainstream of recent programs that predict compound-protein interactions. For example, there is a multimodal method in which the chemical structure of a compound is learned by Graph CNNs and the protein sequence information is learned by CNNs, and they are combined in the middle of the network [23]. Another example is a multimodal method where the compound fingerprint and protein are trained with multilayer perceptron and CNN [24], respectively, and the compound and protein are trained with CNN and long short-term memory (LSTM) [25].

ADME in Pharmacokinetics

Pharmacokinetic studies are involved in the entire process, from compound seed discovery to clinical trials, and play an important role in new drug development [26, 27]. It was reported that pharmacokinetics was the reason for about 40% of dropouts in drug discovery and development until 1985 [28]. Subsequently, due to improvements in in vitro absorption, distribution, metabolism, and excretion (ADME) assays, the rate decreased approximately from 40% to 10% between 1991 and 2000 [29, 30]. One strategy to further improve the success rate of clinical trials is to estimate human clinical doses that exhibit optimal drug efficacy profiles. This requires accurate prediction of human pharmacokinetic parameters from nonclinical data before moving on to human clinical trials [31]. The development of high-throughput in vitro screening technologies has led to the accumulation of high-quality high-throughput ADME data, and in silico prediction of ADME properties using machine-learning methods has also gained significant momentum [32–35]. We introduce the modeling of ADME, which has been reported in recent years.

Absorption

Human intestinal absorption (HIA) is the process by which a drug is transferred from the site of administration to the vascular system. It is a process that determines bioavailability and has a significant impact on the efficacy and safety of drugs. Some studies have used SVM, artificial neural network (ANN), k-nearest neighbor (k-NN), probabilistic neural network (PNN), partial least squares (PLS), and linear discriminant analysis (LDA) to predict HIA and finally reported that the SVM algorithm with a kinetic basis function kernel had the best accuracy [36].

Distribution

Distribution refers to the spread of a drug throughout the vascular network of the body after it enters

the body and its arrival in the target tissue or organ. Prediction of the volume of distribution from nonclinical data has been relatively successful because it is largely determined by the physical properties of the drug, such as protein binding and membrane permeability. For example, QSAR studies have been performed to predict four human pharmacokinetic parameters: volume of distribution at steady state (VD_{ss}), clearance (CL), terminal half-life ($t_{1/2}$), and unbound fraction in plasma (fu). The method is based on feature selection using molecular descriptors of MOE, moldred, and PaDEL, and prediction models are constructed using several conventional machine-learning methods. These models demonstrated excellent stability and prediction ability [37]. A new random forest model has also been proposed, which depends only on six descriptors: MoKa-derived maximum basic pKa (v. 2.6.6, Molecular Discovery, Ltd., UK), minimum acidic pKa, molecular weight, distribution coefficients at pH 7.4 ($\log D_{7.4}$), number of aromatic atoms, and the presence or absence of a sulfur atom. An evaluation of this model using an independent test set showed that it performed as well as the previous benchmark model, which relied on a much larger number of descriptors [38].

Metabolism

Drug metabolism refers to the chemical structural changes that a drug undergoes once it has been delivered. Both experimental and computational approaches have been developed to investigate the metabolism and fate of drugs [39]. Many advances in the prediction of drug metabolism using in silico approaches have been made as part of the drug discovery effort, many of which have been reviewed. Commercial software includes Meteor Nexus, a knowledge-based expert system that predicts the metabolism of a compound from its structure; MetabolExpert (CompuDrug, Bal Harbor, FL, USA) (<http://www.computdrug.com/metabolexpert>); ADMET Predictor (Simulation Plus, Lancaster, CA, USA) (<https://www.simulations-plus.com/software/admetpredictor/metabolism>); and rule-based

expert systems. Free software includes XenoSite [40], a CYP SoM prediction model based on neural networks that improves rank-based stochastic pooling (RSP) in multiple ways, and SMARTCyp [41], which predicts the metabolic sites of compounds via cytochrome P450.

Excretion

Excretion is the process by which drugs are removed from the body involving the liver and kidneys. An animal scale-up was proposed to attempt an empirical prediction of the pharmacokinetic parameters of total body clearance, which is the ability to process drugs in humans. This method is based on the power law of the animal's weight. The error in predicting the clearance value using this method is on average twice as large as the error, but it has not been validated on different datasets. Other methods have been proposed to apply machine-learning methods with fingerprints of chemical structures, physicochemical parameters, and animal clearances as explanatory variables [42, 43]. In addition, some studies have shown excellent prediction results using a multimodal method that uses descriptors calculated from chemical structures (or the graph itself) and clearance value of rats as explanatory variables for predicting those of humans [44].

Data Source for Drug Discovery

For developing an AI, it is extremely important to acquire relevant data. Recent advances in genomics, sequencing, and high-throughput technologies have generated a large amount of diverse data for drug discovery. To use these datasets to search for highly successful target molecules, it is important to elucidate the mechanism of action. In this section, we introduce research using omics and real-world data as big data. The term "omics data" refers to data from the genome, which is the total genetic information; epigenome, which is the information on the modification of the genome; transcriptome, which is the information on all transcripts; proteome, which is the information

on the proteins produced; and metabolome, which is the information on the metabolites produced by the interaction of proteins. On the contrary, real-world data refer to data collected from sources outside the traditional research environment, such as electronic health records (EHRs), administrative claims, and billing data [45].

Omics Data

In drug discovery, the mechanisms of the target disease and of action and side effects of new drugs at the cellular level can be explained by measuring and analyzing omics data. Single nucleotide polymorphisms (SNPs) and copy number polymorphisms (CNVs) have been widely used to characterize diseases. SNPs and CNVs can be identified from genome-wide association studies (GWAS) and whole-genome sequencing approaches and have been comprehensively investigated by next-generation sequencing and used to identify driver genes responsible for selective pathogenic cell proliferation. In addition, with the development of microarray technology, gene expression is measured and used to understand the mechanisms of disease. Recently, expression data of mRNA and ncRNA by RNA-Seq have become available [46].

The analysis of drug discovery and biological data using omics data and information technology (IT) has been conducted for a long time, for example, SNP and GWAS analyses for genomic data, differential expression analysis, and cluster analysis of transcriptome data. With the development of IT, it is now possible to prepare a large amount of omics data and systematically and comprehensively analyze the hypothesized mechanism of action of complex multiple factors. Specifically, this includes gene network estimation and analysis of transcriptome data and protein-protein interaction (PPI) network analysis. These are based on single-omics data, but further development of multiple-omics analysis techniques is currently pursued [47].

The relationships among omics data can be viewed as a multilayered network of omics

species. The lowest layer is the genome and epigenome and above the transcriptome, proteome, and metabolome networks. The interaction of each layer cannot be explained by analyzing single-omics species. If the relationships among biomolecules in the cell are considered as such a multilayered network, then the mechanism of this network is explained using multi-omics data. Information on this network has been collected and edited from the literature and other sources and stored in databases such as KEGG but is limited to a small portion of networks and is not exhaustive. Therefore, it is important to predict and estimate these networks from a large amount of omics data and to compare and analyze them with literature-based knowledge to clarify the mechanisms.

Real-World Data

In recent years, the FDA has been promoting the use of real-world data (RWD) in drug discovery and development [48], which has gained momentum [49, 50]. A recent review [49] on the use of AI in real-world data surveyed 20 studies that used RWD to facilitate drug discovery and clinical research. Sixteen of these studies identified and validated novel phenotypes, disease markers, and biomarkers for patient identification and stratification. Another review [50] identified and surveyed 65 studies by screening titles, abstracts, and full texts. The number of studies using RWD and AI methods in the drug development process, especially in the clinical or post-marketing phase, is therefore on the rise. Most of the data sources were EHRs, especially unstructured clinical notes. The most commonly used AI method was NLP, which is a trans-based model for clinical concept extraction such as bidirectional encoder representations from transformers (BERT) model [51, 52], because it deals with unstructured data. The studies also focused on adverse event detection, optimization of clinical trial recruitment, and drug repositioning. First, in a study on adverse event detection, an NLP system was developed to identify the adverse drug administration by extracting

information from clinical notes. For example, a relationship extraction system using bidirectional long short-term memory (BiLSTM) networks, conditional random fields (CRF) [53], and a recurrent neural network (RNN) model using a LSTM strategy [54] was used to perform clinical name entity recognition (NER) to extract and classify relationships between drugs and drug-related entities. Next, to optimize clinical trial recruitment, most of the studies used clinical notes from EHR data, using information extracted by NLP to identify the populations eligible for clinical trials [55]. Finally, in a study of drug repositioning from clinical data, the use of EHRs and informatics methods was used to suggest that the use of metformin, a diabetes drug, in oncology was associated with lower cancer mortality [56]. However, current research using RWD often relies on a single EHR system and biases the analysis of specific drugs and indications. In addition, the complex and heterogeneous nature of clinical documentation and data quality limits drug repositioning studies [57].

Summary and Future Implications

In this chapter, we present the application of AI and related databases to ligand screening, pharmacology, ADME, and pharmacokinetics in drug discovery processes. Since the actual development process comprises more stages, drug discovery is complex, expensive, and time-consuming and has a low overall success rate. AI technologies are expected to dramatically decrease the cost and time of development by reducing the number of experiments and tests. However, many of the methods introduced here are still under research and development with only a few put to practical use in actual drug discovery. However, considering the limitations of the black box and the quality and quantity of training data needed, various crucial technical issues remain to be solved in AI technologies. The rapid development of AI technologies and the expansion of problem-solving methods will continue to drive the application of AI in the drug discovery field.

Abstract

Clinical evaluation provides the necessary evidence that healthcare interventions are safe, effective, and likely to bring benefit to patients and healthcare system. While a large volume of evidence for in silico performance of AI systems has been published in recent years, prospective clinical trials are only just beginning to emerge. This chapter presents a summary of prospective randomized trials published in AI health interventions to date and discusses new AI-specific reporting standards for clinical evaluations.

Clinical AI Systems Require Robust Clinical Evaluation

The number of publications involving AI methods in biology has grown exponentially in recent years, with over 21,000 papers published in 2020 alone [1], and the global AIM market has grown from \$600 million in 2014 to \$6.6 billion in 2021 [2]. A 2021 study reports 222 AI/ML-based devices approved by regulatory authorities in the USA and 240 devices in Europe to date [3].

Despite this, the widespread routine use of AI/ML-based medical devices is patchy, and concerns over their true clinical effectiveness remain. One obstacle preventing innovative AI technologies from being routinely implemented in clinical practice is a lack of evidence that they remain robust in real-world clinical environments and lead to demonstrable improvement in patient outcomes. Specifically, there has been a general lack of evidence from prospective, comparative clinical trials which focus on health outcomes, rather than measures of performance (such as accuracy) which are several degrees removed from measures of effectiveness.

Most existing evidence for AI healthcare interventions so far comes from retrospective, observational studies. The evidence, as demonstrated in two systematic reviews of AI medical imaging algorithms [4, 5], is promising but insufficient to indicate suitable immediate implementation in clinical practice. This is because these studies

are formulated to ask whether AI healthcare systems do what they were *designed* to do, not what they were *intended* to do. That is to say, they ask whether AI healthcare systems *predict, identify, or produce* a state or experience *reliably and accurately*, not whether they *safely and effectively* predict, identify, or produce a *clinically meaningful* state or experience, *when used in a specific population and setting*.

Evidence that an AI healthcare intervention is safe, clinically effective, and cost-effective is an essential prerequisite to implementation in clinical practice, if the ultimate goal is to bring benefits to patients and society. It is not enough to show that a diagnostic AI algorithm reliably and accurately detects disease from imaging data in a computational context. It also needs to be shown that when applied in a clinical setting, it improves patient outcomes and does so at least as well as healthcare professionals, without causing additional complications and/or harm.

The strongest evidence for the safety, clinical effectiveness, and cost-effectiveness of an AI intervention requires evaluation in the context of well-designed, well-delivered, and well-reported prospective, comparative clinical trials [6]. This is because two fundamental characteristics of clinical trials – randomization and a control arm – allow us to make causal inferences about interventions and their outcomes [6].

Even seemingly benign interventions, such as the example of an acute kidney injury alert system, have been shown to unexpectedly result in patient harm in randomized trials [7]. Findings such as this one, although arising from unclear mechanisms, could not have been discoverable without evaluation through prospective comparative trials. It therefore emphasizes the importance of evaluating AI healthcare interventions in their intended clinical setting, using health outcomes as the primary endpoint, and actively investigating potentially deleterious consequences. Crucially, the evidence from these studies should, like all trials, be reported to the highest standards, to ensure transparency and assessment of potential biases and enable the study to be appraised and the evidence evaluated. Only this way will stakeholders be able to establish which AI healthcare interventions provide real value.

Stakeholders need to know which claims made about AI systems are substantiated and which claims are not: patients, the public, healthcare professionals, healthcare providers, and medicine and medical device regulators need to know which AI healthcare systems are safe and clinically effective; and investors, payers, politicians, and health policy-makers need to know how cost-effective these AI healthcare systems are. The most rigorous and robust way to answer these questions is through prospective, comparative clinical trials. Therefore, although most AI healthcare interventions have not yet been evaluated in prospective, randomized clinical trials, this will be an area of rapid expansion moving forward, as the field of AIM continues to mature.

Randomized Controlled Trials of Clinical AI Systems

At the time of writing, while adoption of clinical AI systems remains in its infancy, there is a growing recognition that AI systems require evaluation in prospective, real-world, clinical settings. There is also an emphasis on such evaluations paying due consideration to the effect of AI systems on the clinical pathway, the representativeness of the population and setting, and importantly the relative benefits of such interventions on patient outcomes.

As of 2021, a comparatively small number of prospective clinical trials for AI systems have been conducted and published. We identified 14 completed and published trials as of December 2020 through the [ClinicalTrials.gov](#) registry, including AI interventions for diagnosis and disease prediction, AI as therapeutic interventions, and AI for streamlining or increasing the efficiency of clinical tasks. Of note, several randomized controlled trials (RCTs) in the field of colonic endoscopy have already been conducted, evaluating the effectiveness of AI for detecting colonic adenomas. This specific use case is by far the most mature in evidence generation across the field of clinical AI.

In this section, we present a selection of illustrative examples of published AI clinical trials as of 2021 (summarized in Table 1).

AI Systems for Disease Diagnosis

AI Systems for Detection of Colonic Adenoma During Endoscopy

Perhaps the most mature area of prospective trials is AI for detection of colonic adenoma. This is likely due to the real-time nature of AI systems applied to endoscopy, which would be otherwise difficult to evaluate in a simulated or observational study.

The adenoma detection rate (ADR) is regarded as the primary indicator of quality during colonoscopy, and an increased ADR through conventional clinician-led endoscopy has been shown to reduce the incidence and mortality of colorectal cancer [21, 22]. More recently, several deep learning models have been shown to yield higher ADRs compared to conventional endoscopy. These studies are summarized below.

A prospective trial of a real-time polyp detection system (Shanghai Wision AI Co., Ltd.) studied 1058 patients, randomized either to an AI-assisted polyp detection ($n = 522$) or to routine colonoscopy without AI ($n = 536$) [12]. In the intervention arm, the AI system was activated during the withdrawal phase of colonoscopy, providing real-time alerts with a hollow blue tracing box and sound alarm upon detection of a suspected polyp. A statistically superior ADR was reported with the AI system, compared to routine colonoscopy (29.1% vs 20.3%, $p < 0.001$). The mean number of adenomas detected per patient was significantly greater with AI (0.53 vs 0.31, $p < 0.001$), with superior detection of diminutive and hyperplastic polyps (185 vs 102 and 114 vs 52, respectively, $p < 0.001$). No significant difference was reported for the detection of larger adenomas ($p = 0.075$). The trial presented promising results and advocated for further research into determining cost-benefit ratios for AI-assisted colonoscopy.

The CADe-DB trial was a double-blinded randomized single-center study that compared ADRs of the intervention arm ($n = 484$) of colonoscopy with computer-aided detection (CADe) to the control arm ($n = 478$) of colonoscopy with a sham system [9]. Patients aged 18–75 presenting to the endoscopy center were consecutively enrolled.

Table 1 Published clinical trials evaluating clinical AI systems

Publication	Disease Context	Population	Intervention	Control	Outcome	Summary of results
Wang et al. [12]	Colonic adenoma Diagnosis	Consecutive enrollment of patients undergoing colonoscopy at the endoscopy center of the Sichuan Provincial People's Hospital, China (Sep. 2017–Feb. 2018)	A deep learning system for real-time automated polyp detection system ($n = 522$)	Standard colonoscopy, in the absence of the automated system ($n = 536$)	ADR	The AI system significantly improved ADR (29.1% vs 20.3%, $p < 0.001$) and the mean number of adenomas per patient (0.53 vs 0.31, $p < 0.001$), as compared to the control arm. This was reported as being due to greater detection of small adenomas (185 vs 102, $p < 0.001$) and hyperplastic polyps (114 vs 52, $p < 0.001$) with the AI system
Wang et al. [9]	Colonic adenoma	Consecutive enrollment of patients (aged 18–75 years) presenting for diagnostic or screening colonoscopy at the endoscopy center to Catang branch hospital of Sichuan Provincial Hospital, China (Sept. 2018–Jan. 2019)	Computer-aided detection (CADe) deep learning automatic polyp detection system ($n = 484$)	Shan system, simulating alerts on polyp-like non-polyp structures ($n = 478$)	Adenoma detection rate (ADR)	Significantly greater ADR in the CADe arm, as compared to the sham control arm (odds ratio 1.36, $p = 0.030$) One or more adenomas detected: 165 of 484 patients (34% in CADe), 132 of 478 in sham control (28%)

Su et al. [10]	Colonic adenoma	Consecutive enrollment of patients presenting for routine colonoscopy screening to Qilu Hospital, Shandong University (Oct. 2018–May 2019)	An automated quality control system (AQCS) to optimize colonoscopy examination ($n = 308$) The system provides withdrawal phase supervision, timer display, steady withdrawal speed prompts, audio alerts for inadequate exposure of bowel segments, and automated alert boxes upon polyp detection	Routine, non-AQCS-assisted colonoscopy ($n = 315$)	ADR, mean number of adenomas detected per procedure, adequate bowel preparation rate, withdrawal time	The AI system (AQCS) significantly improved adenoma detection rate (0.289 vs 0.165, $p < 0.001$), mean number of adenomas detected per procedure (0.367 vs 0.178, $p < 0.001$), adequate bowel preparation (87% vs 80%, $p = 0.023$), and withdrawal time (7.03 min vs 5.68 min, $p < 0.001$), compared to the control
Gong et al. [11]	Colonic adenoma	Consecutive enrollment of patients (aged 18–75 years) undergoing colonoscopy at the endoscopy center in Renmin Hospital, Wuhan University (Jun. 2019–Sep. 2019)	<i>ENDOANGEL</i> convolutional neural network system for adenoma detection ($n = 355$)	Routine, non- <i>ENDOANGEL</i> -assisted colonoscopy ($n = 349$)	ADR	<i>ENDOANGEL</i> significantly improved ADR, as compared to the control arm (odds ratio 2.30, $p = 0.001$) One or more adenomas detected: 58 of 355 patients (16%) in <i>ENDOANGEL</i> , 27 of 459 patients in control arm (8%)
Lui et al. [8]	Colonic adenoma	Consecutive enrollment of patients (aged 40 and older) scheduled for outpatient	Region-based fully connected convolutional neural network (R-FCN): a two-stage	Primary endoscopist performed routine colonoscopy (blinded to AI system) ($n = 52$) ^a	Number of adenomas detected	The AI system detected at least 1 missed adenoma in 14 patients and

(continued)

Table 1 (continued)

Publication	Disease Context	Population	Intervention	Control	Outcome	Summary of results
		colonoscopy at Queen Mary Hospital, University of Hong Kong (Jan. 2020–Feb. 2020)	convolutional neural network which [1] identifies regions of interest and [2] classifies and localizes adenoma lesions ($n = 52$) ^a			increased adenoma detection by 23.6%
Wu et al. [13]	Blind spots in esophagogastroduodenoscopy (EGD)	Patients undergoing routine EGD examination at the endoscopy center of Renmin Hospital, Wuhan University (Aug. 2018–Oct. 2018)	<i>WISENSE</i> deep neural network and reinforcement learning system ($n = 153$) The AI system provides real-time feedback on blind spots, scoring of endoscopy based on the number of observed sites, and photo documentation of each inspected site during EGD	Routine EGD without AI <i>WISENSE</i> system ($n = 150$)	Primary outcome: blind spot rate in the <i>WISENSE</i> and routine EGD groups	Significantly lower blind spot rate in the <i>WISENSE</i> arm, compared to the control arm (5.86% vs 22.45%, $p < 0.001$) Significantly longer mean inspection rate in <i>WISENSE</i> arm vs control (5.03 mins vs 4.24 mins, $p < 0.001$). No significant difference observed in the completeness of documentation (72% vs 79%, $p = 0.11$) <i>WISENSE</i> significantly reduced the number of patients being ignored in the lesser curvature of the middle-upper body, as compared to the control (risk difference, -47.5%, $p < 0.001$)
Kaura et al. [14]	Paroxysmal atrial fibrillation (PAF)	Patients aged ≥ 18 years diagnosed with ischemic	iRhythm Technologies <i>Zio</i> ® patch ($n = 56$)	Conventional short-duration Holter ECG monitoring only, at a	Detection of PAF lasting at least 30 s within 90 days for	Significantly greater rate of PAF detection with <i>Zio</i> ® patch, as

<p>non-lacunar stroke or TIA within the past 72 h at King's College Hospital NHS Foundation Trust (Feb. 2016–Feb. 2017)</p>	<p><i>Zio® patch</i> is a small wearable device applied to the anterior chest wall for a 14-day interval, providing continuous ECG monitoring for detecting PAF (primary outcome)</p>	<p>physician determined duration, but usually 24 h ($n = 60$)</p>	<p>each study arm Economic modeling of stroke incidence and medical cost savings with <i>Zio® patch</i></p> <p>result in avoiding 10.8 more strokes annually, with associated medical savings of £113,630, increasing to £162,491 over 5 years</p>
<p>Lin et al. [15]</p>	<p>Childhood cataracts</p>	<p>Pediatric patients (aged ≤ 14 years) without definitive cataract diagnosis or history of previous eye surgery, at five ophthalmic clinics in China (Aug. 2017–May 2018)</p>	<p>Consultation, with childhood cataract AI platform, CC-Cruiser ($n = 175$)</p> <p>Slit lamp ocular photographs uploaded onto CC-Cruiser website, generating a diagnosis (normal vs cataracts), comprehensive metrics (opacity area, density, location), and treatment recommendation (surgery vs follow-up)</p> <p>Routine senior consultant review of patient in clinic ($n = 175$)</p> <p>The diagnostic performance of CC-Cruiser. As compared to expert consultants</p> <p>Disease severity and treatment recommendations, time required to make a diagnosis and patient satisfaction</p> <p>compared to the expert consultant control group (99% and 97%, respectively). Odds ratio 0.06, $p < 0.001$</p> <p>CC-Cruiser had a significantly reduced mean time for diagnosis compared to the control arm.</p> <p>Mean difference of 5.74 min ($p < 0.001$). Patients reported satisfaction with medical service quality and time-saving ability</p>

(continued)

Table 1 (continued)

Publication	Disease Context	Population	Intervention	Control	Outcome	Summary of results
Disease prediction						
Wijnberge et al. [16]	Intraoperative hypotension	Patients scheduled for elective noncardiac surgery at the Amsterdam University Medical Centers, Location AMC, Netherlands (May 2018–Mar. 2019)	Machine learning-derived early warning system ($n = 31$ analyzed) The system collates 23 metrics from the arterial pressure waveform, generating a numerical percentage risk of intraoperative hypotension within the next 15 min	Standard intraoperative care and monitoring by the anesthesics team ($n = 29$)	Time-weighted average of hypotension during surgery	Significantly reduced median time-weighted average ($p = 0.001$) and median time per patient ($p < 0.001$) of intraoperative hypotension in the machine learning system group, as compared to the control arm
Jaroszewski et al. [17]	Risk assessment and crisis intervention	Users of the <i>Koko</i> app [18] (signed up between Aug. 2017 and Sep. 2017). <i>Koko</i> includes an ML component which interprets semantic information and classifies user posts as “crisis” or “not crisis.” Those with posts classed as “crisis” were included in this study	An App (<i>Koko</i>) which provides access to an anonymous peer-to-peer mental health support community. Within the App, an ML classifier provides automated risk assessment and automatically directs those classified as “in crisis” to an intervention platform (barrier reduction intervention (BRI)) which aims to increase the use of crisis resources and support by lowering barriers to intervention access ($n = 775$)	Standard access to <i>Koko</i> mental health app, without barrier reduction intervention (BRI) ($n = 805$)	Likelihood of the user to use crisis resources	Among the participants providing follow-up data, participants receiving BRI were 23% more likely to use crisis services, as compared to control arm (48.9% vs 39.8%, $p = 0.02$)

Therapeutic treatment					
Nimri et al. [19]	Insulin dose optimization	Patients with type 1 diabetes mellitus (enrolled between Nov. 2017 and Jul. 2019)	AI-DSS; artificial intelligence-based decision support system ($n = 54$) The AI system provides automated insulin therapy adjustment recommendations every 3 weeks, based on continuous glucose monitoring	Physician-guided glucose-level control and insulin dose adjustment ($n = 54$)	The percentage of time spent within the target glucose range
Labovitz et al. [20]	Adherence to anticoagulation therapy	Patients diagnosed with ischemic stroke and on anticoagulation therapy. 12-week study (enrolled between Mar. 2015 and Apr. 2016)	Adherence to anticoagulation therapy using the <i>AiCure</i> app ($n = 15$) The app applies facial recognition to confirm the patient's identity, identifies the medication, and confirms ingestion. Clinic staff are notified if doses were missed, late, or used incorrectly	No daily monitoring of anticoagulation therapy ($n = 12$ analyzed)	Glycemic control (measured through time spent within the target glucose range) with AI-DSS was reported as statistically non-inferior to the physician control arm ($50.2 \pm 11.1\%$ vs $51.6 \pm 11.3\%$, $p < 0.001$) Based on plasma drug concentrations, adherence reported as 100% (15/15) with <i>AiCure</i> and 50% (6/12) in the control arm

R-FCN region-based fully connected convolutional neural network, *CADe* automatic computer-aided polyp detection (*CADe*) system (EndoScreener, Vision AI, Shanghai, China), *AQCS* automatic quality control system, *ENDOANGEL* real-time quality improvement system for monitoring withdrawal speed and timings for intubation and withdrawal in colonoscopy, *ADR* adenoma detection rate, *PAF* paroxysmal atrial fibrillation, *BRI* barrier reduction intervention, *AI-DSS* artificial intelligence-based decision support system, *EGD* esophagogastroduodenoscopy, *WISENSE* real-time quality improvement system for blind spots, *EGD* timing, and photo documentation.

^aLui et al. (2021) (nonrandomized trial): The same 52 patients received both control and intervention endoscopy. First, routine colonoscopy was performed and then during the withdrawal phase the AI system was activated

The CADe deep learning system was connected to the endoscopy processor, providing real-time feedback through alert boxes and sound alarms upon polyp detection by the AI system. In the control group, a sham system simulated alerts on polyp-like non-polyp structures (including wrinkled mucosa, undigested debris, feces, and bubbles), masking operating endoscopists to the allocated study arm. The trial concluded a significantly greater ADR in the CADe arm, relative to the control arm (odds ratio 1.36, $p = 0.030$).

Su et al. evaluated the effectiveness of an automatic quality control system (AQCS) which supervises the withdrawal phase of endoscopy once the scope reached the level of the caecum [10]. The system provided additional information on the monitor viewed by the endoscopist, including a real-time timer display, audio alerts to encourage slower withdrawal speeds, audio alerts for mucosal cleaning/liquid suction at inadequately exposed bowel segments, and alert boxes for detected polyps. In addition to reporting statistically superior ADRs (0.289 vs 0.165, $p < 0.001$), this study found the withdrawal time was significantly increased with the AI system, relative to the control arm (7.03 min vs 5.68 min, $p < 0.001$). The adequate bowel preparation rate was also reported as significantly superior in the intervention arm (87.34% vs 80.63%, $p = 0.023$). Previous literature has suggested that higher ADRs can be achieved with longer inspection times during the withdrawal phase, most likely by increasing frame quality and encouraging comprehensive assessment [23, 24].

Gong et al. evaluated an AI detection system (ENDOANGEL), which provides real-time feedback on withdrawal speeds and times to the operator, delivering prompts to encourage care during the withdrawal phase to reduce blind spots [11]. Its efficacy was investigated in a single-blinded randomized controlled study ($n = 704$). This study found that ENDOANGEL significantly improved ADRs with the AI system (odds ratio 2.30, $p = 0.001$), in comparison to unassisted routine colonoscopy.

In a smaller, more recent, nonrandomized study of 52 participants receiving AI-assisted colonoscopy, Lui et al. showed the ADR could

be increased by 23.6% with the AI system's assistance and was able to detect at least 1 missed adenoma in 14 patients [8].

An AI System for Detecting Blind Spots During Esophagogastroduodenoscopy

Esophagogastroduodenoscopy (EGD) is a key investigation for the diagnosis of lesions of the upper gastrointestinal tract. However, the discovery of gastric precursor lesions and cancers ultimately depends upon the quality of EGD and the insight of the performing endoscopist.

Given the variability of its performance, a real-time quality system for monitoring blind spots during EGD has been developed. WISENSE, a real-time detection system based on deep convolutional neural networks and reinforcement learning, is designed to detect anatomical locations seen during EGD (i.e., esophagus, antrum, duodenal bulb, etc.) and provide a rating of adequate coverage (good, excellent, and perfect when certain percentage of sites were visualized). This feedback is intended to help users be aware of blind spots during EGD [13]. In an RCT, patients randomized to WISENSE-assisted EGD ($n = 153$) received real-time AI feedback during the procedure: monitoring of blind spots on a virtual stomach model, timing, and percentage scoring based on the number of observed sites and blind spots, in addition to photo documentation of each inspected site. Routine non-assisted EGD was performed in patients randomized to the control group ($n = 150$).

WISENSE showed the ability to improve quality of EGD in the trial, monitoring blind spots with an average accuracy of 90.4% and providing a significantly lower blind spot rate (5.86%) compared to the control group (22.46%) ($p < 0.001$).

An AI System for Detecting Paroxysmal Atrial Fibrillation

Atrial fibrillation (AF) is recognized to increase cardiovascular risk, including the risk of ischemic stroke and transient ischemic attack (TIA) [25]. However, AF can often be paroxysmal (paroxysmal atrial fibrillation (PAF)) and may be missed by single or 24-h Holter ECG monitoring [26]. This can lead to idiopathic reporting of

stroke/TIA events, delaying prophylactic anti-coagulation therapy for AF.

A 14-day ECG monitoring patch (Zio[®] Patch, iRhythm Technologies) was developed that can be applied and kept in situ on the anterior chest wall for up to 14 consecutive days [27]. The ECG trace is then interpreted by a deep learning model which detects episodes of AF. AF detection rates by the Zio patch were compared to conventional Holter monitoring in an open-label randomized trial (Zio patch $n = 56$, Holter monitoring $n = 60$) [14]. AF detection was found to be significantly higher with the Zio patch compared to Holter monitoring (odds ratio 8.9, $p = 0.026$). Additionally, the authors carried out cost-effectiveness analysis which projected savings in direct medical and outpatient follow-up appointment costs amounting to annual medical cost savings of £113,630, increasing to £162,491 over a 5-year period.

An AI System for Diagnosing Childhood Cataracts

In the absence of early diagnosis and treatment, childhood cataracts can lead to irreversible vision loss [28, 29]. CC-Cruiser, an ophthalmic AI platform, was developed to automate diagnosis and treatment decision-making for this disease [15].

The accuracy of cataract diagnosis and treatment recommendations made by CC-Cruiser were investigated in a multicenter randomized controlled trial [15]. Slit lamp ocular photographs of patients randomized to the intervention group ($n = 175$) were uploaded onto CC-Cruiser. Upon image processing by the AI system, output parameters were reported: the diagnosis (normal lens versus cataract), statistical measures for disease severity (lens opacity, density, and location), and suggestions for treatment (follow-up or surgical). Patients randomized to the control group ($n = 175$) were reviewed in regular ophthalmic clinics by senior consultants. After the receipt of an initial diagnosis, all patients received a gold standard diagnosis by an expert panel of three cataract specialists. The study found a significantly inferior diagnostic accuracy and treatment recommendation performance by CC-Cruiser (87.4% and 70.8%, respectively), in comparison to the senior consultants (99.1% and 96.7%,

respectively), $p < 0.001$ for both. However, a significantly reduced mean time for diagnosis was reported with CC-Cruiser, with a mean difference of 5.74 min ($p < 0.001$), relative to the senior consultant arm. Patients also reported satisfaction with its medical service quality and time-saving ability.

AI Systems for Disease Prediction

An AI Early Warning System for Detecting Intraoperative Hypotension

Intraoperative hypotension during noncardiac surgery has been associated with an increased risk of postoperative complications including myocardial injury, acute kidney injury, and increased mortality [30–32]. To optimize intraoperative hemodynamics, Wijnberge et al. evaluated the effectiveness of an AI early warning system, which analyses arterial pressure waveform from arterial catheter pressure readings to derive a percentage risk of hypotension within the next 15 min [16]. A risk score in excess of 85% activates a sound alarm and flickering light, alerting the anesthesiologist and encouraging corrective action. In this single-center randomized clinical trial (HYPE trial [16]), patients were randomized to the intervention group ($n = 31$), where the ML system performed alerts, or the control group ($n = 29$), where standard care was provided through monitoring by the anesthesiologist. The study reported a lower median average time of hypotension for patients randomized to the machine learning group (8.0 min) compared to the control group (32.7 min), amounting to a statistically significant median difference ($p < 0.01$).

An AI System for Mental Health Risk Assessment

Natural language processing (NLP) is a subfield of AI and ML which aims to computationally read, understand, and derive meaning from text. It is the technique upon which “chatbots” are built, including those designed to conduct health consultations or understand clinical vignettes [33, 34].

This is the technique underlying the mental health app Koko [18]. Koko provides an anonymous peer-to-peer online social network

community where users can create messages. Among its services includes an AI algorithm that interprets the semantic content of user posts on the app and assigns codes to classify the users' risk (as "in crisis" or "not in crisis"). The intervention being assessed in this RCT was a barrier reduction intervention (BRI) which was provided to users detected as "in crisis." [17] The BRI involves presenting a list of crisis resources to users and asking whether they would like to use the resources shared. It continues to explore the users' reasons for not wanting to access intervention. The intervention arm in this RCT included 775 participants, and the control arm (where the app interaction terminates at the point where crisis resources are presented as a list) included 805 participants.

Among the 652 participants providing follow-up data (control arm $n = 327$, intervention arm $n = 325$), a 23% increase ($p = 0.02$) in the use of crisis services in the intervention arm was reported.

AI Systems for Adjusting Therapeutic Treatment

An AI System for Optimizing Insulin Dose

Achieving optimal glycemic control is essential for reducing diabetes-related complications. However, even with insulin pumps and continuous glucose monitoring (CGM) technologies, achieving glycemic goals can prove challenging for patients with insulin-dependent diabetes [35].

An artificial intelligence-based decision support system (AI-DSS) provides health professionals with insulin therapy adjustment recommendations for type 1 diabetic patients who are using CGM and insulin pumps. The effectiveness of the AI-DSS for achieving glycemic control was studied in a multicenter randomized trial where participants were randomized to receive remote insulin dose adjustment every 3 weeks by either AI-DSS ($n = 54$) or a physician ($n = 54$) [19]. The primary outcome was the percentage of time spent within the target glucose range. Glycemic control with AI-DSS was reported as statistically non-inferior to the physician control arm ($50.2 \pm 11.1\%$ vs $51.6 \pm 11.3\%$,

$p < 0.0000001$), studying the times spent within the target glucose range ($70\text{--}180 \text{ mg dl}^{-1}$).

An AI System for Monitoring Drug Adherence

Direct oral anticoagulants (DOACs) offer a favorable risk-benefit profile for anticoagulation therapy, without the need for routine monitoring given its specificity, wide therapeutic window, minimal interactions, and fixed dosing regimen [36]. However, this in turn intensifies the importance of patient compliance and adherence to their prescription. Given that directly observed therapy has demonstrated benefit for optimizing treatment adherence [37, 38], the role of automated systems for monitoring adherence to anticoagulation therapy in stroke patients has been considered.

AiCure, an AI-based app, utilizes software algorithms to identify the patient and their medication and provides visual confirmation of its ingestion [20]. The patient-sensitive information is encrypted in real time, with patient users and clinical staff being alerted of incorrect medication compliance (late, missed, or incorrect dosing).

The effectiveness of AiCure for optimizing adherence to anticoagulation therapy was prospectively studied in a small, single-site randomized study [20]. Patients with recently diagnosed ischemic stroke were randomized to either the intervention group (AI monitoring, $n = 15$) or a control group (no daily monitoring, $n = 13$). One patient from the control group withdrew participation from the study and was not included in the analysis. The trial demonstrated improved adherence to anticoagulation therapy with AiCure, with plasma drug concentrations indicating 100% adherence with the AI system, by comparison to only 50% adherence in the control group.

Reporting Standards for AI Clinical Trials

The critical appraisal of clinical trials is an essential part of evidence-based practice. Reviewers can assess the quality, value, and relevance of a clinical trial by considering the way it was designed, conducted, and analyzed, to formulate

a judgment on the internal and external validity of its findings. This process supports relevant stakeholders when making considered decisions about whether an intervention should be approved and commissioned.

To help ensure accurate, complete, and transparent reporting of health research, reporting guidelines are a helpful aid for establishing minimum reporting standards. For clinical trials, the SPIRIT (Standard Protocol Items: Recommendations for Interventional Trials) [39] 2013 and CONSORT (Consolidated Standards of Reporting Trials) [40] statements have ensured minimum reporting guidelines for RCTs. These guidelines have been widely endorsed by the International Committee of Medical Journal Editors (ICMJE) [41] and medical journals, which require authors to comply with them at the point of submission [42].

The SPIRIT 2013 [39] and CONSORT 2010 [40] statements were designed specifically for clinical trials evaluating all health interventions, without limitations on the type of intervention. Over time, a number of extensions have been proposed to cover specific trial designs and interventions, including CONSORT-PRO [43], CONSORT Extension for Cluster Trials [44], CONSORT Extension for Pilot and Feasibility Trials [45], CONSORT Extension for Pragmatic Trials [46], SPIRIT Extension for trials in Child Health: SPIRIT-C [47], and SPIRIT-Path [48].

New Reporting Guidelines for AI Trials to Reflect the New Epoch

Two recently published systematic reviews of studies evaluating AI models for healthcare have highlighted major gaps in the reporting of these studies [4, 5]. The risk that AI interventions could be approved and commissioned for use based on incomplete information highlights the need for new, AI-specific reporting guidance. To address this need, the SPIRIT-AI and CONSORT-AI Steering Group announced in October 2019 an initiative to develop evidence-based, international consensus-based, AI-specific minimum reporting guidelines for AI clinical trials [49].

These guidelines are an extension of the existing SPIRIT 2013 and CONSORT 2010 guidelines and were developed using the EQUATOR (Enhancing the Quality and Transparency of Health Research) network framework [50], using Delphi methodology and an international multidisciplinary consortium, to provide the first international standards for clinical trials of AI health interventions. The SPIRIT-AI [51] and CONSORT-AI [52] extension guidelines include 14 and 15 new items considered sufficiently important for AI interventions for clinical trial protocols, respectively, that should be reported in addition to the core SPIRIT 2013 [39] and CONSORT 2010 [40] items.

Key recommendations include asking investigators to provide clear descriptions of the AI intervention enough to allow replication, including the inclusion and exclusion criteria at the level of the input data and participants, instructions and skills required for use, the clinical setting in which the AI intervention is integrated and its intended users (such as healthcare professionals, patients, and the public), the handling of inputs (such as images) and outputs (such as a probability of disease or classification) of the AI intervention, the expected human-AI interaction, and providing analyses of errors. Authors need to specify the version of the AI system used and state whether this changed during the trial or differs from previous validations; describe how images were acquired, selected, and preprocessed before analysis by the AI system; and report the eligibility criteria at both the level of participants and at the level of the input data.

Alongside SPIRIT-AI and CONSORT-AI, several other AI-specific reporting guidelines are in development in 2021. The TRIPOD-AI [53] (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis—Artificial Intelligence) and STARD-AI [54] (Standards for Reporting Diagnostic accuracy studies—Artificial Intelligence) are under development. The TRIPOD-AI guidelines aim to set reporting standards for learning prediction algorithms and harmonize terminology [53], while the STARD-AI extension guidelines aim to improve the reporting of AI-specific diagnostic accuracy studies [54].

Editorial teams of medical journals and peer reviewers are instrumental in ensuring that published studies are reported with the utmost transparency and completeness to promote well-informed readerships. The extent to which journals adopt, endorse, and require authors to comply with these standards largely determines their impact, as observed with the SPIRIT 2013 and CONSORT 2010 statements. The extension guidelines will assist editors, peer-reviewers, and journal readers to understand, interpret, and critically appraise the quality of the AI trial design and potential for bias in reported outcomes.

Future Challenges

AI reporting guidelines will aid in propelling the field forward and will therefore evolve to keep pace with AI's rapid evolution. The recommendations are most relevant to the state of AI in 2020 (which consisted mainly of disease diagnostic algorithms). Advances in computational techniques, including "adaptive/updating algorithms," which continue to "learn" as they are updated or tuned on new training data, will bring new opportunities for innovation that benefits patients (► Chap. 29, "Meta Learning and the AI Learning Process"). However, they may be accompanied by new challenges around study design and reporting, which will need to be addressed by updating the guidelines to continue to ensure transparency, minimize potential biases, and enhance the trustworthiness and generalizability of results.

Abstract

The shape of a protein is important because it dictates the protein's biological function, and a protein will fold into a configuration that minimizes its overall thermodynamic energy. The total number of possible configurations for a given chain of amino acids grows super-exponentially with the length of the chain; therefore, finding the most stable configuration of a protein is a search over the space of all possible configurations using optimization algorithms with respect to the energies of those configurations. We describe the Deep-Mind's AlphaFold successful approach to this problem. The

second part of the chapter describes a current approach to in silico drug discover based on the use of Generative Adversarial Networks, an important technique in the AI "toolbox."

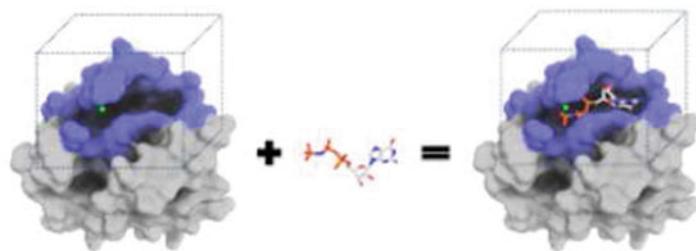

Introduction

In silico drug discovery is the use of computers to find organic molecules that will dock with proteins of interest (Fig. 1). The use of AI for drug discovery is discussed in section "[In Silico Drug Discovery](#)."

The docking of a small molecule with a protein is dependent on the 3D structure of the protein; therefore, in section "[Predicting the 3D Structures of Proteins](#)," we will first look at how computers, and AI, in particular, have been used to predict protein structures.

Predicting the 3D Structures of Proteins

Protein Folding

Proteins are macromolecules consisting of one or more polypeptides. A polypeptide chain will tend to fold into a three-dimensional globular structure (the *native structure*), and the resulting conformation usually has a biological function (Fig. 2). The folding is the result of several forces, and the final structure is determined by the sequence of amino acids forming the polypeptide.

The first step of the overall folding process is the folding of the linear polypeptide chain (the *primary structure*) to a *secondary structure* that consists of α -helices and/or β -sheets. These helices and sheets are a result of intramolecular hydrogen bonds between the amide hydrogen and carbonyl oxygen of the peptide bonds of the primary structure.

The α -helices and β -sheets can contain hydrophilic and hydrophobic portions, and this property of secondary structures aids in the *tertiary structure* of a protein in which the folding occurs so that the hydrophilic sides are facing the aqueous environment surrounding the protein and the hydrophobic sides are facing the hydrophobic core of the protein.

Once the protein's tertiary structure is formed and stabilized by the hydrophobic interactions, there may also be covalent bonding in the form of disulfide bridges formed between two cysteine residues. Tertiary structure of a protein involves a single polypeptide chain; however, additional interactions of folded polypeptide chains give rise to *quaternary structure* formation.

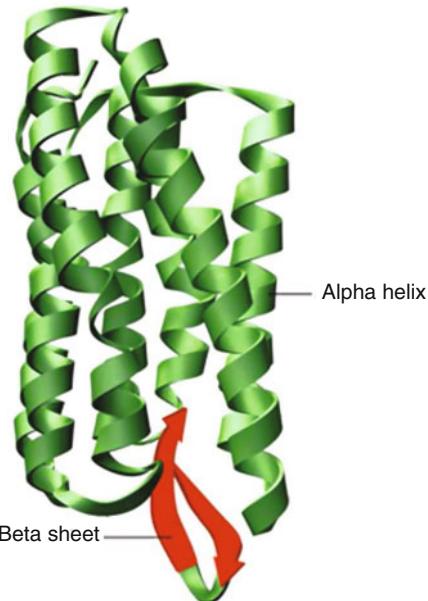

Fig. 2 Bacteriorhodopsin is a protein that acts as a proton pump in bacteria. Its tertiary conformation, which consists of α -helices (green) and β -sheets (red), is essential to its function

Folding is a spontaneous process that is mainly guided by hydrophobic interactions, formation of intramolecular hydrogen bonds, and van der Waals forces, and it is opposed by conformational entropy.

Minimizing the number of hydrophobic side-chains exposed to water is an important driving force behind the folding process [39]. The *hydrophobic effect* is the phenomenon in which the hydrophobic chains of a protein collapse into the core of the protein (away from the hydrophilic environment). In an aqueous environment, the water molecules tend to aggregate around the hydrophobic regions or side chains of the protein,

creating water shells of ordered water molecules [9]. An ordering of water molecules around a hydrophobic region increases order in a system and therefore contributes a negative change in entropy (less entropy in the system). The water molecules are fixed in these water cages, which drives the hydrophobic collapse, or the inward folding of the hydrophobic groups. The hydrophobic collapse introduces entropy back to the system via the breaking of the water cages which frees the ordered water molecules.

Secondary Structure Prediction

One of the earliest algorithms for the prediction of protein secondary structure is the method by Chou and Fasman [8], but this takes into account only the probability that each individual amino acid will appear in a helix, strand, or turn. In contrast, the GOR method [14] takes into account not only the propensities of an individual amino acid to form a particular secondary structure, but also the conditional probability of the amino acid to form a particular secondary structure given that its immediate neighbors have already formed that structure. The GOR method had an accuracy of about only 64%, but one should keep in mind the limited amount of data on protein structures available at the time.

An early application of neural networks to the task of secondary structure prediction was that of Holley and Karplus [21]. This had a maximum overall predictive accuracy of 63%, but the network had only a single hidden layer with two nodes. In contrast, by using an additional hidden layer, Jones [22] achieved 78.3% accuracy, and when deep learning was used via a convolutional neural network, further improvements were made; for example, Wang et al. [55] obtained an accuracy of 84.9%.

β -turns are a particular type of tight turn within a protein consisting of four consecutive residues and they are one of the most common types of nonrepetitive motifs in a protein. β -turns are very significant in protein structure and function partly because, as four-residue reversals, they help in the formation of higher-order structure.

Consequently, their prediction is of importance, and Zhang et al. [59] used a support vector machine to predict β -turns with 77.3% accuracy.

Ab Initio Tertiary Structure Prediction

One way of defining the 3D configuration of a polypeptide based on a sequence S of amino acids is in terms of the relative coordinates \mathbf{x} of all the C carbons present along the polypeptide. Let Ω_x be the space of all possible configurations of \mathbf{x} , then the optimal configuration \mathbf{x}^* of the polypeptide is that for which the resulting energy $G(\mathbf{x})$ is minimal:

$$\mathbf{x}^* = \arg \min_{\mathbf{x} \in \Omega_x} G(\mathbf{x}). \quad (1)$$

This is at the heart of *ab initio* folding prediction; however, the two main problems are the calculation of protein free energy and finding the global minimum of this energy.

Anfinsen's hypothesis [2] is that the 3D structure of a protein in its physiological milieu is the one in which the Gibbs free energy of the whole state is lowest. The Gibbs free energy is given by

$$\Delta G = \Delta H - T\Delta S \quad (2)$$

where enthalpy ΔH is based on bonding energies within proteins including disulfide bonds, hydrogen bonds, van de Waals forces, and electrostatic forces. Entropy ΔS is associated with the hydrophobic effect on proteins, and T is temperature in degrees Kelvin.

A protein structure prediction method must explore the space of possible protein structures which is astronomically large. These problems can be partially bypassed in *homology modeling* [7] and fold recognition methods, in which the search space is pruned by the assumption that the protein in question adopts a structure that is close to the experimentally determined structure of another homologous protein. But what if there is no protein in the Protein Data Bank (PDB) related to the target protein's sequence?

In *fragment assembly* [23], a target protein sequence is deconstructed into small, overlapping fragments. A search of the PDB is performed to identify known structures of similar fragment sequences, which are then assembled into a full-length prediction. The qualities of fragments and their assemblies are assessed by using some form of scoring function that aims to select more native-like protein structures from among the many possible combinations. But note that fragment-assembly techniques do not reliably scale to longer proteins (i.e., ≥ 70 residues).

Predicating the native form of a protein without recourse to fragment assembly or homology modeling has been the grand challenge [11]. *De novo* approaches depend on an effective conformation searching algorithm and good energy functions to build protein tertiary structures, and it is the arrival of deep-learning techniques that have led to significant progress in protein folding prediction [49]. An example of this is the use of a

CNN to predict the torsional angles of a protein from S as a step toward 3D structure prediction [6]. The other steps included residue-contact prediction via pseudo-likelihoods [13] and molecular dynamics simulation [24], but a more eloquent and highly successful approach is arguably that of Deep-Mind's AlphaFold, which we now describe.

AlphaFold

Like most modern prediction algorithms, AlphaFold [47] relies on multiple sequence alignment (MSA). The sequence S of the protein whose structure we intend to predict is compared across a large database. The underlying idea is that if two amino acids are in close contact, mutations in one of them will be closely followed by mutations of the other, in order to preserve protein structure (Figs. 3 and 4).

The central component of AlphaFold is a convolutional neural network that is trained on

Fig. 3 The dihedral torsion angles within residues

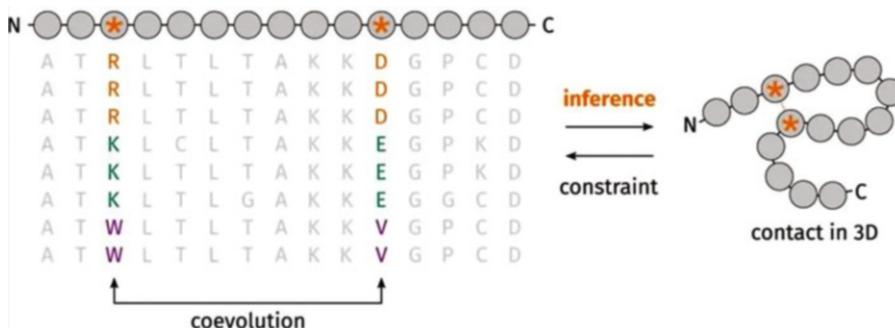

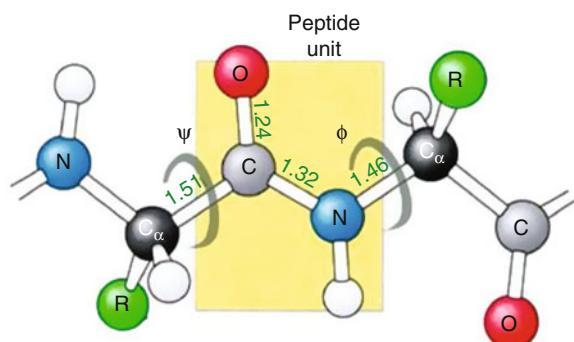

Fig. 4 Protein structure prediction by coevolution. For a given sequence S , homologous sequences can be used to create a multiple sequence alignment MSA (S). Some positions coevolve (orange asterisk) where, for a change at one position, a suitable change at the second position can

be observed. This connection at sequence level implies spatial proximity of both residues. The predicted contacts are used as constraints of a subsequent structure reconstruction in order to find an optimal three-dimensional structure [4, 33]

protein structures to predict the distances $d_{i,j}$ between the C_β atoms of pairs, i, j , of residues of a protein. On the basis of the amino acid sequence S of a protein, and features derived from the MSA (S) of that sequence, the convolutional network predicts a probability distribution $\mathbb{P}(d_{i,j}|S, \text{MAS}(S))$ for every i, j pair. The convolutional network also predicts a probability distribution of backbone torsion angles $\mathbb{P}(\psi, \phi|S, \text{MAS}(S))$.

The backbone atom coordinates \mathbf{x} of a protein (i.e., the relative coordinates of the C_β atoms of the residues) are given as a function $G(\psi, \phi)$ of all the torsion angles.

The total potential $V_{total}(\psi, \phi)$ of a candidate protein structure (ψ, ϕ) with amino acid sequence S is a combination of distance and torsion potentials:

$$V_{total}(\psi, \phi) = V_{distance}(G(\psi, \phi)) + V_{torsion}(\psi, \phi) + V_{score2_smooth}(G(\psi, \phi)),$$

where

$$\begin{aligned} V_{distance}(G(\psi, \phi)) &= - \sum_{i,j, i \neq j} \log \mathbb{P}(d_{i,j}|S, \text{MSA}(S)) \\ &\quad - \log \mathbb{P}(d_{i,j}|\text{length}), \end{aligned} \quad (3)$$

$$V_{torsion}(\psi, \phi) = - \sum_i \log \mathbb{P}(\psi_i, \phi_i|S, \text{MSA}(S)),$$

(ψ_i and ϕ_i are the torsion angles of the i -th residue), and score2_smooth refers to the Rosetta score function [30], which is a linear combination of weighted score terms (listed in Fig. 5) that balance physics-based and statistically derived potentials. This potential is added to prevent steric clashes because it incorporates a van der Waals term E_{vdW} . Term $\mathbb{P}(d_{i,j}|\text{length})$ in Eq. 3 is included to provide a reference distribution that is independent of the protein sequence [48].

As each term of $V_{total}(\psi, \phi)$ is differentiable, it is minimized using gradient descent; however, since the “landscape” of $V_{total}(\psi, \phi)$ over (ψ, ϕ) -space can have many local minima, DeepMind

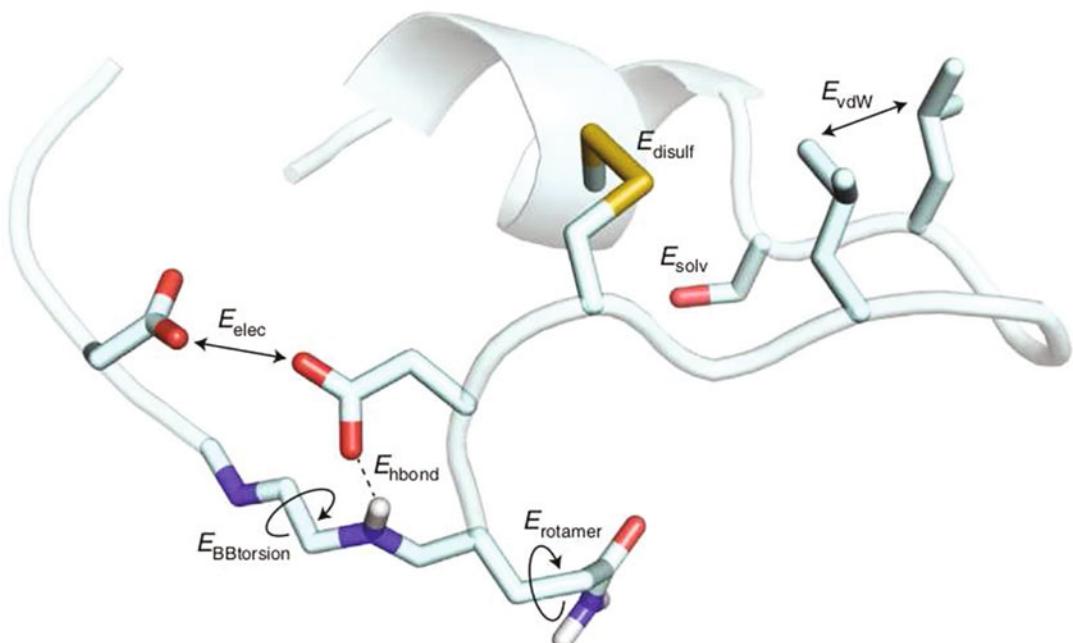

Fig. 5 The elements of Rosetta scoring [30]. E_{vdW} : van der Waals Lennard-Jones potential. E_{hbond} : hydrogen bonding. E_{elec} : electrostatic interaction between charges. E_{disulf} : disulfide bonds between cysteines. E_{solv} : implicit

solvation model. $E_{BBtorsion}$: backbone torsion preferences from main-chain potential. $E_{rotamer}$: side-chain torsion angles from rotamer library. E_{ref} : unfolded state reference energy

restarted the gradient descent using different randomly chosen initial positions in (ψ, ϕ) -space in order to discover the global minimum and thus the optimal protein structure (ψ^*, ϕ^*) for S :

$$V_{\text{total}}(\psi^*, \phi^*) = \arg \min_{x \in \Omega_{(\psi, \phi)}} V_{\text{total}}(\psi, \phi).$$

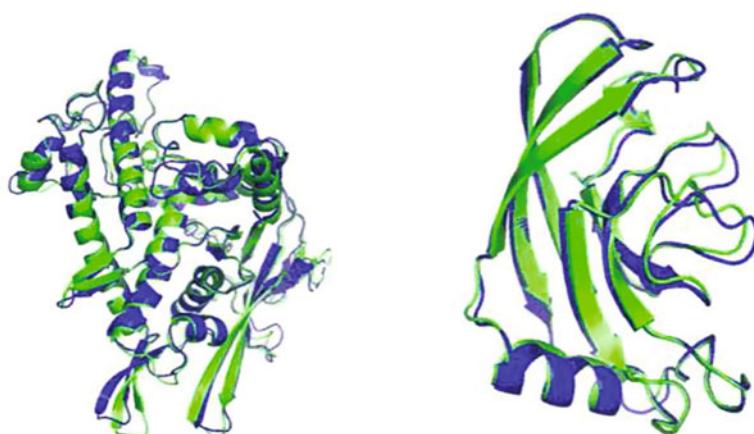

The *Critical Assessment of Structure Prediction* (CASP) is a biennial assessment of protein structure prediction, and it has become the gold standard for assessing predictive techniques for over 20 years. Participants must blindly predict the structure of proteins that have only recently been experimentally determined and have their predictions compared to experimental data.

CASP uses the Global Distance Test (GDT) metric to assess accuracy, which is a percentage ranging from 0 to 100 [58]. AlphaFold achieved a median score of 92.4 GDT across all protein targets, and predictions had a root-mean-square deviation of atomic positions of approximately 1.6 Å, which is comparable to the width of an atom. Figure 6 shows two predictions made by ALPHAFOOLD.

In Silico Drug Discovery

Drug discovery is the process by which new candidate medications are discovered; however, despite advances in pharmacology and a greater understanding of biological systems, drug discovery is still a lengthy, expensive and difficult

Fig. 6 Predictions made by AlphaFold (blue) compared with experimental data (green) for CASP 2020 [10]. The protein on the left is associated with bacterial RNA polymerase (predicted with 90.7 GDT); the one on the right is part of a bacterial adhesion (predicted with 93.3 GDT)

process with low rate of new therapeutic discovery. In 2010, the research and development cost of each new molecular entity was about US\$1.8 billion [40].

Because of the high failure rate of drug development, there is a need for early target validation. This concern has prompted the exploration and implementation of a wide range of computational methods for de novo drug design, and deep-learning neural networks have been shown to be particularly promising in this regard.

Drug Repurposing

Drug repurposing refers to taking a drug that has been developed for one disorder and “repositioning” it to treat another. In contrast to the rising costs, cycle times, and risks associated with drug discovery and development, the repositioning sector has a relatively low company failure rate [37]. In addition, there are 400 million people affected with rare diseases such as cystic fibrosis, but given the nonviability of developing de novo therapies for each of the 8000 rare diseases in existence, drug repositioning offers an alternative approach.

Drug repurposing can now be performed either experimentally or computationally [1], including the use of genome-wide association studies [45].

Deep Neural Networks

Deep neural networks (DNNs) generally outperform other machine-learning methods in

terms of predictive accuracy [15] due to their ability to approximate complex functions by abstracting information hierarchically from data; for example, Ma et al. [31] showed DNNs performing generally better than random forest classifiers across 15 diverse QSAR data sets, including those for CYP P450 3A4 inhibition and human thrombin inhibition. Unterthiner et al. [51] also demonstrated this with regard to drug-target interaction, and this led Vanhaelen et al. [53] to stress the potential of DNNs to drug repurposing. Unterthiner et al. used a multitask DNN to perform QSAR predictions for 5069 targets and 743,336 compounds recorded in the ChEMBL database (Table 1).

ATOMNET [54] is a deep convolutional neural network designed by AtomWise to perform structure-based predictions of protein-ligand activity on target proteins having little, if any, bioactivity data. Wallach et al. found AtomNet to significantly outperform SMINA [29], which is a variant of AutoDock Vina [50]; for example, AtomNet achieved an AUC greater than 0.9 for 57.8% of the targets in the DUDE dataset [36].

Recently, Vamathevan et al. [52] provided a comprehensive description of machine-learning applications to drug discovery, in which they emphasize the results of Mayr et al. [34] that show deep-learning neural networks significantly outperform other methods (Fig. 7) and that the predictive performance of deep learning was in many cases comparable to that of tests performed with *in vitro* assays.

It is important when using machine learning for drug discovery that the ligand-protein data used to test the machine-learning system is not biased [5].

Generative Adversarial Networks

A recent development in the field of neural-based computation is the use of DNNs as data generators, the aim of which is to learn, from a given set of observed data \mathbf{x}_{obs} , a model (the data generator) that emulates a distribution $p_{data}(\mathbf{x})$ from which observed data was sampled.

The usual approaches to drug discovery tend to be restricted to the space Ω_{known} of known chemical compounds, which is a subset of the space of all possible compounds, Ω_{chem} . In contrast, the generative approach allows the discovery of new compounds lying outside of Ω_{known} (Fig. 8).

One type of generator system is the *generative adversarial network* (GAN) [17]. Here, the generator $G(\mathbf{z}; \theta_G)$ begins by generating some data \mathbf{x}_{gen} and a neural network $D(\mathbf{x}_{gen}; \mathbf{x}_{obs}, \theta_D)$ attempts to discriminate between the generated data and the observed data by adjusting its weights θ_D (Fig. 9). Once the neural network succeeds, the generator again generates another set of data to try to challenge the neural network's ability to discriminate between two sets of data (hence "adversarial") by modifying θ_G . This game-theoretic cycle continues via an evaluation function $V(D, G)$ (Fig. 10) until neither the generator nor the neural network can progress any further. More precisely, the training of a GAN involves cycling between minimizing $V(D, G)$ with respect to G and maximizing it with respect to D until the optimal value is obtained, which is at a saddle point. At this point (a Nash equilibrium), the probability mass function of the generator $p(\mathbf{x} | \theta_{gen})$ approximates that from which the observed data was sampled $p_{data}(\mathbf{x})$ [17], and this enables the estimation of data sampled from $p_{data}(\mathbf{x})$.

There are, however, some issues with GANs, including the following:

Table 1 Performance accuracy (in terms of AUC metrics) of a multitask DNN against a support vector machine, binary kernel discrimination, logistic regression, and k -

nearest neighbor. The p -value refers to a paired Wilcoxon test comparing the multitask DNN with the alternative method [51]

Method	AUC	p -value
Multitask DNN	0.830	
Support vector machine	0.816	<0.001
Binary kernel discrimination	0.803	<0.001
Logistic regression	0.796	<0.001
k -Nearest neighbor	0.775	<0.001

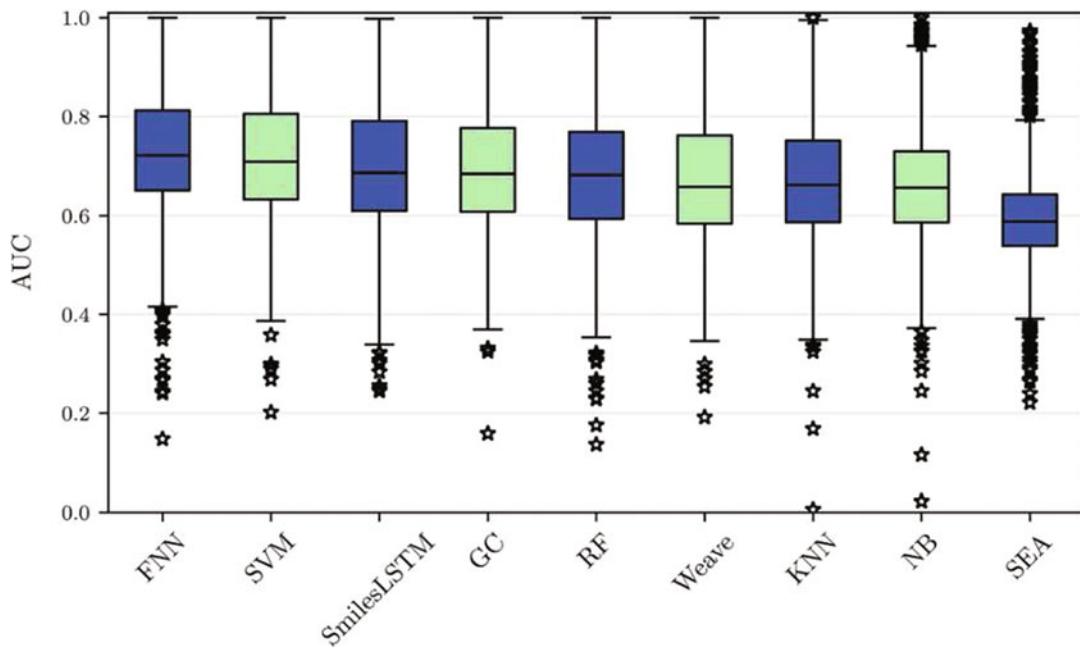

Fig. 7 Performance comparison of drug-target prediction methods [52]. Each method yielded 1310 AUC values from a set of modeled assays. On average, a DNN (FNN) performed best followed by support vector machine (SVM), recurrent neural networks with long short-term

memory (SmilesLSTM), graphical convolution network (GC) [57], random forest (RF), another graphical convolution network (Weave) [26], k-nearest neighbor (KNN), naive bayes (NB), and the similarity ensemble approach (SEA) [27]

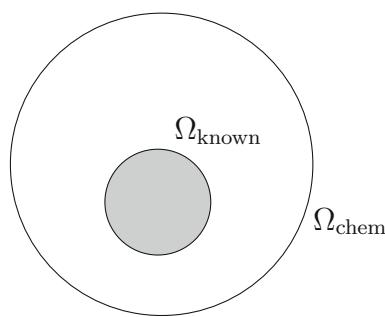

Fig. 8 Ω_{chem} is the space of all possible chemical compounds, and Ω_{known} the set of all known organic compounds. Subset Ω_{known} is not drawn to scale as the cardinality of Ω_{known} is about 60 million whereas as that of Ω_{chem} is about 166 billion [43]

1. There is a need to make sure that neither the generator nor the discriminator becomes too “strong” compared to the other. If the discriminator “wins” and classifies all true data correctly, the error signal will be poor and the generator will not be able to learn from it. If the generator “wins,” it is usually exploiting a nonmeaningful weakness in

the discriminator, which can result in oscillations.

2. A GAN is attempting to move $p_{\text{generator}}(\mathbf{x})$ towards $p_{\text{data}}(\mathbf{x})$, but \mathbf{x} could be very high-dimensional. In this case, it can be better to use a lower-dimensional alternative such as an adversarial autoencoder.

The *adversarial autoencoder* [32] is based on the concept of an autoencoder [3] (Figs. 11 and 12). Unlike the case with GANs, the adversarial autoencoder discriminates with respect to the latent values within the middle layer of an autoencoder, and when Kadurin et al. [25] trained an adversarial autoencoder with 6252 compounds profiled on the MCF-7 cell line (Fig. 13), it generated, and thus predicted, 640 possible new anti-cancer drugs.

In contrast to *variational autoencoders* [28, 42], GANs do not require log-likelihood estimation; however, the cyclic conflict between the adjustment of θ_G for the generator of a GAN and of θ_D for its discriminator can lead to

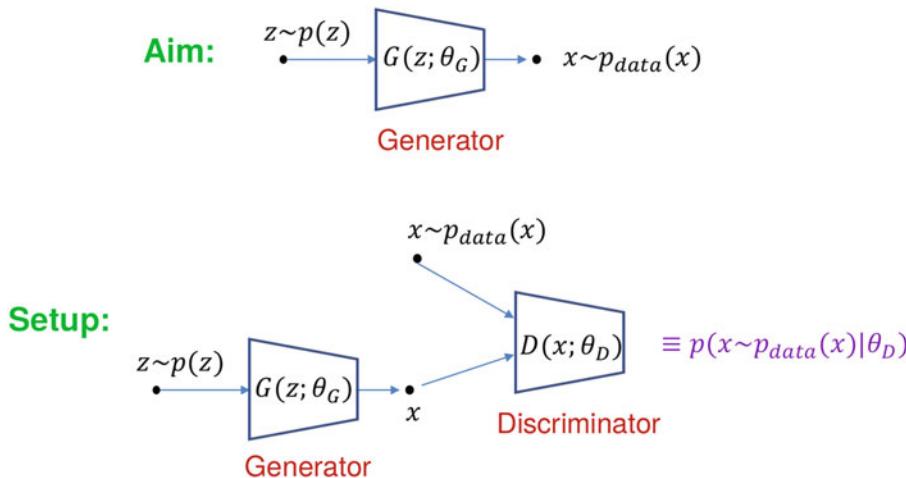

Fig. 9 Schematic of a generative adversarial network

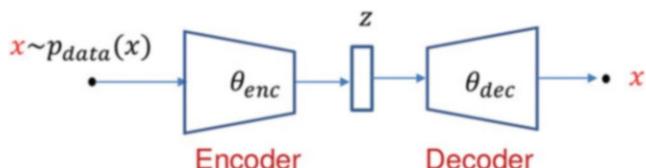

Fig. 10 GAN evaluation function $V(D, G)$

$$V(D, G) = \mathbb{E}_{x \sim p_{data}(x)} [\log D(x)] + \mathbb{E}_{z \sim p_z(z)} [\log(1 - D(G(z)))]$$

Expected probability that real data will be correctly identified

Expected probability that generated data will be correctly identified

Fig. 11 Schematic of an autoencoder

nonconvergence [35, 44]. In response to this issue, Salimans et al. [44] and Grnarova et al. [18] suggested modifications to GAN structures to mitigate the potential instability of GANs. Olivecrona et al. [38] avoided this issue by using a nonadversarial generative technique based on recurrent neural networks and reinforcement learning. This enabled new molecules to be generated with predefined desirable qualities.

Inputting Molecular Structures

Molecular structures can be mapped bijectively to strings; for example, Smiles [56] is a formal grammar that describes molecules with an alphabet of characters; for example, the Smiles for benzene is c1ccccc1. Given that *recurrent neural networks* [41] are able to learn language models from data

[16], Segler et al. [46] used a recurrent neural network with Long Short-Term Memory [20] to generate the SMILES of molecules that are active against targets of interest (i.e., the receptor 5-HT_{2A}, the parasite *Plasmodium falciparum*, and the bacterium *Staphylococcus aureus*). An alternative approach to using molecular fingerprints such as Smiles is to take the entire 3D structure of a molecule as input [26, 57].

Conclusion

The application of AI to the *ab initio* prediction of protein structures has been critical to the advancement in this field, and the development of AlphaFold is undoubtedly a major scientific

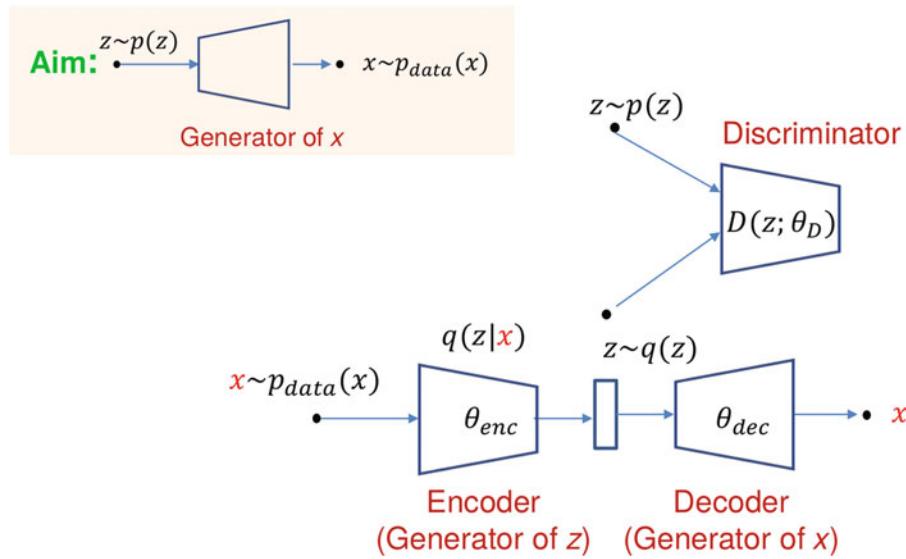

Fig. 12 Adversarial autoencoder

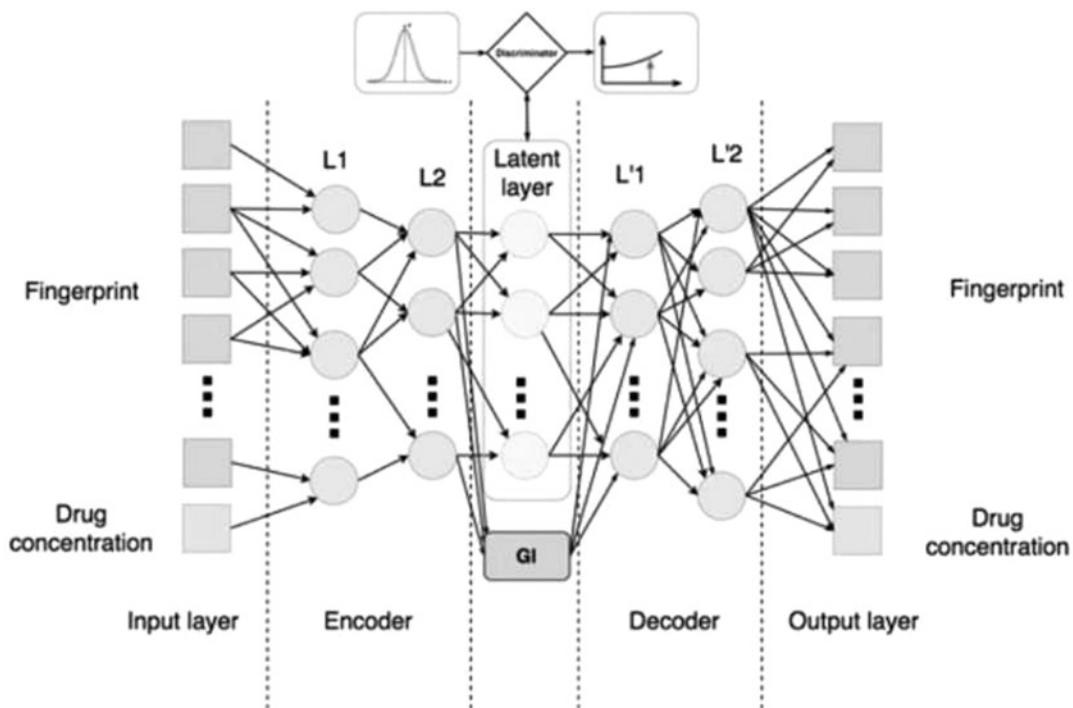

Fig. 13 Adversarial autoencoder used by Kadurin et al. [25]

breakthrough, and it already in use to predict the structures of proteins of SARS-CoV-2, the causative agent of COVID-19 [19].

As for AI and drug discovery, deep neural networks are the leaders. But consider ATOMNET: how can we discover what chemistry ATOMNET

has learnt from the vast amount of ligand-protein-interaction data used to train it for *in silico* drug screening? Being able to answer this question moves drug discovery from prediction to scientific discovery [12].

Implications of AI for the Endocrinologists	682
References	683

Abstract

This chapter focuses on applications of artificial intelligence (AI) in endocrinology. Endocrinology is the field of medicine that relates to the endocrine system that is consisted of endocrine glands, hormones, target organs, and feedback loop to maintain metabolic homeostasis. Endocrinology covers a broad range of health-related issues from common diseases such as diabetes mellitus, osteoporosis, and hypothyroidism to the rare diseases such as Cushing disease and acromegaly. The principle of endocrine system is based on feedback loop mediated by hormones, which makes it ideal to deploy AI system by both mechanistic (deductive) and statistical (inductive) modeling. In this chapter, we will review the current AI applications in major domains of endocrinology including diabetes mellitus, bone and mineral disorders, thyroid disorders, and pituitary and adrenal disorders. Each domain has unique tasks that may be improved by AI application. Supervised learning is the most commonly used algorithm, with increasing trend to apply unsupervised or reinforcement learning. To apply AI in screening, diagnosis, risk prediction, and treatment decision of endocrine disorders, various data sources (electronic medical records, medical images, laboratory tests) are currently being used in combination or separately. Finally, we conclude with a perspective for endocrinologists regarding current AI applications in endocrinology fields.

Keywords

Endocrine system · Machine learning · Deep learning · Hormone · Diabetes mellitus · Osteoporosis · Digital therapeutics · Artificial pancreas

Introduction

This chapter focuses on applications of artificial intelligence (AI) in endocrinology. Endocrinology encompasses a broad range of studies of endocrine glands, hormones, target organs, and feedback system [1, 2]. The term hormone, derived from a Greek meaning “to set in motion,” describes the dynamic nature of hormones and their actions on regulating physiologic responses through feedback system to maintain metabolic homeostasis. AI can be defined as “the science and engineering of making intelligent machines, especially intelligent computer programs,” based on the definition proposed by John McCarthy [3, 4]. Current AI mainly focuses on learning and reasoning, although more broad concepts of intelligence including self-awareness, introspection, heuristics, and practical knowledge can be encompassed in the concept of AI. Machine learning (ML) can be defined as a subset of AI, that is, an AI technique to design and train software algorithms to learn from and act on data [5]. The endocrine system can be assessed primarily by evaluation of hormone concentration, providing ideal milieu for deploying AI (or ML) that can be integrated instantly into clinical scenario. The inherent nature of hormone as circulating biologic mediator suggests the potential of AI to improve the prediction of complex systemic responses by dysregulation of hormone system. Major domains of endocrinology include diabetes mellitus, bone and mineral disorders, thyroid disorders, and pituitary and adrenal disorders. The number of AI-related publications is increasing exponentially from early 2000 in all domains (Fig. 1).

Each domain requires the active role of AI to solve unmet needs in various aspects of clinical practice including screening, diagnosis, subtyping, risk prediction, and therapeutic response prediction. In this chapter, we will review exemplary

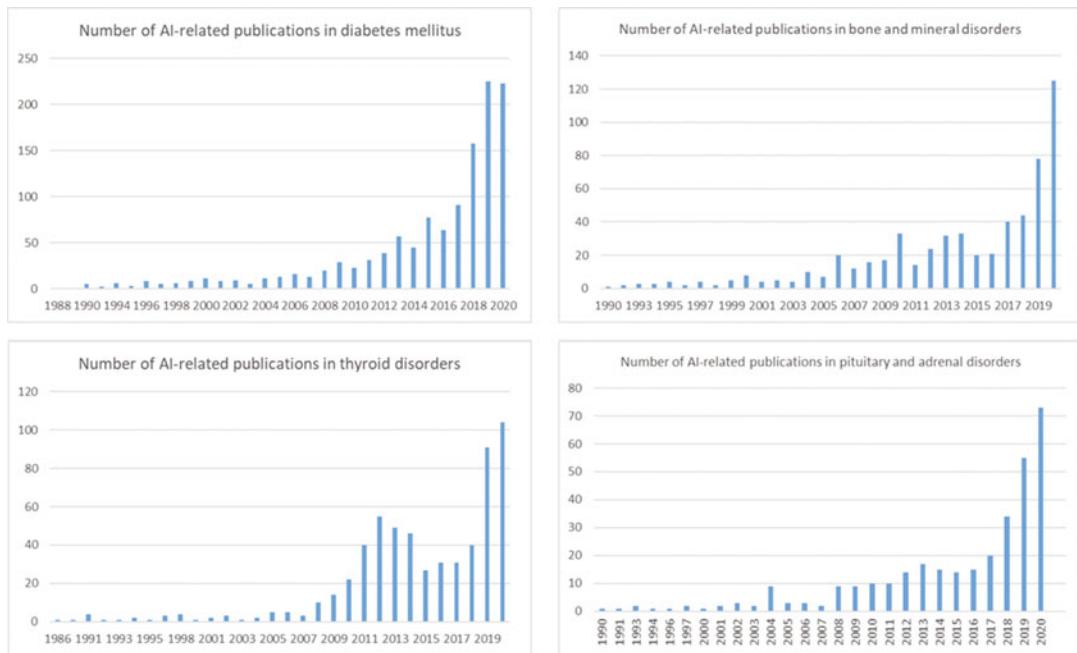

Fig. 1 Number of AI-related publications in major domains of endocrinology (<https://pubmed.ncbi.nlm.nih.gov/>, accessed on Feb 18, 2021)

studies that aimed to deploy AI to tackle the clinical unmet needs in the endocrinology field. Well-performed AI-related studies in endocrinology fields had clearly defined clinical problem and hypothesis in common, with the application of AI algorithms suitable to the characteristics of the problem. Most of studies are based on supervised learning that requires a labeled dataset with mapped output to input dataset to train the model. Recent advances in AI enabled inductive modeling approach to find novel risk factors or clusters by unsupervised learning algorithms, which explores patterns in unlabeled datasets. A few but important studies addressed potential to apply reinforcement learning in optimizing dose adjustment of hormone replacement, which is a learning algorithm to find optimal strategy in unstructured and complex environment to maximize rewards and minimize penalty. Choosing the right metrics to measure model performance is another key step to adequately prove the clinical utility of AI models. Most of studies presented the area under the receiver operating characteristic curve (AUROC, plotting true

positive rate against false positive rate) as the primary performance metric, which describes model classification performance (close to 1 indicates better classifier). Other metrics were also presented together along with AUROC including precision (positive predictive value), recall (sensitivity), accuracy, F1 score, and area under the precision-recall curve (AUPRC) appropriately. Of note, AUPRC may have advantage over AUROC in estimating model performances in an imbalanced dataset, which is a frequently observed case in real-world clinical data [6].

AI Applications in Diabetes Mellitus

AI-Driven Diabetes Care: Changing the Landscape

The role of AI technology is rapidly emerging in diabetes care, with the hope for data-driven precision care [7, 8]. AI-driven changes occur in various domains of diabetes care including the

detection of diabetic complications such as retinopathy, diabetes risk prediction, patient empowering, and lifestyle intervention. The Food and Drug Administration (FDA) provided intensive guidance to company for the development, clinical trial, and review of health-related AI software in 2018, which indicate the rapidly growing healthcare need for AI-driven approach [9]. As reflecting the current trend toward AI-empowered clinical practice in diabetes care, association of Italian diabetologists presented official position statement that AI and new digital technologies can be the key for scientific innovation and accomplishment of precise medicine, if well used [10].

Prediction of Diabetes Risk

Thirty to 80% of patients with prediabetes or diabetes remain undetected worldwide, posing serious gap between disease detection and accurate preventive action [11]. Leveraging accurate prediction of individuals at high risk for diabetes by AI solutions may enable targeted preventive intervention. In a cohort of 852,454 individuals with prediabetes, Cahn and colleagues built machine learning models based on 4.9 million time points using 900 features [12]. The models outperformed logistic regression model in all validation sets, with AUROC above 0.85. Zhang and colleagues reported robust performance of various machine learning models in rural Chinese cohort setting, with plateaued model performance of AUROC 0.87 with 30 clinical variables [13]. In National Health and Nutritional Examination Survey 2013–2014 dataset, combined use of feature selection and machine learning approach increased the predictive performance of prediabetes screening model compared to CDC prediabetes screening tool [14]. In a meta-analysis of 23 studies with 40 prediction models to predict the risk of diabetes, performance of AI models to predict type 2 diabetes was good (pooled c-index 0.812) in the community setting [15]. These studies indicate the potential of AI-driven models as an effective a priori screening tool for individuals at high risk of diabetes onset that can be integrated

into large clinical system [16, 17]. Wearable sensors, Internet-of-thing (IOT)-based monitoring applications, and synthetic data approach showed potential to improve prediction for the diabetes risk in addition to conventional clinical features, although further improvement of sensor accuracy and standardization of collected dataset need to be obtained to realize this approach in prediction of individualized risk of diabetes [18, 19]. Avram and colleagues used smartphone-based photoplethysmography data to create a deep neural network (DNN) model to detect prevalent diabetes [20]. DNN-based score achieved AUROC of 0.830 alongside age, gender, ethnicity, and body mass index, which retained independent predictive value after adjustment for other covariates. This result suggests the feasibility of digital biomarker from smartphone signals, which can be extended to various domains.

Gestational diabetes occurs in 3 to 9% of pregnancies, usually diagnosed at 24–28 weeks of gestation [21]. Because gestational diabetes is associated with adverse outcomes, early intervention to reduce the risk of gestational diabetes is important. To establish an AI model to improve the prediction of gestational diabetes at earlier phase, Artzi and colleagues performed retrospective cohort study using nationwide electronic health record of 588,622 pregnancies from 368,351 women between 2010 and 2017 in Israel [22]. The dataset included demographics, anthropometrics, diagnosis codes, pharmaceutical claims, and laboratory tests. Developed AI model outperformed the standard screening tool (AUROC 0.80 vs. 0.68). More importantly, they derived a simple nine-question self-reportable survey form which may enhance prediction of gestational diabetes even at the initiation of gestation. Improvement of AUPRC was more evident than that of AUROC, providing implication about the importance of comparing AUPRC in imbalanced dataset in real-world setting. Similar approach was successful in developing seven-variable simple model in predicting individuals at high risk for gestational diabetes in Chinese women, with modest to good performance (AUROC 0.77) [23]. While most of AIs trying to predict the risk of gestational diabetes risk are

based on electronic medical record dataset, some researchers tested the performance of AI-based mobile application that showed modest discrimination above AUROC 0.7 using various algorithms, which showed potential to improve current clinical practice with less operation cost and higher efficacy [24, 25].

Retinopathy Detection

Diabetic retinopathy is the most common serious complication of diabetes mellitus leading to vision loss [26]. Early detection of diabetic retinopathy would prevent vision loss by effective intervention modality. However, traditional care models of diabetic retinopathy have failed to ensure access to care, particularly in low-income countries, at least partly due to lack of medical profession to interpret retinal images properly. This clinical major gap calls a novel, innovative approach to screen diabetic retinopathy. Gulshan and colleagues developed retinal image classification model using deep convolutional neural network using the 128,175 retinal images as train dataset. The model showed high sensitivity (>90%), specificity (>90%), and AUROC (>0.9) in two separate, external validation sets [27]. Application of AI for diabetic retinopathy screening is now moving forward to real-world clinical application beyond research level [28]. A group of studies validated deep learning algorithms externally in different countries [29–33]. AI solutions for diabetic retinopathy screening have also cleared regulatory approval in the United States and Europe based on reported performance of AI solutions in clinical trials. The first medical device (IDx-DR), an AI software program that analyzes retinal camera images, enabled on-site screening of diabetic retinopathy by non-eye professionals in primary care settings, which resulted in improved access to standard care and higher patient satisfaction [34]. Furthermore, a group of studies addressed the possibilities of utilizing AI to interpret retinal images from handheld portable fundus camera or smartphone-based retinal imaging, which may have potential to improve the accessibility even further

[35, 36]. In Singapore, the estimated annual savings by adopting semi-automated diabetic retinopathy screening model is projected to be \$15 million by 2050, providing strong rationale for using deep learning system as assistive screening tool for diabetic retinopathy in economic aspects [37].

Prediction of Diabetic Complications

Diabetic complications include microvascular complications (retinopathy, nephropathy, and neuropathy) and macrovascular complications (peripheral artery diseases, coronary artery diseases), which lead to serious morbidity and mortality [38]. Hypoglycemia during diabetes treatment may contribute to increased risk of cardiovascular events. Diabetes is also related to increased risk of pancreatic cancer [39, 40]. Therefore, accurate prediction of the complication risk in patients with diabetes mellitus would enable individualized intervention, which may reduce or prolong the onset of complication, related morbidities, and mortality. In 2287 patients with type 2 diabetes who underwent metabolic surgery matched 1:5 to 11,435 nonsurgical patients, Aminian and colleagues built the machine learning models to predict 10-year risk for all-cause mortality, coronary artery events, heart failure, and nephropathy [41]. All models showed modest to good performance (0.73 to 0.81), with the ability to calculate personalized risk for patients with type 2 diabetes with or without metabolic surgery. Similar approach using electronic medical record type of data also yielded prediction accuracy between 73% and 83% when recurrent neural network models were used, which outperformed the 66% to 76% accuracy of traditional models [42]. Longitudinal electronic health dataset can provide rich features to predict trajectory to diabetic complications when the proper dataset meets the appropriate machine learning tools. In a study, electronic health records were analyzed with temporal-enhanced gradient boosting machine to predict 1-year chronic kidney disease risk (AUROC 0.78 to 0.83), which outperformed other models [43]. Various machine learning

algorithms were applied to create AI models to predict the risk of coronary heart disease, heart failure, diabetic foot, and hypoglycemia [42, 44–49]. Segar and colleagues developed WATCH-DM score to predict the risk of heart failure using data from 8756 patients with diabetes who were enrolled in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial [50]. A model based on simple seven variables well predicted the risk of heart failure (C-index 0.74 in external validation set). Most importantly, authors derived easy-to-use integer-based calculator (WATCH-DM score) from machine learning model which can be calculated by hands, with comparable discriminatory performance to that of random survival forest model (C-index 0.70). This study gives unique insights in several aspects. First, post hoc analysis of well-conducted, validated dataset from large randomized clinical trials ensured the high quality of data and annotation of clinical events. Second, creating easy-to-use hand calculator for clinicians provided opportunity to utilize the results from the study even in primary clinic setting without the need to access the machine learning models, although the validity of this score needs to be further tested in various populations.

Continuous Glucose Monitoring and Closed-Loop Artificial Pancreas System

Recent advances in continuous glucose monitoring system (CGMS) and artificial pancreas broadened the therapeutic options for patients with diabetes, which was empowered by advances in cloud computing power [9]. In order to attain desired glucose level while avoiding hypoglycemia in patients with type 1 diabetes, right amount of insulin needs to be delivered subcutaneously at the right time according to circulating blood glucose level, which is one of the main roles of the pancreas as an endocrine organ in human body. In the ADVICE4U trial, a 6-month, multicenter, randomized, non-inferiority trial in 108 participants with type 1 diabetes on insulin pump therapy, the percentage of time spent within the target glucose

range in the AI-based decision support system (AI-DSS) arm was statistically non-inferior to the expert physician arm [51]. Of note, three severe adverse events (two hypoglycemia and one diabetic ketoacidosis) were reported in the physician arm, whereas none were reported in AI-DSS arm. This study reveals the AI-DSS can be non-inferior to expert physician, which may be a breakthrough for individuals with type 1 diabetes on insulin pump who have limited access to specialized clinic. For the automated closed-loop system, the FDA approved artificial pancreas system (Control-IQ) that delivers insulin as needed according to CGMS signals in 2020 [52]. During the long waiting for the results of clinical trials and the FDA approval for closed-loop artificial pancreas system, an interesting phenomenon was observed that patients with diabetes themselves developed the DIYPS (Do It Yourself Pancreas System) and OpenAPS (Open Artificial Pancreas System) using available CGMS, insulin pump, and cloud computing instead of awaiting for the regulatory body approval [53]. Although the DIYPS or OpenAPS is not medically approved or regulated yet, this phenomenon clearly provides an example of rapidly evolving healthcare environment and patient-led healthcare model empowered by AI. At the same time, it raises many ethical and legal considerations and accountability issues that need to be solved between patients, healthcare providers, manufacturers, and regulatory agents. Nevertheless, there is still room for improvement by AI in making better artificial pancreas system, such as more delicate control of bihormonal artificial pancreas delivering both glucagon and insulin according to individual need of patients [54].

Therapeutic Lifestyle Modification

Zeevi and colleagues continuously monitored glucose level after 46,898 meals in a cohort of 800 individuals [55]. They developed an AI algorithm to predict individual response to meals via analyzing multimodal dataset including blood parameters, dietary habits, anthropometrics, physical activity, and gut microbiota. They further

validated the algorithm in randomized clinical trial of 100-person cohort, which revealed significantly lower postprandial responses and alteration in gut microbiome in intervention arm. This study provides ideal example of translating AI-driven knowledge to real-world practice, suggesting that personalized diet recommendation may be key to successfully alter metabolic consequences rather than conventional, fixed recommendation. Digital therapeutics is defined as a new class of digital health that provides health-related intervention with digital technologies (usually apps or Internet-based) [56]. Digital therapeutics can improve self-confidence of patients, which effectively changes the health behavior of patients by tracking daily log, weight and activity monitoring, and providing nutrition guides and feedback leading to decreased hemoglobin A1c and depression [57, 58]. A study estimated that digital therapeutics would save health resource utilization up to \$145 per patient per month, with higher potential benefits in patients with diabetes [59]. Rapidly increasing amount of patient-generated health data may enhance the feasibility and efficacy of digital therapeutics market, although the firm, successful models in digital therapeutics in both clinical efficacy and marketing are still awaited.

AI Applications in Bone and Mineral Disorders

Fracture Identification

Imaging data plays a pivotal role to diagnose fracture. Deep neural network models to detect fracture may assist clinical practice of radiologists with improved accuracy and lessened time-intensive workload in interpreting plain x-ray, computed tomography (CT), or magnetic resonance imaging (MRI) scans [60]. Several studies demonstrated good diagnostic performance of AI models, sometimes achieving discriminatory performance similar to human expert-level performance, using deep learning to detect fracture at various sites [61–64]. Of note, deep learning approaches to computer-aided detection of

fracture significantly improved diagnostic accuracy of wrist fracture from x-ray scans from 81% (unaided) to 91% (aided), with 47% reduction of misinterpretation rate in average clinician [61]. The FDA has cleared a deep learning, AI software to help in the identification of wrist fracture in adults (OsteoDetect, Imagen) in May 2018, showing innovative changes in premarket review pathway of regulatory bodies to accelerate the development of AI to aid in clinical practice [65]. Fracture liaison service, a program to prevent re-fracture after initial fracture, can be a feasible target to integrate image-based fracture detection in clinical practice [66]. Radiology reports can be a good source to enhance fracture detection by AI utilization in the setting of fracture liaison service. White and colleagues developed XRAIT, a natural language processing algorithm to detect fracture from radiology reports, which showed better performance in detection of fracture cases than manual finding [67].

Opportunistic Screening of Osteoporosis and Sarcopenia

Proper detection of osteoporosis, a status of low bone strength with impaired bone quantity and quality, is important to detect individuals at high risk of fragility fracture. Dual-energy x-ray absorptiometry (DXA) is the current standard tool to diagnose osteoporosis, defined as low bone mineral density (BMD, T score – 2.5 or lower) at the spine or hip [68, 69]. However, limited accessibility to DXA machine in some regions is one reason that contribute to current underdiagnosis of osteoporosis [70]. AI-driven opportunistic screening of osteoporosis from various data sources (mainly plain x-ray or CT) can be a solution to optimize the diagnosis of osteoporosis. In studies of Pickhardt and a group of researchers, Hounsfield unit (HU) of trabecular bone region in L1 vertebra obtained from routine clinical CT scans showed linear decreasing trajectory across age, with the potential thresholds within the range of 90 to 135 HU corresponding to DXA-defined osteoporosis [71]. Importantly, the measurement of L1 HU was performed fully

automatically with high agreement with manual assessment, suggesting the feasibility of large-scale application for the screening of osteoporosis in clinical practice. Features obtained from radiomics approach also have potential to improve osteoporosis detection in routine clinical CT scans [72]. Vertebral and femoral strength can also be analyzed with finite element modeling from routine abdominal CT, which showed good agreement with DXA-derived areal BMD [73]. AI application in CT images holds promise for detecting impaired muscle mass and function (sarcopenia), which is another potential therapeutic target to prevent falls leading to incident fracture [74, 75]. Plain x-ray can be a source to predict DXA-equivalent BMD, although several issues in preprocessing of image quality and heterogeneity in scan protocol need to be overcome [76]. AI-driven opportunistic screening of osteoporosis from dental panoramic images has been developed to improve the diagnosis rate of osteoporosis, which merit further investigation to improve accuracy with external validation in large scale [77].

Fracture Risk Assessment

Accurate fracture risk assessment is the key step to initiate personalized therapeutic interventions to prevent fracture including pharmacologic and non-pharmacologic strategies [69, 78]. There are well-validated fracture risk estimation models, such as FRAX, based on clinical predictors with or without BMD values, which served well to identify individuals at high risk of fracture [78]. Alongside the current standard clinical models, recent studies are seeking novel AI-based algorithms to enhance fracture risk prediction using various data sources including electronic health records, imaging, or omics dataset. Leslie and colleagues developed convolutional neural network algorithm to detect vertebral fracture in lateral spine images obtained from DXA [79]. Developed deep learning algorithm well detected the vertebral fracture with AUROC (0.94) comparable to that of expert, with additive prognostic value for incident nonvertebral

fracture independent of baseline FRAX probability. Although several AI models showed potential to improve fracture prediction based on structured clinical variables, artificial intelligence may have wider application in unstructured data sources rather than structured dataset [80–84]. In a small proof-of-concept study using DXA images, patient-specific finite element modeling with machine learning application showed potential to outperform standard DXA BMD in prediction of fracture [85]. In a community-based older men cohort (MrOS cohort), genomic risk score calculated from 1103 associated single nucleotide polymorphisms showed modest to good discrimination for incident fracture along with clinical variables, although the feature importance of genomic risk score was lower compared to conventional clinical predictors such as BMD, age, and weight [86]. Natural language processing can be useful to develop fracture prediction model based on electronic health record data. Cummings and colleagues developed an AI based on natural language processing, Crystal Bone, to predict short-term fracture risk within 1 to 2 years from electronic health record data of over one million patients [87]. The model predicted short-term fracture risk with high accuracy (AUROC 0.81), with significant improvement of identifying high-risk individuals when compared to human performance retrospectively. These findings suggest the potential role of AI in opening the new opportunity to improve fracture prediction by utilizing unstructured features along with well-established structured clinical predictors, which need to be validated in future studies.

Finding Novel Biomarkers Related to Bone Metabolism

AI-driven approach can have unique strength in identifying novel features correlated to bone metabolism in complex, unstructured dataset, potentially leading to identification of new biomarkers or biologic pathway. AI application enabled the integration of transcriptome-wide association study and genome-wide association study that revealed novel candidate genes associated with

osteoporosis [88]. High-throughput sequencing of transcriptomic or proteomic profiles in human, powered by bioinformatics, may reveal differentially expressed RNA profiles and protein networks related to alteration in bone and muscle metabolism, leading to the discovery of novel diagnostic or therapeutic target [89, 90].

AI Applications in Thyroid Disorders

AI Application in Thyroid Cancer

Diagnosis of thyroid cancer is frequently performed by thyroid ultrasonography. In a large scale, retrospective multicohort diagnostic study performed in China, deep convolutional neural network model improved specificity in identifying patients with thyroid cancer (88% vs. 69%) compared to radiology experts while maintaining similar sensitivity (85% vs. 89%) in an external validation set [91]. Of note, machine learning-assisted ultrasonographic visual approach showed better diagnostic performance than ultrasonography alone (AUROC 0.95 vs. 0.92), with significant reduction of unnecessary invasive needle aspiration procedure from 30% to 5% compared to current standard risk stratification system [92]. Radiologic features of thyroid nodules in ultrasonography may also convey information of genetic risk. A study found that automated machine learning applied to ultrasonography were able to detect thyroid nodules with high-risk mutations on molecular testing, which showed possibility for the diagnostic application of AI for predicting noninvasive high-risk mutation in thyroid nodule [93]. The diagnosis can remain indeterminate even after cytologic examination by fine needle aspiration of thyroid nodule. Machine learning algorithms based on next-generation RNA sequencing data obtained from cytologic examination were able to discriminate benign nodule in cytologically indeterminate thyroid nodules [94]. The algorithm showed high sensitivity and accuracy for identifying benign nodules with increased specificity, which potentially reduces unnecessary diagnostic surgery. As the frequency of fine needle aspiration procedure

is increasing along with increasing incidence of thyroid nodule, the role of AI is also expanding in interpreting thyroid pathology, particularly for indeterminate pathologic findings. A systematic review of 19 studies revealed modest to high correlation between AI-aided diagnosis and expert pathologist diagnosis, suggesting promising results for AI application in thyroid pathology if technical issues such as computational burden due to a large size of whole slide images can be resolved [95]. Although determining lymph node metastasis risk in papillary thyroid cancer is the key information that guides diagnosis and treatment process, the performance of lymph node metastasis detection by ultrasonography remains suboptimal. In a retrospective cohort of 3172 patients, transfer learning radiomics model enhanced the prediction for lymph node metastasis at preoperative phase, which outperformed clinical statistical model [96]. These findings provide good examples on how AI technology can drive clinical practices in managing thyroid cancer toward enhanced patient safety and higher diagnostic accuracy.

AI Application in Functional Thyroid Disorders

Graves' disease is a common autoimmune disorder resulting in hyperthyroidism. Although anti-thyroidal drugs, radioactive iodine, or surgery can effectively control the excessive production of thyroid hormones in some patients, the therapeutic options for severe, refractory, or recurrent cases are still limited. A study of key gene co-expression modules and functional pathways in Graves' diseases revealed the pivotal role of bioinformatics and AI in providing novel insights of pathogenesis of Graves' disease [97]. Neural network modeling using clinical features of patients with Graves' disease were able to predict recurrence of disease within 2 years of anti-thyroid drug withdrawal [98]. When total or completion thyroidectomy is performed due to various etiologies, synthetic thyroid hormone replacement is inevitable, but the scheme for dose adjustment remains suboptimal. In a study that analyzed

598 patients who underwent total thyroidectomy due to benign thyroid disorders, machine learning model with Poisson regression outperformed conventional weight-based dosing (correctly predicting dose in 64.8% vs. 27.4%) [99]. These studies illustrate the potential of AI application to improve quality of care in functional thyroid disorders.

AI Applications in Pituitary and Adrenal Disorders

Diagnosis and Subtyping

Some endocrinologic disorders, such as hypercortisolism or acromegaly (excessive production of growth hormone), have unique facial characteristics which can have diagnostic value. Usually the recognition of facial characteristics was the role of expert endocrinologists; however, AI principle has the potential to aid in “facial diagnosis” in clinical scenario. In a group of studies, deep neural network algorithms have shown successful results in discriminating patients with acromegaly or hypercortisolism (Cushing’s syndrome) in various dataset [100–102]. MR images play a key role in the diagnosis and subtyping of pituitary tumors, which guide following evaluation and treatment plans. In related MRI-based AI studies, majority of machine learning tasks were classification of nonfunctioning pituitary adenoma versus functioning tumor and prediction of tumor proliferation index [103, 104]. Machine learning-based metabolomics analysis has potential to improve diagnosis and subtyping of endocrine disorders, providing opportunities to explore novel biologic mechanisms and biomarkers [105]. Plasma or urine steroid metabolites revealed a fingerprint of adrenal cortical carcinoma, which predicted the recurrence of cancer with high accuracy [106, 107]. By combining metabolomics with immunohistochemistry data of pheochromocytoma tumor tissue, genetic alteration with prognostic value, such as succinate dehydrogenase mutational status, could be predicted [108]. Well-established clinical features can be a good data source to create a useful machine learning model. Mulatero and colleagues

designed a machine learning-based score to predict subtype of primary aldosteronism using clinical features that are collected during standard clinical practice [109]. This model may have potential to guide surgical decision in centers where the gold standard test adrenal vein sampling, an invasive, technically demanding procedure, is unavailable.

Prediction of Treatment Outcomes

In patients with pituitary or adrenal tumor, it is important to predict clinical outcome of surgical or medical treatment to support therapeutic decision. This is particularly the case when the surgical procedure accompanies high risk of complications, such as hypophysectomy in pituitary tumor. Machine learning approach based on image or clinical data has shown several remarkable results in predicting treatment outcomes in patients with pituitary tumors such as acromegaly or Cushing’s disease [110–113]. MRI alone provided high discriminatory performance (AUROC 0.85) for classifying responders to drug treatment in patients with acromegaly [114]. Similarly, machine learning models using CT-derived texture features of adrenal metastatic masses predicted tumor progression and survival, revealing potential of image data as a window to biologic heterogeneity in endocrine tumors [115].

Implications of AI for the Endocrinologists

In this chapter, we reviewed current applications of AI in the field of endocrinology. As Eric J. Topol clearly addressed in his article, the narrative of bringing AI to medicine just has begun, with hope for improving workflow, reducing medical errors, and empowering patients [116]. Given the current trend of exponentially increasing publications regarding AI applications in various domains of endocrinology, this may also hold true for endocrinology sector. Application of AI in endocrinology has potential to transform current clinical practice to more connected care (Fig. 2). However, clinical gestalt of endocrinologists should play a

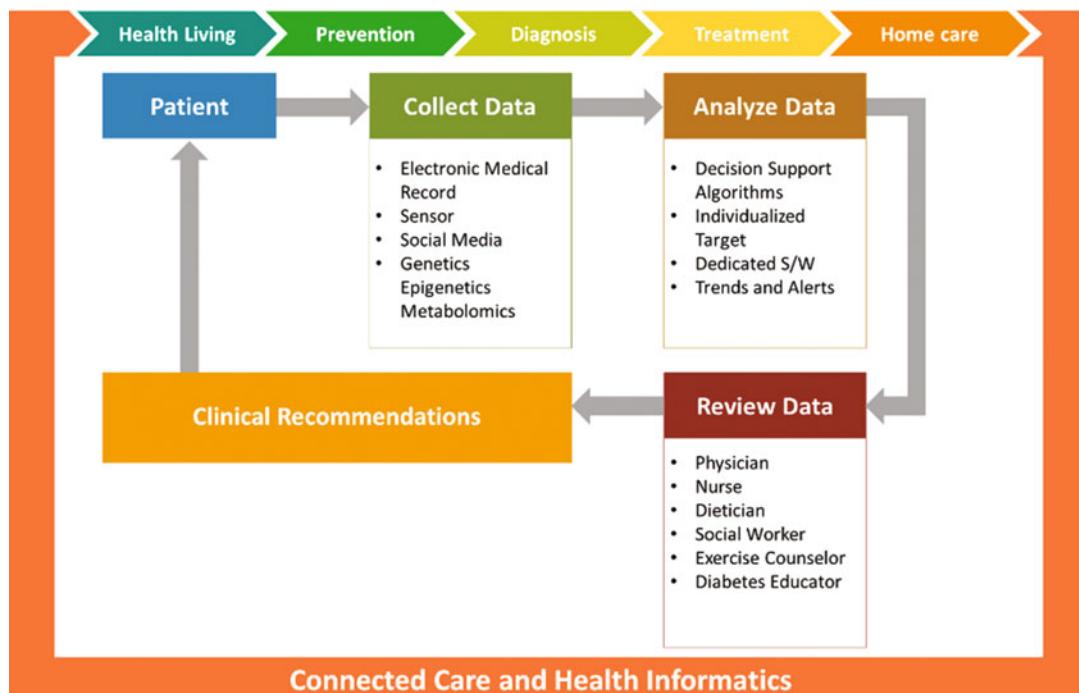

Fig. 2 Transforming current endocrinology practice to more connected healthcare using AI application

pivotal role in evaluating whether the results from AI models are believable, with scrutiny and scientific rigor. While AI is finding its way to the integration into clinical application in endocrinology, endocrinologists need to learn how to understand and use AI, with healthy skepticism [117]. In clinical perspectives, moving toward the application of precision medicine in endocrinology requires high-performance AI models that are well validated, easy to access, and easy to use [118].

Abstract

The number of hypertensive patients is increasing worldwide. Since high blood pressure is strongly associated with the development of cardiovascular diseases, blood pressure control is essential. More than 90% of hypertensive patients have essential hypertension, which is caused by multiple factors, including lifestyle, physical constitution, and genetics. Blood pressure variability, which is the change in

blood pressure over a certain period, is also associated with cardiovascular diseases. Therefore, regular blood pressure measurements outside the hospital for blood pressure control are required.

The increase in popularity of wearable devices and smartphones has made it easier than ever to gather biometric and environmental information. Blood pressure and lifestyle monitoring using these devices will improve our understanding of the timing of blood pressure rise and fall along with the factors contributing to blood pressure changes. Moreover, the development of novel analysis methods that provide alternatives to conventional statistical methods is expected to improve the accuracy of treatment effect estimations, taking into account individual interpatient differences.

This chapter describes the role of artificial intelligence for blood pressure measurement, factor analysis of blood pressure change, and blood pressure forecasting in personalized

Hypertension · Cardiovascular disease · Machine learning · Blood pressure measurement · Blood pressure forecasting · Blood pressure prediction · Personalized medicine · Causal inference · Surrogate model

Introduction

Hypertension is associated with an increased risk of developing cardiovascular diseases (CVD). The number of hypertension patients worldwide has increased from an estimated 594 million in 1975 to 1.13 billion in 2015 [1]. Increasing the number is a significant public health problem. More than 90% of hypertension patients have essential hypertension, which is diagnosed in the absence of a secondary cause. A combination of factors, including lifestyle, physical constitution, and genetics, contribute to the development of essential hypertension [2]. Guidelines for hypertension management in the USA, Europe, and Japan summarize blood pressure (BP) measurement procedures, diagnostic criteria, and treatment strategies [3–5]. However, researchers have described the “hypertension paradox”; over the past decade, the number of hypertension patients has been increasing despite advances in treatment [6]. Moreover, an epidemiological study based on a general Japanese population has reported that 33.1% among hypertensive patients were unaware of their own hypertension [7]; regular BP measurement occasions are necessary. Recently, BP variability, which is short-, medium-, and long-term BP changes, also has been reported as an independent risk factor associated with CVD [8]. Therefore, appropriate treatments based on continuous BP and lifestyle monitoring are necessary to control BP perfectly.

We believe three components are essential for the realization of personalized medicine for

hypertension management: accurately understanding current BP, clarifying appropriate BP control methods, and forecasting future BP. This chapter introduces the following three artificial intelligence (AI) approaches for hypertension management:

1. Surrogate measurement for BP
2. Factor analysis for BP changes
3. Forecasting for future BP

Fig. 1 shows a schematic of these AI. The standard BP measurements for hypertension management are auscultation and oscillometry [3–5]. The disadvantages of these methods include discomfort by the inflated cuff and the need for bulky equipment. Cuffless measurements using AI have been developed as a convenient alternative complement to current BP measurement methods. Easily measurable non-BP indicators were selected as surrogate models for measuring BP. We introduce an AI-surrogate model for measuring BP from pulse waveform by wearable biometric sensors and estimated blood flow using smartphone cameras and discuss the benefits and challenges of these methods.

Next, we review methods for estimating treatment effects and explainable AI (XAI) for hypertension patients as a factor analysis of BP changes. Recent hypertension studies have required analyses that take into account heterogeneous treatment effects (HTE). However, a recent major randomized clinical trial on hypertension management described the limitations of conventional treat-to-target trials [9]. In contrast, AI can estimate HTE among individuals through causal inference using machine learning (ML). XAI is also developed to improve interpretability in AI. In addition to the analysis results, XAI shows the influence of BP-associated factors on an individual’s BP changes. We will describe the application of these AI methods for BP change factor analyses.

Finally, we introduce BP forecasting using AI as a predictive medicine approach for hypertension management. Guidelines for hypertension management recommend measuring BP outside the hospital (out-of-office BP). By forecasting

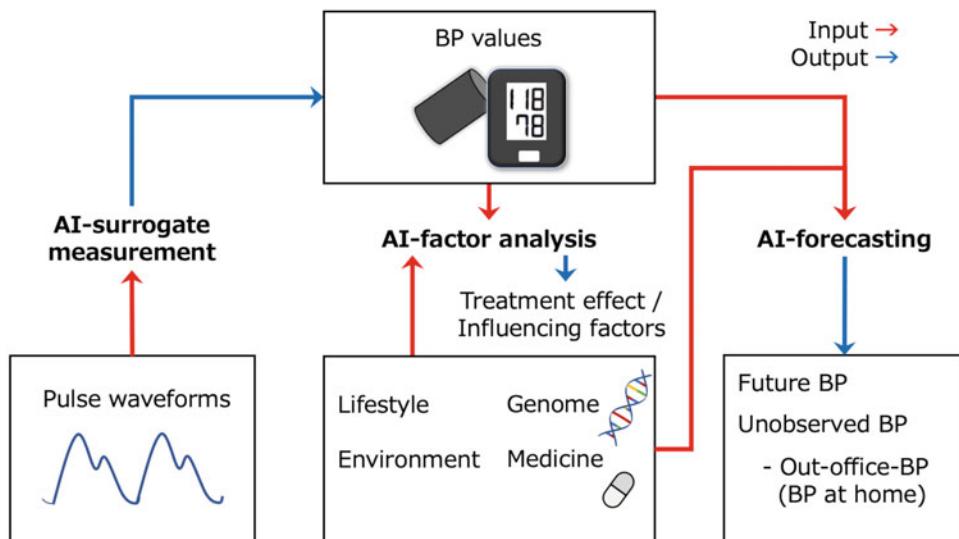

Fig. 1 Scope of artificial intelligence (AI) for hypertension management; AI-surrogate measurement for blood pressure (BP), AI-factor analysis for BP changes, and AI-forecasting for future BP

still unobserved out-of-office BP at the medical examination, physicians can treat hypertension based on the guidelines before patients measure out-of-office BP. In addition, forecasting future BP using time-series data of past BP facilitates preemptive intervention for the patient's future BP. We present the forecasts using cross-sectional data and time-series data.

Artificial Intelligence Approaches for Hypertension Management

AI-Surrogate Measurement for BP

The oscillometric method is used for the standard measurement of out-of-office BP, such as home BP and ambulatory BP monitoring. In the oscillometric method, a cuff wrapped around an upper arm or wrist is inflated with air to obtain the pulse wave amplitude. BP measurement devices calculate systolic and diastolic BP based on changes in the amplitude and the pressure inside the cuff. Discomfort from the inflated cuff and bulky equipment are the main disadvantages of the oscillometric method. BP measurement using pulse transit time (PTT) has been studied in order to achieve cuffless BP measurement [10]. PTT is

the transit time of pulse waves between any two arbitrary arterial sites. PTT is inversely proportional to diastolic BP. The PTT method overcomes the disadvantage of the cuff and provides continuous BP measurement. However, the cardiovascular system provides complex and dynamic feedback in response to BP changes, and its characteristics change over time. For this reason, the PTT method requires calibration for measuring BP.

This section provides surrogate models for measuring BP using an ML as a part of AI, providing a solution to the challenge of oscillometric and PTT methods. PTT methods use waveforms such as electrocardiogram (ECG) and plethysmography (PPG). In this section, we mainly describe PTT methods using the ECG-PPG waveform because consumer devices such as patch-style devices and smartwatches measure these waveforms. The waveforms of ECG and PPG contain hemodynamically relevant indicators such as waveform interval and amplitude in Fig. 2. Surrogate measurements for BP use a combination of signal processing and ML with these raw waveforms and hemodynamically relevant indicators. With improved smartphone cameras and CPUs, convenient BP measurements using smartphones have also been suggested.

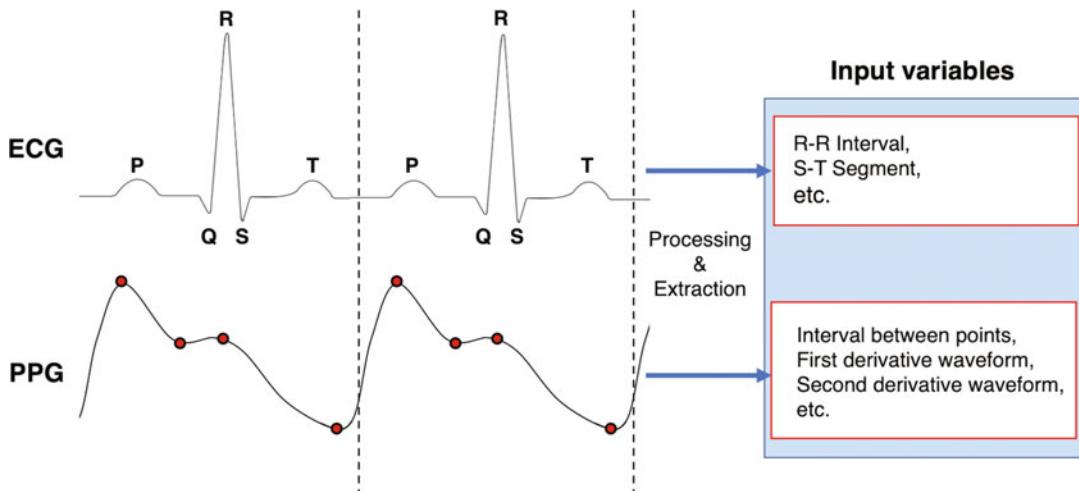

Fig. 2 Input variables for surrogate measurement models for blood pressure using electrocardiography (ECG) and plethysmography (PPG) waveforms

Related studies are described in subsections of this section.

Surrogate BP Measurement Using Wearable Sensors

Calibration is the main challenge in the PTT method using ECG-PPG waveform. Measurement using bidirectional long short-term memory (bidirectional LSTM), a deep neural network (DNN) approaches, was proposed to overcome the challenge [11]. Although DNN approaches were often applied to BP measurement using ECG-PPG waveforms, Su et al. [11] incorporated the residual connection to the DNN for BP surrogate measurement. The residual connection allowed deepening layers of DNNs for high measurement performance without frequent calibration. The proposed method showed that root mean square errors between estimation and reference about systolic and diastolic BP were within 6 mmHg, and the performance was maintained over 6 months.

Additionally, DNNs suitable for time-series data, such as bidirectional LSTM, are often used to measure BP from pulse waveforms [12, 13]. In particular, the attention mechanism, a promising method for improving DNN performance, was powerful for BP measurement [13]. This approach measures BP by inputting the ECG, PPG, and ballistocardiogram (BCG) waveforms without

extracting the amplitude and interval beforehand. Related studies have required much time and are labor intensive for extracting input variables for a surrogate model from waveforms. This measurement method showed the mean absolute error (MAE) and the standard deviation (SD) were 4.06 ± 4.04 and 3.33 ± 3.42 mmHg for systolic and diastolic BP, respectively. In addition, the results in terms of measurement accuracy complied with global standards.

Since some wearable devices can already acquire ECG and PPG waveforms and new sensors will be implemented in the future, we expect to measure BP by incorporating AI into these devices. With the advantage of continuous measurement, wearable devices will conveniently measure BP that is difficult when using cuff-based BP monitors: nocturnal BP during sleep and daytime BP in stressful environments such as the workplace. Therefore, wearable devices will facilitate hypertension detection and the establishment of diagnostic criteria and treatments for BP variability.

Surrogate BP Measurement Using Smartphone Cameras

Conventional BP measurement using ECG-PPG requires a device to capture the waveform data. If common devices such as smartphones could accurately measure BP, hypertension patients who still

have not BP monitor increase the opportunity to aware of BP. For this reason, smartphone-based BP measurements have been developed [14, 15]. Pulse waveforms related to BP are obtained through contact between the smartphone camera or external attachment and the patient's finger. Contactless BP measurement using a smartphone camera has been proposed as a more convenient method [16]. Contactless approaches have used self-captured facial videos; BP is estimated using ML by extracting transdermal blood flow from the videos. The color changes in the facial videos reflect changes in the blood flow under the transdermal conditions; the colors reflect quantities of hemoglobin protein in the blood and melanin pigment in the skin. The proposed method extracted color signals from 17 regions of interest in the videos and estimated BP by applying frequency filtering and ML to the color signals. ML successfully extracted multiple features that effectively estimated BP from those signals. The mean error \pm error SD between systolic and diastolic BP estimation and reference were 0.39 ± 7.30 mmHg and -0.20 ± 6.00 mmHg, respectively. Furthermore, this approach measured BP without requiring calibration or contact with the body. The widespread availability of smartphone-based BP measurement will facilitate early-stage hypertension detection in the future.

Challenges

This section reviewed the available AI approaches for surrogate BP measurement. Although the advantages of these AI methods have been demonstrated, some obstacles remain to be overcome. Validating the accuracy of surrogate BP measurements using AI is challenging because they do not completely comply with existing global standards. Recent studies have discussed the lack of validation for BP measurement accuracy [17, 18]; existing global standards specify measurement procedures and participant attributes in addition to measurement values. Moreover, these standards still do not describe continuous BP monitoring by wearable sensors. Therefore, developing a new validation protocol for continuous BP monitors is necessary to enable global standard compliance of AI-surrogate BP measurement.

AI-Factor Analysis for BP Changes

Hypertension is caused by a combination of factors, including lifestyle, physical constitution, environment, and genetics. Patients with low CVD risk are treated with lifestyle modification, whereas both lifestyle modification and medication are recommended for patients with high CVD risk [3–5]. The Systolic Blood Pressure Intervention Trial (SPRINT) has discussed the target systolic BP for hypertension management [19]. SPRINT research is a landmark study that assessed CVD outcomes on intensive and standard controls for hypertension in patients with high CVD risk. The results show that intensive BP control (systolic BP < 120 mmHg) is more effective than standard BP control (systolic BP < 140 mmHg) for reducing the development of CVD. However, adverse events were reported in the intensive BP control group; thus, physicians are cautious about recommending intensive control measures. Furthermore, the intensity of treatment (e.g., dosage) differs among individual patients, and analyses that take into account heterogeneous treatment effects (HTE) are required. Conventional randomized clinical trial approaches cannot assign enough participants into subgroups for estimating HTE. For this background, a previous study has suggested a new HTE estimation [9].

This section reviews causal inference using ML and XAI approaches for hypertension management. Causal inference using ML has been developed for the HTE estimation not only to hypertension management but to various fields [20]. Additionally, the XAI approach unravels the black box reasoning, which facilitates analysis of individual patient's hypertension factors. In subsections, we present previous studies about factor analyses for BP changes.

Causal Inference Using ML for Hypertension

Causal forests are random forest (RF)-based methods for HTE estimation [20]. RFs are decision-tree algorithms that cluster hierarchically like a tree diagram. Samples with similar attributes (e.g., patients) are assigned to nodes in the tree diagram. Causal forests use nodes of RF to assess the treatment effects among samples within

the same node. This method is used to tackle the challenge of subgroup analysis in randomized clinical trial datasets. Similar RF- or decision-tree-based methods have been developed for HTE estimation [21]. Scarpa et al. [22] identified a group of adverse events in the SPRINT using HTE estimation results from an RF-based algorithm. In the intensive BP control group, significantly higher incidences of CVD were detected in patients with both systolic BP ≥ 144 mmHg who also smoked.

Künzel et al. [23] developed X-learner to estimate HTE on an individual basis rather than a group basis, using a method that does not use causal forests. X-learner uses some regressions to calculate the individual treatment effect on a counterfactual framework. These regressions took into account the effect of nonlinear patient backgrounds using ML; X-learner was used for secondary analysis to the SPRINT datasets [24]. Duan et al. [24] compared the performance of treatment effect estimation using logistic regression and X-learner. The results showed that X-learner accurately predicted reductions in CVD risk within 3 years of treatment. However, logistic regression showed that the high baseline risk was proportional to a high treatment effect, but X-learner showed that it was not. Thus, X-learner-estimated HTE was not associated with baseline CVD risk and was not considered by linear models.

Causal inference using ML is rapidly evolving within the computer science field and can also be applied in various fields outside of medicine. This method will be the key to developing personalized medicine for hypertension management.

Explainable AI for Hypertension

Causal inference using ML focuses on estimating HTE of the intervention (e.g., lifestyle modification and medications). ML also accurately predicts incident hypertension and BP values by training big data related to hypertension. However, ML is a black box approach; big data inputs into nonlinear models make interpreting outputs difficult. XAI has been developed for understanding the black box.

Elshawi et al. compared the interpretability of XAI against the hypertension prediction model by ML [25]. The dataset consisted of 43 variables related to hypertension from 23,095 participants. Seven methods for interpreting the ML prediction model were applied, and two among seven methods could effectively evaluate individual hypertension prediction variables: Local Interpretable Model-agnostic Explanations (LIME) [26] and SHapley Additive exPlanations (SHAP) [27]. The experiment results showed that LIME is unstable because it produced different interpretations for two individuals with similar backgrounds. SHAP was a more suitable method because it enabled comparisons between individuals on an evaluation axis using SHAP value for each variable.

SHAP also have been used to evaluate the effect of hypertension management apps [28]. App-based hypertension treatment is expected to affect treatment continuity and BP reduction. The study predicted whether app-based hypertension treatment would be continued for 10 weeks and identified variables that contribute to treatment continuation. The dataset consisted of 427 participants on days one, three, and seven of the study. The dataset included 19 variables, including smartphone OS and email domain as social background variables, the number of plant-based meals reflecting engagement with the treatment, and weight and BP as biometrics. This study built a prediction model for hypertension management continuity using RF. SHAP was used to interpret the individual effect of the model. The results based on SHAP suggested that continuous weight measurement, exercise reports, smartphone OS, and email domain of study participant were related to whether the app-based hypertension treatment would be continued for 10 weeks. SHAP provided new insights from the ML model, which could not be interpreted using black box approaches.

Challenges

Causal inference using AI, and XAI was demonstrated to be a powerful tool in hypertension research. However, many clinical databases on hypertension to which the described AIs could

be applied are not publicly available. Clinical databases are collected on human subjects; thus, the cost for collecting and managing data is high, and data protection and privacy regulations also are strict. To address this issue, a clinical dataset generation approach using DNNs has been proposed [29]. This approach can generate clinical data while protecting patient privacy. If datasets similar to real-world clinical data can be created and made publicly available, AI-factor analyses will facilitate the establishment of BP management evidence for personalized optimal treatment.

AI-Forecasting for Future BP

Hypertension is diagnosed in patient's office/hospital systolic BP of ≥ 140 mmHg and/or diastolic BP of ≥ 90 mmHg, or out-of-office systolic BP of ≥ 135 mmHg and/or diastolic BP of ≥ 85 mmHg [3–5]. If physicians could accurately forecast future or unobserved BP, BP could be managed based on the forecast. Previous studies have proposed out-of-office BP predictions using age, height, weight, lifestyle, medical history, and office/hospital BP measurements. A recent study compared new and existing strategies for predicting out-of-office BP in the context of diagnostic costs related to hypertension [30]. Existing diagnostic strategies use office/hospital BP for an initial decision. If the office/hospital BP of a hypertension-suspected patient exceeds diagnostic criteria, the patient has to measure out-office BP for a certain period. Physicians then diagnose whether hypertension based on the out-office BP requires the patient to continue measuring out-office BP for BP management as a final decision. In contrast, the new diagnostic strategy uses predicted difference between office/hospital BP and out-of-office BP based on individual's characteristics; thus, physicians diagnose hypertension by using prediction value instead of out-office BP for a certain period as a final decision. The study suggested that the new diagnostic strategy for hypertension management is more cost-effective than existing diagnostic strategies.

In hypertension research, BP variability has been identified as an independent risk factor for

CVD [8]. BP variability is defined as the SD and coefficient of BP variation over a certain period. However, the periods vary from beat-to-beat, day-to-day, and office/hospital visit-to-visit. Therefore, treatments and criteria for BP variability have not been established. BP variability is a potential indicator of future BP that can guide management recommendations. Variables of BP time-series data are related to past BP change patterns and are useful for forecasting future BP as shown in Fig. 3. The following subsections describe BP/hypertension forecasting approaches and challenges.

BP Forecasting with Cross-Sectional Data

We can describe future BP or hypertension forecasts using BP-related cross-sectional data. Essential hypertension, which is caused by a combination of factors, accounts for approximately 90% of all hypertension cases [2]. The influence of nongenetic factors can be significant, and even patients with hypertension-related genetic factors can achieve lower BP via lifestyle modification [31]. Therefore, high-performance hypertension forecasting requires datasets including congenital genetic factors as well as acquired lifestyle and physical characteristics such as BMI, age, and sex.

Pei et al. [32] proposed a method for incident hypertension prediction using genetic and environmental factors. Twelve single-nucleotide polymorphism markers were included as genetic factors, and height, weight, gender, age, occupation, smoking status, drinking situation, family history of hypertension, and family history of coronary heart disease were included as environmental factors. Three hypertension prediction models were prepared using an ML: one using only genetic factors, one using only environmental factors, and one using genetic and environmental factors. The dataset consisted of 559 patients with hypertension and 641 healthy individuals. The best prediction performance was obtained using the model that included genetic and environmental factors. The sensitivity and specificity of the model were 63.3% and 86.7%, respectively. The sensitivity and specificity of the genetic-factor-only and environmental-factor-only

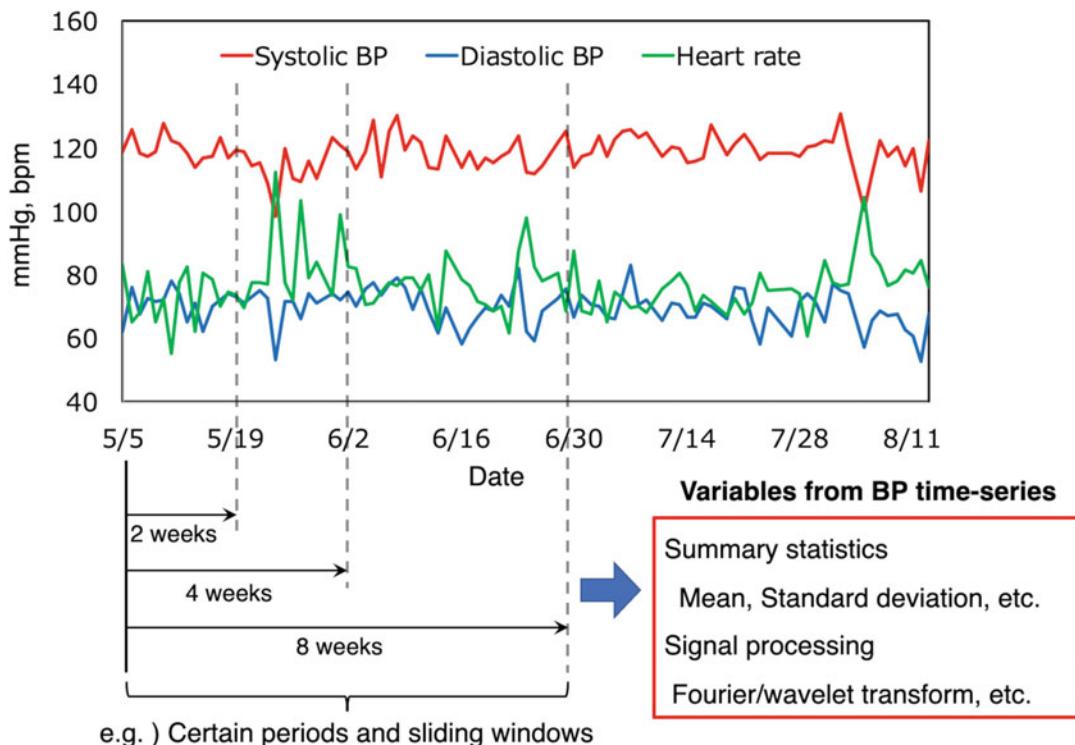

Fig. 3 Example variables of blood pressure (BP) change patterns for future BP forecasting

models were 65.5% and 45.8% and 59.3% and 85.1%, respectively. These results suggested that environmental factors were better hypertension predictors than genetic factors when using this ML prediction approach.

Yang et al. [33] reported incident hypertension prediction within 1–3 years based on lifestyle and physical constitution. The study included 34,719 participants in the US working population, aged 18–54 years. Hypertension in the working population has a greater economic impact due to health care expenditure and hypertension-related productivity reduction. A multistate Markov model was implemented to predict the underlying transition patterns among BP states; namely, normal ($SBP < 120$ mmHg and/or $DBP < 80$ mmHg), elevated ($SBP 120\text{--}129$ mmHg and/or $DBP < 80$ mmHg), and hypertensive ($SBP \geq 130$ mmHg and/or $DBP \geq 80$ mmHg or taking antihypertensive medicine) states, as defined by the American College of Cardiology/American Heart Association (2017

ACC/AHA) guideline [3]. The Markov model is a classical stochastic process in which the state at any time depends only on the previous state. The Markov model predictions were consistent with common hypertension findings, showing that obese and male patients were more likely to develop hypertension. Yang et al. [33] also developed a web application to simulate the probability of developing hypertension with weight loss. Future work will aim to validate the effectiveness of the application as a decision support tool for health care professionals.

Ye et al. [34] also developed an ML-based incident hypertension prediction model. The 1-year incident hypertension risk model was constructed using statewide electronic health records from a retrospective cohort of 823,627 individuals. The model performance was then tested on a prospective cohort of 680,810 individuals. XGBoost [35] was selected to achieve high-performance hypertension prediction. XGBoost is

a decision-tree-based ML approach, known as a high-performance algorithm for regression and classification tasks. The model obtained area under curves (AUCs) of 0.917 and 0.870 in the retrospective and prospective cohorts, respectively. The incident hypertension prediction model has already been deployed in some states; thus, future studies will investigate the health care cost reduction and patient outcome improvement achieved using this model.

BP Forecasting with Time-Series Data

BP can be forecasted using time-series data such as visit-to-visit and day-to-day BP measurements. A previous study has reported daily BP prediction by the statistical method as complement method unobserved BP of time-series data [36]. This subsection introduces BP forecasting using ML approaches.

Lacson et al. [37] analyzed the associations between changes in the SPRINT BP time-series data, including BP variability and CVD development. In addition to the summary statistics, time-series data included various variables such as periodicities and amplitudes for certain periods. The model extracted individual BP characteristics from BP time-series data by wavelet transform signal processing. CVD onset was predicted from the extracted BP data using RF; the CVD prediction model obtained an AUC of 0.71, BP time-series data after wavelet transformation, which is a feature of time-series changes in BP, were effective for CVD prediction. This result suggests that BP time-series data can improve the performance of BP and CVD-related prediction. Therefore, BP forecasting, which aims to prevent CVD development, should incorporate time-series BP data.

Li et al. [38] developed an approach to predict future BP from past BP time-series data using DNNs. The prediction model is implemented LSTM [39], a DNN for time-series data, to predict the monthly mean BP 1–3 months in the future. BP and BMI were time-series data inputs, and other BP-related factors were included as snapshot data. The MAE between the reference and predicted BP was within 7 mmHg and 5 mmHg

for systolic and diastolic BP, respectively. If BP is predicted sequentially, as in this approach, it will complement BP when hypertension patients did not take measurements. Furthermore, daily BP forecasts with high performance will enable physicians to understand BP variability beforehand. Hypertension management based on BP forecasts using time-series data will provide novel patient stratification using BP change patterns for personalized medicine.

Challenges

This section reviewed AI applications for future and unobserved BP forecasts. High-performance BP forecasts are useful for estimating future health care costs. However, the clinical significance of BP forecasts has not been validated. BP and BP-related lifestyle and environment data can be continuously acquired from wearable devices and smartphones; therefore, it is essential to validate BP forecasting in the real world as well as the laboratory. Moreover, daily and weekly BP time-series databases are rarely available. From this viewpoint, as described in section “[AI-Factor Analysis for BP Changes](#),” database generation [29] is required to accelerate research regarding BP forecasting using time-series data.

Conclusions

This chapter discussed the current research on AI for surrogate measurement for BP, factor analysis of BP changes, and BP forecasting for hypertension management (Table 1). Surrogate BP measurements enable continuous and convenient BP measurement to recognize when patients experience rising BP. Factor analyses of BP changes can facilitate the realization of personalized medicine for hypertension management by estimating individual treatment effects. BP forecasting will be advanced by the increasing availability of BP and BP-related data acquired from wearable devices. In the future, these AI approaches for hypertension management will contribute to reducing hypertension incidence and associated health care costs.

Table 1 Artificial intelligence (AI) approaches for hypertension management

AI approaches	Categories	Authors	Year	Contents
AI-surrogate measurement for BP	Measurements using wearable sensors	Su P et al. [11]	2018	Systolic and diastolic BP estimation using ECG-PPG waveforms.
		Franco G et al. [12]	2019	Systolic and diastolic BP (continuous BP waveforms) estimation using ECG-PPG waveforms.
		Eom H et al. [13]	2020	Systolic and diastolic BP estimation using ECG, PPG, and BCG waveforms.
	Measurement using smartphone cameras	Luo H et al. [16]	2019	Systolic and diastolic BP, pulse pressure estimation using facial videos.
AI-factor analysis for BP changes	Causal inference	Powers S et al. [21]	2018	Suggestion of HTE estimation methods on SPRINT study.
		Scarpa J et al. [22]	2019	Identifying using ML of attributes in adverse event group on SPRINT study.
		Duan T et al. [24]	2019	HTE estimation in an individual, comparison of causal Inferences by logistic regression and ML.
	Explainable AI	Elshawi R et al. [25]	2019	Comparisons of interpretability by explainable AI.
		Guthrie NL et al. [28]	2019	Exploration of the relationship between long-term engagement and mobile app intervention using AI.
AI-forecasting for future BP	Forecasting with cross-sectional data	Pei Z et al. [32]	2018	Incident hypertension prediction from genetic and environmental factors using ML.
		Yang J et al. [33]	2020	Incident hypertension prediction based on stochastic process and its application to physician support tool.
		Ye C et al. [34]	2018	Incident hypertension prediction using large-scale electronic health records.
	Forecasting with time-series data	Lacson RC et al. [37]	2019	CVD prediction using BP time-series data including BP variability.
		Li X et al. [38]	2017	Future BP forecasting using past BP and BMI time-series data.

Abstract

Artificial Intelligence is set to revolutionize diabetes health care. Diabetes is the increase in blood glucose levels above normal range. It is tied to the human body's inability to produce insulin or utilize it. Diabetes has taken form of a global pandemic with over 463 million people suffering from it, worldwide. The current health care system is finding it hard to keep up with the demands of diabetes with the existing structure proving to be both expensive and ineffective. In artificial intelligence, we have a tool that has the capability of transforming the current system for good. The shift has already started to take place with many scientific studies focused on artificial intelligence

for diabetes management are being realized into commercialized products that are replacing existing methods of diabetes treatment and management. Artificial intelligence finds its use in various aspects of diabetes health care that benefits both the patients and diabetes health care professionals. This chapter dwells in on all the problems faced by diabetics and how artificial intelligence can come up with solutions for these problems.

Introduction

Artificial intelligence (AI) is set to bring about a radical alteration in medicine and health care [1]. In diabetes, in particular, AI promises a lot of good things. Diabetes is the increase in blood glucose (BG) levels above a critical limit in the human body. The human body contains certain regulatory mechanisms that keep the body's BG levels in an optimal range. The healthy range of BG is 70 mg/dL to 140 mg/dL. It is the function of hormones like insulin and glucagon to keep the BG levels regulated with insulin keeping the higher levels in check by absorbing glucose and glucagon taking care of low BG levels by converting stored glycogen into glucose when needed. It is when the BG levels surpass the higher limit of 140 mg/dL that diabetes is diagnosed. Diabetes may be categorized in multiple types with type 1 diabetes (T1D), type 2 diabetes (T2D), and gestational diabetes being three of its main classifications [2].

T1D is an autoimmune disease in which the pancreas produces little or no insulin [3]. It is caused when the insulin producing beta cells are destroyed by the immune response of human body. On the other hand, T2D is caused when the body cells do not respond to insulin and hence the glucose level keeps on increasing in the human blood stream [4]. The exact reason of why T1D is caused is unknown and is majorly

believed to be genetic. While the cause of T2D is also been connected to genetic factors, it is also believed that environmental factors and obesity are contributors to its occurrence as well. On the other hand, gestational diabetes is the increase in BG levels of women during pregnancy [5]. The reason for this is the production of hormones by placenta for sustaining pregnancy that causes cell resistance to insulin. In most cases, gestational diabetes is cured after pregnancy.

It is understood that diabetes is a disease that cannot be cured completely. It can, however, be controlled by medications and a change in lifestyle. This is the reason that the term diabetes management has been coined. Diabetes management refers to a group of different measures taken to regulate BG and increase the time of a person's BG profile in normoglycemic range. Over the years, multiple methods and tools have been used for the purpose of diabetes management. Technological advances like Internet, wireless communication, and high-end sensors have aided to the goal of a highly efficient diabetes management system that is capable of keeping the BG profile of a diabetic patient in the normoglycemic range all the time. The field of AI holds promise in coming up with solutions to the problems faced by patients suffering from diabetes and the diabetes health care professionals.

AI involves methods and techniques that enable a computer program to imitate human ways in intelligently figuring out the outcomes of various processes. With the advent of sensors such as the continuous glucose monitor (CGM), the acquisition of blood glucose (BG) data became possible and with it the doors of artificial intelligence in diabetes opened. In the past, majority of AI in health care was dominated by methods like case-based reasoning (CBR) and rule-based reasoning (RBR) [6]. However, it was with advances in machine learning (ML) and artificial neural networks (ANN) that revolutionized AI. AI owe most this success to the availability of large amount of data. From expert systems (ES) to decision support systems (DSS) to prediction and diagnostic tools, AI provides solutions to transform almost every aspect of diabetes health care.

This chapter provides an overview of the latest advances in AI in diabetes. The discussion commences with an account of the problems faced by

diabetic patients followed by the solutions provided by AI to these problems. The solutions are then subcategorized in different areas of diabetes health care that can be targeted with the help of AI. Rest of the chapter is distributed as: section “[Problems Faced by People with Diabetes](#)” I explains the problems faced by diabetic patients. Section “[The AI Approach](#)” explores the solutions in AI for the problems discussed in section “[Problems Faced by People with Diabetes](#).“ Section “[Discussion](#)” provides a discussion of the entire chapter and a conclusion to the chapter is given in section “[Conclusions](#).“

Problems Faced by People with Diabetes

Diabetes is a world pandemic with over 463 million people suffering from it, worldwide. This figure is expected to rise to 700 million by 2045. In 2019 alone diabetes was cause to 4.2 million deaths [7]. What is even more alarming that every 1 in 2 people is undiagnosed. Moreover, people suffering from diabetes experience various adversities in the form of physical and mental traumas that considerably reduce the quality of their lives. It is, thus, a matter of critical importance that measures be taken to control the devastating effect of this disease and to improve the life quality of people who are suffering from it.

The occurrence of diabetes in a human may lead to a multitude of different complications. These complications are often referred to as long-term comorbidities. When a patient suffers from diabetes for a longer duration and takes no precaution for BG regulation, these complications are very likely to arise. Cardiovascular diseases, neuropathy, retinopathy, nephropathy, foot damage, skin conditions, hearing impairments, Alzheimer’s disease, and depression can all be the comorbidities arising because of diabetes mellitus. In T1Ds the occurrence of hypoglycemia is a major complication. It occurs when the BG levels go below the critical levels. The happening of hypoglycemia may cause loss of consciousness, confusion, trouble talking, seizures, and in extreme cases death.

Although, T1D is genetic and cannot be prevented, there is a chance T2D may be prevented.

As already discussed, the cause of diabetes is often unknown in all cases. In T2D, however, prediabetes is an indicator of a future occurrence of diabetes. Prediabetes is the rise in BG levels above normal levels and can serve as a warning to the patient prior to the diagnosis of diabetes. Gestational diabetes can also lead to T2D in some cases. The diagnosis of diabetes itself is a problem faced by many patients. This is confirmed by the fact that almost half of all the diabetes cases around the world are diagnosed late or not diagnosed at all.

Keeping the BG levels in normoglycemic range is one of the major challenges in diabetes management. For T1Ds, management of the insulin intake regime is necessary. The amount, time, and intensity of basal and bolus insulin need to be specified according to the dynamics of a patient’s BG profile. The management of insulin is also important for T2D patients on insulin. In T2D, the patients need to have a thorough idea of their diet and other lifestyle choices that may lead to complications. Diabetic patients are prone to mental stress. In case of T1D the unpredictability of events like hypoglycemia can add immensely to the fear and stress of a patient. This can reduce the life quality of a patient and may trigger other mental issues such as depression. Moreover, stress is also understood to be one of the factors that increases the risk of T2D.

With the increase in global population, our health care system finds it hard to keep up with the health care demands of the increasing number of diabetes patients. The existing infrastructure does not allow for a diabetic patient to enjoy the attention they deserve. Limited diagnostic facilities and a shortage of medications worldwide have lead us to a point where the demand for a radical shift in the current system seems obligatory. AI can provide us with the platform for the shift in diabetes health care that is utterly necessary.

The AI Approach

The term AI has been around for a good five decades now. It was first coined by the ground breaking science article of Alan Turing entitled “Computational Machinery and Intelligence.” There is no single definition of AI that is

universally accepted. However, the authors of “Artificial Intelligence: A Modern Approach,” a landmark book in the field of AI, defines AI as “the study of agents that receive precepts from the environment and perform actions.” With advances in ML and deep learning (DL) in the past decade, this field of computer science has taken shape of a revolution. Even though AI finds its use in a large group of applications, health care in general and diabetes health care in particular can benefit from it greatly. The problems discussed in the last section can all be addressed with AI-based techniques. Some of the major AI-based solutions in diabetes health care are stated next.

Expert Systems Versus Decision Support Systems

As shown in Fig. 1, almost all of the AI-based tools designed for diabetes health care will eventually find their use in either ES or DSS or both. Diabetes ES are systems that are designed with a focus on mimicking the real-life diabetes expert.

These systems determine the condition of a diabetes patient by analyzing different parameters related to the physiological condition of a patient. These parameters are often obtained in form of laboratory tests, electronic health records (EHRs), patient secure messages, or questionnaires. The ES of past were mainly based on RBR or CBR and followed an if-else conditional structure. The CBR-based ES look at similar cases from the past and determine the outcome of a specific case, whereas RBR-based ES determine the outcome of a case based on certain rules. These rules are similar to the ones used by clinicians while analyzing the condition of a patient by questioning them. With advances in ML and DL, many ES now utilize algorithms that learn from data.

DSS on the other hand are software platforms used to help the diabetic patients and the clinicians with their decisions regarding a certain scenario by giving out suggestions. The suggestions DSS give a diabetic patient or clinician are often based on outcomes obtained from AI-based models. These suggestions when adopted in the course of action are supposed to improve the outcome of a

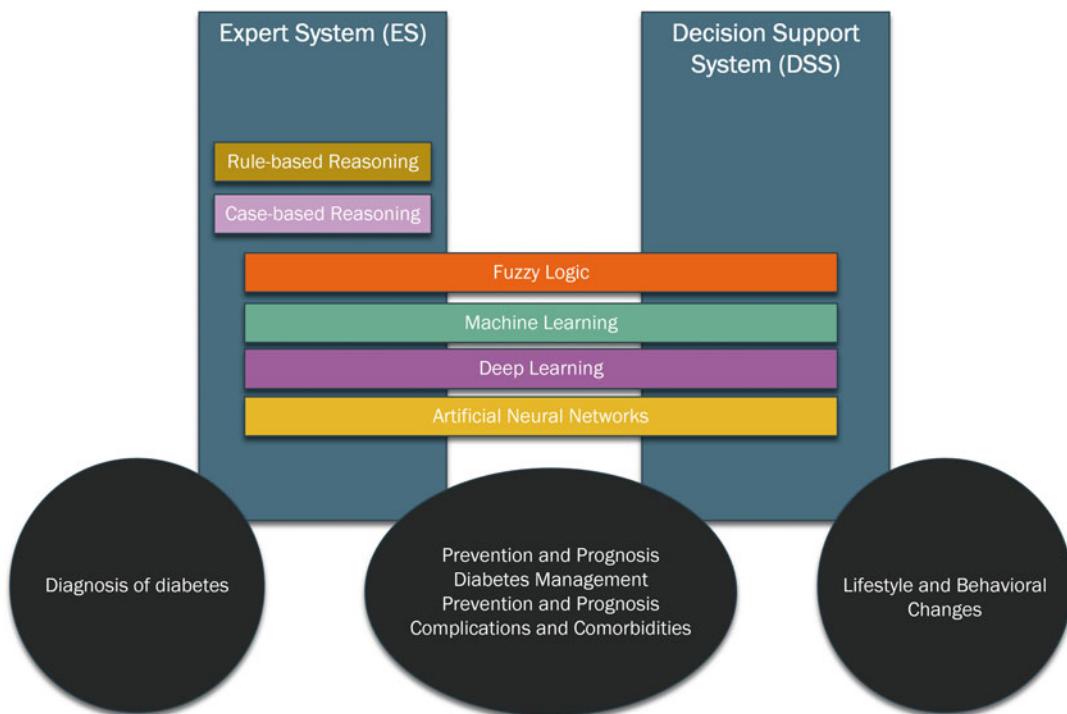

Fig. 1 An outline of AI impacting different areas of diabetes health care

patient's glycemic profile. Like ES, the DSS also utilize ML and DL models to predict, determine, and identify various trends in relevant data and base its decision on it.

Prevention and Prognosis

The prognosis of diabetes concerns the patient as well as the health care professionals. The knowledge of an individual developing habits or the physiological indicators that may lead to diabetes in future may tempt the patient to act proactively in order to save themselves from diabetes. Healthcare professionals may find this knowledge useful in recommending lifestyle changes and prescribing drugs to the individuals with diabetic tendencies.

T1D is developed in childhood or adolescent and its causes are often genetic. In almost all cases, it is impossible to predict the occurrence of T1D. On the other hand, T2D is more likely to happen in people after the age of 40. Though genetic factors could contribute greatly to the occurrence of T2D, majority of the time it is our lifestyle choices that triggers it. It is, therefore, possible to predict the risk of occurrence of T2D by analyzing different aspects of a person's lifestyle. This is a perfect ML problem that could be tackled by either classification or regression techniques. According to a review study, in 2018, the most common application of AI for T2D was screening and diagnosis in different stages [8]. In past ML models have been used to predict the risk of individuals developing T2D by using different demographic characteristics such as smoking, drug history, etc. [9]. AI-based models have also been used to predict the risk of diabetes from several other types of data like electronic health records (EHRs) and genetic data [10, 11]. Many other examples could be found in literature that predict the occurrence of T2D using AI and suggest different strategies for its prevention [12–14].

Diagnosis of Diabetes

As discussed earlier, almost half the diabetes cases around the world remain undiagnosed. What is even more alarming, a lot of the diagnosed cases

are wrong diagnosis. The danger of misdiagnosis is that the patients are put on inappropriate treatment regimes. Moreover, misdiagnosis increases the risk of diabetic ketoacidosis among T1D patients by about 18% [15]. The reasons for this could be many. Ranging from the scarcity of health care facilities to the accuracy of the diagnostic equipment diabetes patients remain at the risk of a late diagnosis, misdiagnosis, or no diagnosis at all. Early and accurate detection of diabetes can save many lives. AI-based tools can improve the situation in this area of diabetes health care. From labeled data of correctly diagnosed patients in the past, ML techniques may efficiently recognize whether a person suffers from diabetes or not. Moreover, diagnosis of comorbidities developed with diabetes through AI is also a trending area of research with diseases like diabetic retinopathy being diagnosed by various research studies [16, 17].

T1D is often diagnosed at an early age. T2D on the other hand may develop in the later part of life. T2D patients often develop prediabetes before they are diagnosed with diabetes. It means the rise in BG levels above normal range but not enough to be labeled as diabetes. Prediabetes may go unnoticed for years until serious issues arise. Studies have tried to diagnose prediabetes by using ML techniques trained on diabetes-related variables like age, family history, weight, and body mass index [18, 19]. Other studies have used data like plasma glucose concentration, diastolic blood pressure, and body mass for the diagnosis of T2D [20]. Screening of gestational diabetes has also been the topic of multiple studies [21, 22]. Whereas data like age, fasting BG, and mRNA have been used for training the ML models.

Diabetes Management

Diabetes management broadly means measures taken to keep glycemic profile of a diabetic patient within normal range. In the context of AI, diabetes management is a group of different tasks performed to keep the BG profile of patient inside healthy limits. AI-based diabetes management systems may use individual tasks or a

combination of such tasks to reach this goal. Blood glucose control strategies, BG prediction, detection of adverse glycemic events, insulin bolus calculators, and advisory systems and detection of meals, exercise, and faults [23] are all tasks that can be performed by an AI-based diabetes management system.

BG control strategies emerged as an area of study in diabetes management that is associated with the concept of artificial pancreas (AP). An AP's closed loop consists of a CGM, a control algorithm, and an insulin delivery system. Control engineering theory have been employed in giving shape to many of such control algorithms and up to a respectable accuracy. AI, however, is proving to be an improvement on these traditional control methods with techniques like ANN, fuzzy logic, and reinforcement learning. BG prediction is another task that AI is performing efficiently. Training ML models with BG values along with their associated time stamps can result in the forecast of future BG values. By forecasting the BG values of a diabetes patient at some time in future, a management system can help the patient in preparing for the possible occurrence of an adverse event. ML finds hidden nonlinear relationships in the training data and forms decisions based on these relationships. In case of diabetes, by routing these relationships we can detect the adverse glycemic events in present.

Insulin intake is a mandatory therapy for all T1Ds and some T2Ds. Insulin delivery to the body can be performed in multiple ways. Insulin taken at the time of meal intake is referred to as bolus insulin. This type of insulin tackles the sudden surge of BG caused by a meal. On the other hand, insulin taken in between the meals is called basal insulin. Figuring out the correct doses of bolus and basal insulin is a tricky process and something that a diabetic patient must always do correctly. AI has provided us with models that can compute the amount of insulin needed to keep the BG levels in normal range up to a certain level of accuracy [24, 25]. AI-based tools have been designed that detect events affecting the glycemic control of diabetic patients. These events may contain exercise, meals, or faults in the equipment [26–28]. The detection of such events may prove

vital in lifestyle decisions being suggested by an AI-based DSS.

Lifestyle Interventions/Behavioral Change

Decisions related to lifestyle and behaviors have a huge impact on the overall health of diabetics. These decisions may prevent diabetics from falling prey to any of the adverse glycemic events such as hypoglycemia and extreme hypoglycemia, etc. Moreover, if anticipated early, opting to a healthy lifestyle may prevent T2D from happening altogether. Diabetes DSS are platforms that help diabetics correct their lifestyle in order to avoid complications arising because of their illness and to live a normal life [29]. These lifestyle decisions may contain eating habits, exercise, sleeping habits, and insulin recommendations.

The DSS platforms often utilize ML models to compute measured impact of these decisions and give away suggestions to the diabetics so that they may avoid any unfavorable circumstance. With advances in smartphone technology, these DSS platforms are now more realizable than ever. A diabetic patient with an AI-driven DSS system on their smartphone is virtually under expert supervision at all times. A DSS running on a smartphone device in integration with CGM and PA sensors give birth to the idea of a potentially brilliant DSS. An apt DSS platform predicts the future course of BG values and then informs the diabetes patient about the action needed to avoid any trouble. These actions, based on the nature of adverse event, the type of diabetes, and variability of BG profile, may suggest different things to the patient such as the type of food consumption, the intensity of physical activity, and the dose of insulin.

Lifestyle and behavior changes suggested by the DSS along with reducing the risk of comorbidities and other adversities also ensure an improved life quality. The growth of diabetes is often linked with lifestyle behaviors that encourage obesity. Research studies have proposed strategies to prevent obesity endorsing habits that may cause diabetes later on

[30]. AI-based studies also encourage the patient's role in managing diabetes to meet the required targets. Indeed, a potent DSS can only be effective if the patient is willing to adopt the changes suggested by the system. Such self-management approaches are also referred to as patient-driven systems.

Risk Stratification

Risk stratification refers to quantifying the risk of an adverse event happening in present or is predicted to occur in future. It necessarily means that after detection and prediction, the AI algorithms are also capable of quantifying the risk a certain event poses to a diabetic patient. Risk stratification may prove to be a vital tool in scenarios where an extreme form of some adverse glycemic event poses a life threat to the diabetic patient. For instance, hypoglycemia is referred to as the decrease in BG below critical levels. Normally, when the BG levels drop down below 70 mg/dL a hypoglycemic event is diagnosed. An extreme case of hypoglycemia is reported when the BG levels drop below a level of 54 mg/dL. Extreme hypoglycemia can prove deadly if not dealt with in time. The concept of risk stratification in a scenario like this seems critical. If an AI-based system can predict the future occurrence of a hypoglycemic event and with it the risk of an extreme case, a complete hypoglycemic risk prediction system can be brought into realization.

Studies have measured the risk of hypoglycemia and certain other adverse glycemic events with the help of ML. Maniruzzaman et al. [31] has proposed a diabetes risk stratification study that uses the random forest model to assess the risk of diabetes. A risk stratification system that predicts the risk of gestational diabetes by using electronic health records was presented by Bilal et al. [32]. The application of risk stratification is not only limited to diabetes and its associated adverse events but also spans an entire group of comorbidities arising because of diabetes. Studies have used ML-based risk stratification strategies to quantify the risk of heart complications in diabetes patients [33–35].

Complications and Comorbidities

As discussed already, in many cases if the diabetes patients do not manage their illness properly, there is always a risk that other harmful conditions will start to appear in the body. These conditions that appear in the human body because of diabetes are called diabetic comorbidities [36, 37]. The most common of these comorbidities is hypertension, heart diseases, retinopathy, nephropathy, neuropathy, depression, autoimmune thyroiditis, foot damage, skin conditions, hearing impairments, and Alzheimer's disease. AI tools can be used for the detection and diagnosis of these comorbidities. Techniques like ANN and DL have made it possible to diagnose diseases from medical images and other types of medical signals. Many studies have used AI for the automatic screening of diabetic retinopathy [17, 38]. Other studies have utilized ML for the diagnosing and risk stratification of heart complications in diabetics [35]. Furthermore, studies have used AI in diagnosing cardiovascular complication that arise due to diabetes as well as the progression of diabetic kidney [39, 40]. Certain other works have diagnosed and predicted diabetic foot ulcers in diabetes patients [41, 42].

Discussion

AI has brought upon a revolution in health care that is set to transform almost all areas of the traditional health care system. In diabetes health care, AI is set to revolutionize major aspects of the system. From detection to prevention of diabetes, AI can be used to put a halt to the growing pandemic. This can result in saving billions of dollars spent each year in regard to direct medical cost and reduced productivity. For diabetic patients, AI can mean higher life expectancy, ease of access to professional-level advice, self-operating closed-loop insulin delivery systems, and peace of mind. AI-based blood control strategies are capable of replacing conventional control methods in AP. Moreover, these strategies have the potential to perform better than conventional methods. AI-based BG level prediction may pave way to

highly efficient DSS platforms that can provide professional-level advice based on future forecasting. An AI-based forecasting method can prove vital in the prevention of adverse glycemic events such as hypoglycemia. Such a method when combined with a risk stratification technique can prove to be a potent warning system in case of extreme adversity. AI-based DSS can be loaded with functionality to provide lifestyle advice to diabetic patients. Such DSS platforms can provide suggestions regarding diet, physical activity, and other habits of patients based on personalized AI models. AI-based screening of diabetic comorbidities can save time and money on both the patient and services side.

Conclusions

AI-based methods, with applications in almost every field of diabetes health care, have the potential to transform the scene of the entire system and have far-reaching results. It is now high time that the world recognizes AI in diabetes as a distinguished field of research. However, it is understood that AI is a field that will grow and reach perfection with time as the pool of available relevant data grows. Researchers need to explore new methods and continue experimenting with the existing AI models by coming up with hybrid techniques and cascaded models that may target any of the potential problems diabetics face.

Abstract

Primary healthcare is a highly interesting generalist field in medicine. Over the coming years, this field will continue to profoundly benefit from AI in medicine, which will result in positive changes in the everyday lives of patients.

Medical specialist knowledge will reach out to primary healthcare settings, profoundly altering the whole referral system and its indications. Specialist domains will be distributed widely and remotely, as scientific advances will reach primary care patients and doctors more frequently, rapidly, and accurately, thus tilting the dependency balance in the patient–doctor relationship.

Personalized and precision healthcare will reach out to every clinic and patient, and nowhere will it be as obvious as in the primary healthcare setting. AI in primary care will also

speed up disease theranostics, which will impact management decisions. Decision support will be abundant for the GP and the patient. Patient power will likely see an increase as patients become more active, well-informed, and independent in information discovery and learning about their own disease, a trend that has already occurred in most developed economies. This trend will likely continue in emerging economies through AI-powered mHealth platforms thanks to the rise in smart phone technologies.

Many areas within primary care are entering a revolution: *Pharmacogenomics* will profoundly change the way we prescribe medications. All types of pattern recognition in image-based specialties will essentially strengthen their presence in the primary care clinic: radiology ranging from flat X-rays to ultrasonography, dermatology, pathology, and parts of ophthalmology and

scopic inspections, where other image pattern recognitions can be further expanded. Moreover, interpersonal psychotherapy, follow-ups, and compliance will be armored with surveillance, coaching, and instructing components.

Verily, in primary healthcare, the whole medical AI symphony will reach its soaring tutti and eventually the energetic confluence of all the thematic lines – incorporating the *Allkunstwerk* of AI in medicine.

Introduction

Accenture estimates that the health AI market in a country like the USA will grow at a 40% annual rate, reaching \$6.6 billion by 2021 (pre-SARS-COV-2). Reports by the WHO and World Bank suggest that the globalization of health system economies will leverage preventative/predictive AI to shift the management decisions from treatment to prevention [1, 2]. This can mitigate the growing cost of noncommunicable diseases (NCDs) linked with high morbidity and mortality, which are estimated to cause a cumulative loss to global output of \$47 trillion between 2011 and 2030 [1, 2]. Moreover, the WHO estimates staffing shortages of up to 12.9 million by 2035 [1, 3]. To this end, the primary care physician will be at the heart of a new wave of exciting patient-focused AI-based healthcare innovation and transition bringing about effective transformation of healthcare delivery for the improvement of outcomes.

As the gatekeeper to secondary healthcare access, general practice or family medicine involves early interaction with the patient identifying their initial presenting complaint and assessment prior to referral for specialist intervention or emergency services. AI in medicine is expected to cohere into a burning focus inside the domains of primary healthcare [4, 5]. Hence, we will

summarize this chapter into a condensed but relevant and frontline overview of all the possibilities and ongoing developments within the field of primary care. As many aspects as possible will be elaborated on in order to cover the effect of how AI will impact and be impacted by primary healthcare. This chapter will review all areas, applications, specialities, and tools, which we believe will impact primary healthcare.

Several changes including the shift towards digitization and the transition to electronic health records for most societies will continue to evolve the doctor-patient interaction enabling patients to gain legally binding ownership of their data. In doing so, patients will also need to become more aware of the ethico-legal responsibilities that surround ownership of their personal data management and what constitutes mishandling of data and security breaches. This issue will require a security backed AI system that will support and alert the patient of such a breach or ideally prevent such breaches. This will be tied in with patient education about their condition, the right source of data, data integrity and data security, etc. It would not be surprising to see the emergence of a private patient owned health cloud in some countries, with perhaps even a global potential for regulated information discovery.

This central storage place with the patient at the center and with the invited professional human in the loop, likely in the form of the patient's own general practitioner, would enable a phenomenal overview and new insights. This setup will give patients and clinicians the opportunity to deliver personalized treatment, i.e., real precision medicine. No future primary healthcare would be complete without the in-depth integration of genomic data, which would bestow upon us the opportunity for real prevention. Equally, pharmacogenomics will give the patient the optimal drug immediately, instead of trial and error. The integration of microbiomics will also take the primary care dietician's role to an evolved level [6]. Deep diet will allow machine learning support for optimizing nutritional value, with significantly greater evidence-based backing. Hence, AI supported evidence-based medicine (EBM) in primary healthcare will facilitate effective multidisciplinary primary care management decisions.

A macrotrend with AI will be the moving of more specialist tasks and knowledge closer to the hands of the patient and their GP. Though, it can also be argued that in some situations the patient can directly seek the highest specialist competence, seemingly bypassing the GP to enter secondary care via emergency medicine, AI triaging systems supporting out of hours services will grow in prominence over the coming decades. As mentioned before, the role of the GP may evolve into taking on a more God-view holistic approach and subspecialist forms may even become technical with GPs programming management algorithms for AI systems to meta-learn. However, in a forest of narrow AI applications, it will still be continuously valuable to have an overviewing general practitioner who has the empathy and knowledge base to support the patient. Although in some economies, the time pressures and resource constraints limit such effective doctor-patient interaction. That said, there will always be room for deep empathy and counselling, and even thinking outside the black box in more intricate cases. In fact, more, not less, may be required from these primary care specialists.

In the discussion of AI in primary healthcare, it is a mistake to only refer to the changing landscape of the healthcare and situation in Europe or the USA – the effect will be as, if not more, dramatic in countries with emerging economies [1, 3]. Globally, we will see the dawn of primary healthcare with precision, individualism, specialist assets, prevention, and broader patient engagement. The enormous spread of mobile smart devices will further fuel this inevitable major global trend.

Given the fact that most medical conditions, including those requiring highly advanced specialist treatment, e.g., in hematology, immunology, interventional radiology, or oncology, all enter the hospital labyrinth through the gate of primary healthcare, the GP will remain in an advantageous seat to leverage big data to generate insights that will support patient management. They usually oversee and know a lot about the patient's family, environment, work, and other circumstances – a knowledge base greater than what could easily be achieved by a naïve AI. GPs will prove crucial in

improving explainability and overcoming the "black box" nature of an AI, thus helping to improve the limited capability of some narrow algorithms.

In summary, the primary healthcare specialist sits at the crossroads of human destinies, relations, subtle facts, and almost literary conditions, which cannot always be fully transcribed, no matter how delicately a medical record text is composed. It is a matter of deep empathy, knowledge, and dedication in the care of a fellow human being. AI will hopefully help to augment and progress the doctor-patient relationship, while allowing patients to become independent in understanding their disease better and co-managing it with their GPs.

Opportunities of AI in Primary Care Include:

- Gathering and synthesizing disparate patient data leading to the efficient integration of health information (text, images, and knowledge) – also increasingly relevant with data from wearables, sensors, and remote monitoring
- Increased efficiency of establishing diagnoses and treatment
- Predicting and possibly averting complications and reducing unnecessary services/costs
- Saving time on administrative tasks
- Allowing each member of the care team to perform at the highest level

Shift of Balance in Healthcare

In most developed and developing economies, multiple drivers such as patient demographics, gender differences, availability of services and financial support limit the balance of patient-primary care practitioner healthcare provision [7]. The advent of technology and the internet is helping to shift the balance more towards patient self-empowered healthcare delivery. Patients are researching their conditions online and will usually come into a general practice consultation very much more well-informed.

The difficulty is ensuring that the information for the patient is the right information provided by reputable sources. Over the coming years, artificial intelligence can help in the source verification process to facilitate this process for primary care patients. The shift in balance of healthcare information delivery will no longer be focused on the GP giving the information to the patient, but the patient taking charge of researching their own condition. The GP's role as well as offering treatment will shift towards empowering the patient to independently interpret the growing complexities of available data, and this can be achieved using AI platforms.

Electronic Health Records and Data Ownership

Sinsky and colleagues conducted a study in 2016 which found that physicians spent 27% of their office day on direct clinical face time with their patients and 49.2% on electronic hospital records and desk work [8]. When in the examination room with patients, physicians spent 52.9% of their time on EHR and other work. Physicians who used documentation support such as dictation assistance or medical scribe services engaged in more direct face time with patients than those who did not use these services. In addition, increased AI usage in medicine not only reduces manual labor and frees up the primary care physician's time but also increases productivity, precision, and efficacy.

In many developed and some emerging health economies, the shift towards digitization and the transition into the electronic health record has to coincide with schemes that improve the patient's understanding about the legally binding responsibilities associated with them owning and controlling their own data. Moreover, there needs to be an obligation to support the understanding of the ethico-legal responsibilities that surround the patient's owned and personalized data management [9–11]. This constitutes the education of data mishandling and security breaches, which is difficult for the digitally naïve to appreciate. This issue will require a cybersecurity-aware AI system primed on healthcare data breaches, and a policy that will support and alert the patient of

such a breach. This will be tied in with patient education about their condition, the right source of data, data integrity, and information governance, as well as data security, etc. [9–11]. Patients will need to know about ransomware and adversarial attacks or be supported in multiple methods to help them become aware of this or detect this if they are to own and manage their data. AI platforms that take into account encryption systems could support these issues.

Proponents have leaned towards patient data being co-located within a central private cloud infrastructure and co-controlled and accessible by both the patient and the primary healthcare provider [12, 13]. While others desire a more decentralized system where current technologies mean that various forms of data and the storage of all the big-omics data, e.g., genomics and gut microbiome, and all health records including radiological, dermatological, pathological, and other clinical images, laboratory results and the written record have to be handled effectively. Relatedly, such data has to be made rapidly available to the physician in their consultation or provided as insights and dashboards for rapid decision support [14]. This would mean that patients cannot attend a clinic forgetting to take crucial data with them, which usually leads to delays in consultation or a feeling that the visit to the clinic was fruitless for the patient. It is for this reason that one proposed efficient delivery, where the storage system is a digital server or personalized secured cloud-based infrastructure.

Those deeply in-favor of the patient-centric approaches to data management assert that clinical data is not complete without including possible verbatim comments made by the patient for medicolegal purposes. How this patient information is captured in the initial consultation may need to shift towards a more digital record using AI processing of audio-centric recordings. AI systems that can auto-transcribe interactions between the GP and their patient is something that has also been reported [15]. Platforms that keep the GP and patient in the loop about any updates including results from recent investigations will become more prominent in a co-owned system.

The lack of communication between electronic health records is also a major issue when it comes

to information transfer across primary care systems, or between primary and secondary care either cross-border or locally. Although internet platforms currently allow email encryption for data transfer. Usually patients end up receiving printed paper copies of their data in a non-environmentally friendly and unsecure manner. AI systems that can encode information from one data system to another data system for rapid retrieval and that take into account intersystem security protocols will become invaluable. Decentralized systems aim to deliver potential safeguards, but it remains to be seen whether this will be the case and ubiquitously utilized in primary care.

Though it should be added that security codecs are not necessarily AI, but when a specific recognition is included, e.g., by a translation or text expansion/interpretation step, AI would be justified.

Global Macrotrends [1–3]

Tourism and migration have been linked to a trend towards cross-border globalization of healthcare being powered by the internet and tele-health platforms, which are simplifying the move towards the cross-border delivery of care. These trends are going to be augmented by AI for the benefit of effective primary healthcare delivery. It is not infeasible that migrant patients will be able to receive integrated healthcare with information management between their primary care physicians in their home countries and specialists in their country of residence. The financing of this type of system adds additional complexities that will require cross-border treaties and policies to be established to facilitate this, taking into account the language barriers and the need to have AI systems that can aid translation. It did, however, become clear that during the 2020 SARS-CoV-2 pandemic, cross-border dissemination of information was deemed feasible to enable vaccine development, all of which was powered by machine learning techniques. However, this also required a coordinated effort within local community healthcare teams to facilitate vaccinations using AI platforms to support the effort. In summary:

The impact of AI on primary care is linked to patient treatment decision support systems, public health surveillance systems, and clinical trial management and follow-up.

Symptom Checkers and Dissemination of Specialities

Several AI-based symptom checkers have been developed with the aim of improving the accuracy and the reliability of any advice, guidance, or signposting. In a vignette-based audit of 23 symptom checkers available for use by the public, the appropriate triage advice was considered to have been provided in 57% of evaluations, rising to 80% for emergency cases [16]. These numbers must, however, be put in perspective – how good is a human expert on average when confronted with the same signs, opinions, or measurements?

Unfortunately, a major problem with most symptom checkers is that they are risk averse, encouraging users to seek help from their GP for conditions when self-care would be perfectly reasonable and safe. Striking a sensible balance between missing a serious condition and overwhelming GP workload is tricky. As many symptoms presenting to GPs are self-limiting, one option to consider is the development of AI tools that enable certain symptoms to be monitored over time [17]. AI systems can also be fine-tuned to improve diagnostic yield and optimize their screening potential to identify when to involve the general practitioner.

In some areas where primary care services offer remote care to the patient detached from urban regions and hospitals, the consultant/specialist might be required to intervene remotely to action emergencies occurring in primary care. Newer referral principles that can facilitate this will be augmented by artificial intelligence. Various specialist services including dermatology and pathology, etc. may greatly benefit from augmented diagnostic approaches using trained machine learning models to direct diagnostics ensuring prompt referral for specialist support is achieved [18, 19]. Smartphones can now be used as the diagnostic tool of choice with peripherals that can image the ear drum, or in the case of dermatology, a skin lesion [18–20]. These machine learning

algorithms will tirelessly classify these lesions and provide feedback to the patient and facilitate remote specialist input from the clinician. Doing so frees up hospital clinic slots, bed space, and emergency rooms for the admission of critically unwell patients. There are also developments where a smartphone can be exploited to make high-resolution retinal images, e.g., for screening for and longitudinal monitoring of diabetic retinopathy (see *smartphone retinal camera*, in Table 2).

Altered Roles

The evolution of the roles of nurses, physiotherapists, psychologists, curators, and the effect on the whole primary care team mean that these specialists will benefit from artificial intelligence systems to help manage patients with evolving expectations within a digitized economy. On one hand, there is also redistribution of roles in primary care, with concepts such as digital first

using e-consult/telephone triaging replacing in-person patient appointments. Others mention that huge swathes of the population are yet to embrace the use of smartphones in some parts of the world. However, a significant proportion of the global population have smartphones making AI-based mHealth systems an ideal approach to support the masses.

The transition of a patient from secondary care back to the primary care environment usually requires input from a multidisciplinary team of, for example, community physiotherapists and other clinicians. AI platforms can, and in some instances already do, coordinate this process within the community. Figure 1 summarizes a great many medical areas that are benefitting from AI for primary care. Table 1 summarizes the machine learning models in this space, and Table 2 presents a handful of the companies working on AI for primary care. We next discuss AI for other specialty body systems that usually require primary care input.

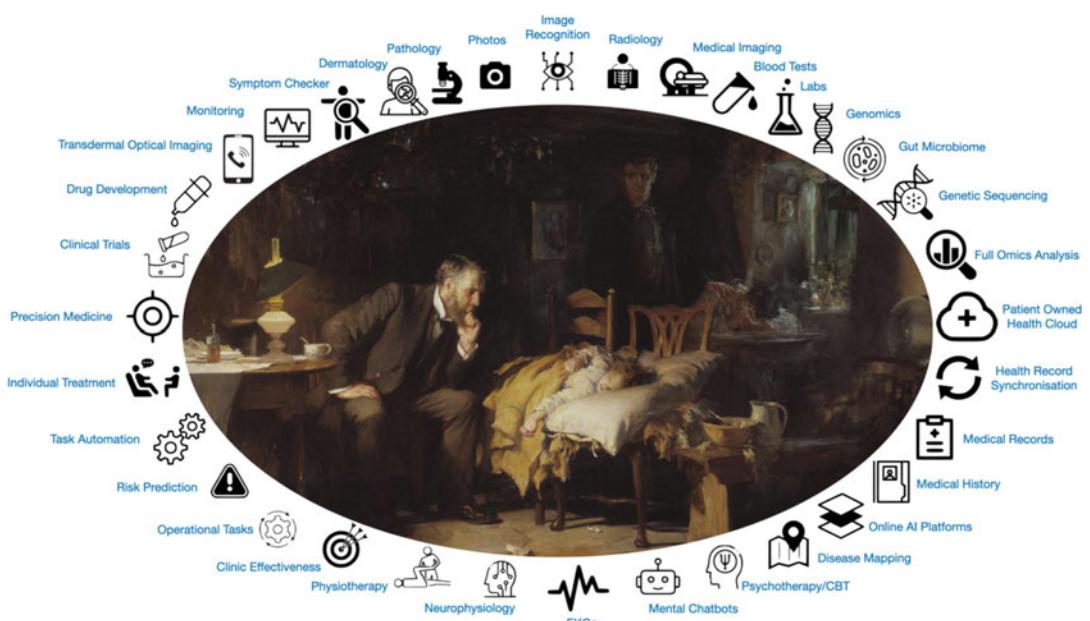

Fig. 1 The archipelago of artificial intelligence applications in primary healthcare at the time of the fourth industrial revolution of the 2020s. In the center *The Doctor*, exhibited 1861. Sir Luke Fildes 1843–1927. Tate/Tate Image. Central Image permission granted by Original Owners. Adaptation and re-imagination by Dr. Niklas Lidströmer. It demonstrates a striking connection between what doctors could do, then the evolution up to where we

are and what patients themselves and their doctors will soon be able to accomplish bound by developments in machine learning. The icons present a summary of the multidisciplinary aspects of general practice and subspecialties that interface with primary care where developments from AI are being made to support optimal patient care

Table 1 List of global companies working on AI platforms that will benefit primary care

Company	Main area	Actions	Reference site	Location
PathAI	Pathology	Reduced error. Personalized care	pathai.com	Cambridge, Massachusetts
Buoy Health	Symptom checker	Chatbot. Diagnosis. Treatment guidance	buoyhealth.com	Boston, Massachusetts
Enlitic	Radiology images, blood tests, EKGs, genomics, patient medical history	Multifaceted analysis platform	enlitic.com	San Francisco, California
Freenome	Screenings, diagnostic tests, and blood work	Cancer testing. Detection in the earliest stages	freenome.com	San Francisco, California
Beth Israel Deaconess Medical Center	Microscope bacteria scanning	Very early infection diagnostics	bidmc.org	Boston, Massachusetts
Zebra Medical Vision	Radiology assistant	Automatic analysis for clinical findings	zebra-med.com	Shefayim, Israel
Bioxcel Therapeutics	Drug development in immuno-oncology and neuroscience	AI to find new applications for existing drugs and identify new patients	bioceltherapeutics.com	New Haven, Connecticut
Berg Health	Disease mapping of common and rare diseases	Discovery and development of breakthrough medicines. Found new links between chemicals and Parkinson with AI	berghealth.com	Framingham, Massachusetts
Xtalpi	AI + cloud + quantum physics. The ID4 platform	Predicts the chemical and pharmaceutical properties of small-molecule candidates for drug design and development	xtalpi.com	Cambridge, Massachusetts
Atomwise	Focus on serious diseases, including Ebola and multiple sclerosis. AtomNet	Screens with AI 10–20 million genetic compounds per day. Results 100 times faster than traditional pharmaceutical companies	atomwise.com	San Francisco, California

Deep genomics	Drug candidate identification	Neuromuscular and neurodegenerative disorders	deepgenomics.com	Genomics will be a naturally integral part of all future primary healthcare	Toronto, Canada
Benevolentai	Right treatment to the right patients at the right time	Better target selection and provide previously undiscovered insights	benevolent.com	Drug licensing and easily transportable medicines for rare diseases may be integrated into primary healthcare	London, England
Olive	Automation of healthcare's most repetitive tasks, freeing up administrators to work on higher-level ones	Eligibility checks to unadjudicated claims and data migrations so staffers can focus on providing better patient service	oliveai.com	Automation tools will integrate into the plethora of softwares and tools in primary healthcare	Columbus, Ohio
Qventus	Platform solving operational tasks, e.g., related to emergency rooms and patient safety	Prioritizing patient illness/injury, tracking of clinic waiting times, charting the fastest ambulance routes	qventus.com	A multitude of these tools have relevance to primary healthcare	Mountain View, California
Babylon hHealth	Personalized and interactive healthcare	Anytime face-to-face appointments with doctors and/or chatbots	babylonhealth.com	Solutions such as this one will integrate with physical primary healthcare clinics	New York, New York
Cloudmedx	Generating insights for improving patient journeys throughout the healthcare system	Clinics management of patient data and clinical history with predictive analytics to intervene at critical junctures in the patient care experience	cloudmedxhealth.com	Primary healthcare providers could use these insights to likely more efficiently move patients through the system with less of the traditional confusion	San Francisco, California
Cleveland Clinic	With IBM. Gathering information on trillions of administrative and health record data points to streamline the patient experience	AI and vast databases help personalize healthcare plans on an individual basis	clevelandclinic.org	As in the Cleveland clinic, primary healthcare clinics throughout the Worlds will benefit from insight from the marriage of AI and gigantic medical records and all other medical databases	Cleveland, Ohio
Johns Hopkins Hospital	With GE. Predictive AI techniques to improve the efficiency of patient operational flow	Hospital effectiveness program resulted in, e.g., augmented patient admission and discharge before noon	hopkinsmedicine.org	Applicable also to clinic effectiveness in primary healthcare	Baltimore, Maryland
Tempus	World's largest collection of clinical and molecular data in order to personalize healthcare treatments	Collection and analyses of data in everything from genetic sequencing to image recognition, that can give physicians better insights into treatments and cures	tempus.com	A massive data library for personalized care would also benefit primary healthcare	Chicago, Illinois

(continued)

Table 1 (continued)

Company	Main area	Actions	Reference site	For primary healthcare	Location
Kensci	Prediction of clinical, financial, and operational risk by taking data from existing sources	Foretelling anything from who might get sick to what's driving up a clinic's healthcare costs	kensci.com	Prediction tools of various sorts relevant for primary healthcare to best use the means and get the best healthcare for the money	Seattle, Washington
Proscia	Detection of patterns in cancer cells. Connection of data points that support cancer discovery and treatment	Helps pathology labs eliminate bottlenecks in data management	proscia.com	Digitalized pathology will move closer to primary healthcare in ways, also involving cancer pathology and oncology and its complex plethora of best treatment considerations	Philadelphia, Pennsylvania
H2O.AI	Data analysis of a healthcare system to mine, automate and predict processes	Prediction of ICU transfers, improve clinical workflows, or pinpoint a patient's risk of hospital-acquired infections	h2o.ai	Prediction and detection of sepsis, which ultimately reduces death rates, are clearly advantageous in primary healthcare	Mountain View, California
IBM	Harnessing data to optimize hospital efficiency, better engagement with patients and improve treatment	Watson is currently applying its skills to everything from personalized health plans to genetic testing results and catching early signs of disease	ibm.com/watson-health	Integration of Watson and other AI tools into primary healthcare will be a tangible game changer	Armonk, New York
Google DeepMind Health	In use by hospitals all over the world to help move patients from testing to treatment more efficiently	Doctor alerts when a patient's health deteriorates. Can help in the diagnosis of ailments by combining its massive dataset for comparable symptoms	deepmind.com	Also by collecting symptoms of a patient in primary healthcare and putting them into the DeepMind platform, doctors will be able to diagnose more quickly and effectively, especially in more rare and complicated cases	London, England
Icarbonx	Uses AI and big data to look more closely at human life characteristics in a way described as "digital life"	Analysis of health and actions of human beings in a "carbon cloud," with intentions of managing "all aspects of health"	icarbonx.com	Gathering of data to better classify symptoms, develop treatment options, in various solutions and forms, will most likely be integrated to the new primary healthcare	Shenzhen, China
Nuralogix	Transdermal Optical Imaging	Most vital signs given with the smartphone camera	nuralogix.ai	Of great use for screening not only in clinics but everywhere and in the hands of the patients	Toronto, Canada

BeeHealthy by Mehiläinen	Medical platform for online clinics. Offering over branding	Digital clinic with triage, online bookings, and digital patient journey	beehealthy.com	The AI-embedded online primary healthcare will be open 24/7, also offering access remotely, and where healthcare will be subject to “patient experience” monitoring	Helsinki, Finland
DayTwo	Gut microbiome. Evidence-based, precision nutrition	Deep diet – EBM personalized diet in diabetes, obesity, metabolic and gastrointestinal disorders	daytwo.com	Diabetes, metabolic and GI disorders are very large groups – the microbiome will be an integral part of evidence-based primary healthcare	Tel Aviv-Yafo, Israel
MyBioma	Gut microbiome	As above	mybioma.com	As above	Vienna, Austria
Kaiser Permanente Foundation	Electronic health record synchronization	An example of an organization which has integrated the EHRs and opened them for its patients	healthy.kaiserpermanente.org	An enormous global and local problem is the lack of integration and compatibility between EHRs	Oakland, California
Aysa	Dermatology	Analysis of skin pictures	askaysa.com	Of great relevance. Patients and GPs will be guided to the fastest route	Buenos Aires, Argentina
Mindler	Psychotherapy	Online CBT	mindler.se	Great relevance	Stockholm, Sweden
Betterhelp	Psychotherapy	Online CBT	betterhelp.com	Great relevance	Mountain View, California
SwordHealth	Physiotherapy	AI-embedded physiotherapy	swordhealth.com	Great relevance	Porto, Portugal
ADNtro	Complete genetic analysis	Genomics. At the core of preventative and individualized precision medicine	adntro.com	Genomics will be an integral part of future primary healthcare	Mallorca, Spain
MissionBio	Multi-omics screening	Interplay of genotype and phenotype	missionbio.com	Future primary healthcare with multi-omics with simultaneous detection of SNVs, CNVs, and protein at the single-cell level	San Francisco, California

Table 2 List of machine learning algorithms applied to specialties that interface or directly affect primary care patient management

	Area	Action	Machine learning algorithm	Explanation	Example	Reference
	Image recognition	A ground principle applicable to a long range of medical images; x-rays, photos of skin, eardrums, throats, faces, pathology slides, etc. Timing with the dramatically increased use of electronic medical records and diagnostic imaging	Convolutional neural network is one of the most prominent approaches	Medical image recognition or classification, e.g., based on deep features extracted by deep models and statistic feature fusion with multilayer perceptions	Filipovych et al. (2011) provide a recent example of semi-supervised learning to image recognition. There is a tremendous amount of successful ML in image recognition examples	[51, 52]
	Radiology images	AI will move radiology much closer to primary healthcare, enabling patient and GP insight into a long range of radiological images subtypes	Both unsupervised and semi-supervised learning are frequently employed in cluster analysis. The Cruz-Roa image recognition algorithm, employs supervised learning, in which the algorithm is presented with a training set of instances that provide, for each instance, both the covariates and the ground truth	ML algorithms have proved equal or superior to humans in interpreting X-ray and MRI images and slides. For example, Cruz-Roa et al. (2017) demonstrates that a trained ML algorithm achieves near-perfect detection of breast cancer at a microscopic level	Segar et al. (2020) provide a recent application of unsupervised learning to cluster analysis of heart failure. Another example from lung CT images: automated detection of pulmonary nodules: with morphologic matching algorithms	[53–55]
	X-rays, CT, MR, ultrasounds	All types of radiology, auto-diagnostics, radiology assistants	Supervised learning algorithms	Decreasing the burden of routine tasks, spreading radiological competence to primary healthcare	For example, Cruz-Roa et al. (2017) demonstrates that a trained ML algorithm achieves near-perfect detection of breast cancer at a microscopic level. Their algorithm, like other image recognition algorithms, employs supervised learning, in which the algorithm is presented with a training set of instances that provide, for each instance, both the covariates and the ground truth	[53]

	Blood tests	Quick and accurate medical diagnoses	Support vector machines (SVM), with the scikit-learn implementation SVC, which is based on the libsvm library	With respect to the tunable parameters, we experimented with both linear and radial basis kernels. The Γ parameter was calculated by the heuristic 1/number of attributes. The penalty parameter C was tuned using internal cross-validation in the training set	E.g., in hematological diagnoses	[56]
	Labs	To safely reduce the laboratory test ordering	Algorithm-based decision rule methodology	The number of tests can be reduced while missing critical values in only a small fraction of patients. Testing algorithms such as these can be used to reduce laboratory test ordering without compromising the quality of patient care	Decision rules to define appropriate intervals at which repeat tests might be indicated for commonly ordered laboratory tests for hospitalized patients	[57]
	Genomics	Analysis of full of genome sequencing	Clustering algorithms	Microarray technology has enabled measuring expression of thousands of genes simultaneously, hence the use of clustering algorithms	To discriminate pathologies based on their differential patterns of gene expression	[58]
	Gut microbiome	“Deep diet,” evidence-based diet for specific conditions, e.g., diabetes, obesity, metabolic disorders, etc.	E.g., the RDP classifier algorithm and gut microbiota-based random forest algorithms	Often a combination of several sets and types of algorithms; e.g., the random forest algorithm can be used to create a classification model	EBM approach to weight loss, but gut microbiota-based algorithms can also be used in the prediction of metachronous adenoma in colorectal cancer patients following surgery	[59]
	Genetic sequencing	It can become commonplace in primary healthcare with genetic sequencing, integrated in the medical records	GECKO is a genetic algorithm to classify and explore high throughput sequencing data	Genetic algorithms and feature selection to comprehensively explore massive volumes of sequencing data to classify and discover new sequences of interest	GECKO for GEnetic Classification using k-mer Optimization is effective at classifying and extracting meaningful sequences from multiple types of sequencing approaches including mRNA, microRNA, and DNA methlyome data	[60]

(continued)

Table 2 (continued)

	Area	Action	Machine learning algorithm	Explanation	Example	Reference
	Full omics analysis	In the future of primary healthcare not only genomics will be present but also other major factors, commonly called “omics”, e.g., genomics, transcriptomics, methylomics, proteomics, microbiomics	Multi-omics and multi-view clustering algorithms	Recent high throughput experimental methods have been used to collect large biomedical omics datasets. Different cancer types can be used as benchmarks	Clustering of single omic datasets has proven invaluable for biological and medical research. The decreasing cost and development of additional high throughput methods now enable measurement of multi-omic data	[6]
	Patient owned health cloud	As growing volumes of patient data are stored on externally hosted platforms, worries are mounting among patient advocates that patient data might be at risk of privacy breaches. It can be argued that the natural owner of the entire data related to a patient is the <i>patient</i>	Eric Topol (director and founder of Scripps Research Translational Institute in San Diego, California) noted that advances in mathematics, computing power, cloud computing, and algorithm design have accelerated the development of methods that can be used to analyze, interpret, and make predictions using these data sources	AI has the potential to transform the delivery of healthcare in a large national system, from streamlining workflow processes to improving the accuracy of diagnosis and personalizing treatment, as well as helping staff to work more efficiently and effectively	Louisiana's largest health system, Ochsner Health System, used advanced machine learning algorithms to create a predictive model leveraging Epic's machine learning platform powered by Microsoft Azure to accurately predict patient deterioration hours before an adverse event	[61]
	Health record synchronization	Currently electronic health records are spread out and cannot interact with each other – this is one the most serious global healthcare conundrums. With synchrony both the patient and primary healthcare will see massive benefits	A synchronized medical record would be more complete and more useful for deep learning CNNs. Moreover such an omni-EHR would contain omics data, imagery, smartphone and wearable vital sign monitoring data, etc.	Patient data synchronization processes in a continuity of care environment is pivotal, locally and globally – to ensure exchange and access to EHR data	An XML-based synchronization model that is portable and independent of specific medical data models. The implemented platform consists of several servers, of local network clients, of workstations running user's interfaces, and of data exchange and synchronization tools	[62]

	Medical records	Medical records are seldom ergonomic, and there have even been publications about doctor and nurse burnouts, “caused by the EHRs.” The EHR of the future primary healthcare must be improved, AI-embedded, and easily managed	Skim-gram algorithm	To improve the management ability of patient information and establish a feasible electronic medical record (EMR) management system, combined with the characteristics of e-commerce	The design of electronic medical records system using Skip-gram algorithm. Moreover cross-system compatibility is pivotal – Prognos (see below) uses machine learning to run its software which analyses electronic medical records from various hospitals and healthcare systems	[63]
	Medical history	A patient’s EHRs, if assembled, and synchronized and containing a wide range of data, is a veritable goldmine for medical AI	Pieces™ by Pieces Tech, KenSci, ZEUS by CareScore	Predictive Analytics (e.g., Pieces™ or KenSci), Diagnostic Analytics (e.g., Prognos), Prescriptive Analytics (e.g., ZEUS)	Based on a patient’s medical history, also Random Forest can be used to predicting the risk of disease	[63]
	Online AI platforms	Increased demand from primary healthcare, online telemedicine has led to several AI-embedded medical platforms on the market	Pieces™ Decision Sciences (DS) by Pieces Tech or KenSci or Prognos (the latter trained on a database of clinical diagnostics information with data for 50 diseases and its 1,000 algorithms are trained to analyze over 14 billion medical records for 180 million patients)	Machine learning and natural language processing can build a software platform to interpret patient data and recommend personalized treatment approaches	Pieces™ and KenSci are examples of predictive analytics. KenSci’s platform integrates with clinical systems such as electronic medical records (EMRs) so recommendations may be implemented by healthcare teams. See also Google’s site (referred on the side) on build-in cloud AI-platform algorithms	[64]
	Disease mapping	Spatiotemporal disease mapping models are a popular tool to describe the pattern of disease counts	Counts are usually formulated in a hierarchical Bayesian framework with latent Gaussian model. Or with INLA	Computationally expensive Markov chain Monte Carlo algorithm can be used for parameter estimation which might induce a large Monte Carlo error	An alternative method using integrated nested Laplace approximations (INLA) has recently been proposed	[65]

(continued)

(continued)

Area	Action	Machine learning algorithm	Explanation	Example	Reference
 Psychotherapy/ CBT	In primary healthcare, there is a shortage of educated and available human psychotherapist, which can offer, e.g., cognitive behavioral therapy (CBT). There is likely an over-prescription of selective serotonin reuptake inhibitors (SSRI), since the available therapists are often fewer than the demand. Patients are left without proper medication follow-up or CBT, despite the well-published benefits of therapy	There are two broad types of supervised and unsupervised learning (Friedman et al., 2001), relevant here. Supervised learning aims to solve prediction problems. For example, patients' features can be used to forecast the future development of clinically relevant events or measures. Unsupervised learning aims to solve classification problems, such as the discovery of emergent clinical phenotypes or processes	AI-empowered and/or online psychotherapy; see also chatbots below, will likely help the situation with a shortage of therapist or can help triage or classify of definite problem, so that therapist can focus more on the defined core of a problem. Not to forget to mention the valuable focus of human interaction per se; listening and what Eric Topol coined <i>Deep Empathy</i>	Supervised learning examples of clinically relevant events (e.g., treatment dropout) and of measures (e.g., symptom severity). Unsupervised learning examples of discovery of emergent clinical phenotypes (e.g., patients with similar features) or processes (e.g., interpersonal patterns encoded in textual, acoustic, image or biometric data)	[66]
 Mental chatbots	To interact, guide, and/or triage patients in psychiatry	High-level natural language understanding (NLU), and emotion recognition based on multimodal approach	Studies have even shown, that in some cases, especially of very sensitive problem nature, a patient can feel more comfortable speaking to a chatbot, at least during a certain period of the therapy	A chatbot for psychiatric counselling in mental healthcare service based on emotional dialogue analysis and sentence generation	[67]
 EKGs	Automatic 12-lead EKG interpretation overriding the present EKG interpretations	Deep neural network (DNN)	Models composed of stacked transformations that learn tasks by examples	Telehealth Network of Minas Gerais, collected under the scope of the CODE (Clinical Outcomes in Digital Electrocadiology) study.	[39]
 Neurophysiology	The specialty of neurophysiology will move closer to primary healthcare with the recent AI-advances, and which will change referral patterns	Three major categories for seizure detectors; EEG-based seizure-event detectors, EEG-based seizure-onset detectors, and EEG/ECG-based seizure-onset detectors	Epilepsy is a chronic disorder of the CNS that predisposes individuals to recurrent seizures and is used as an example here. Neurophysiology contains a plethora of disorder specific algorithms	Seizure detection algorithms based on analysis of EEG and ECG signals. Computerized seizure detection algorithms can enable alerting systems that may decrease the harm of the seizures	[68]

	Physiotherapy	A veritable explosion of smart devices and especially wearables, and mHealth in general, will fuse casual wearing, sporting, and medical monitoring with primary healthcare, i.e., the semantic definition of healthcare will be widened	Data can be collected in a clinic under supervision and can be used to train and validate ML algorithms. Validated algorithms will then be used to assess home physiotherapy adherence from the inertial data collected at home	AI-driven physiotherapy diminishes drop-out, the commonest causes of less effect of an exercise program. The concept lowers the threshold for good compliance and for study participation for patients in primary healthcare	[19]	Adherence tracking with smart watches for shoulder physiotherapy in rotator cuff pathology. Smart gadgets can be integrated into protocols of, e.g., longitudinal cohort studies in physiotherapy
	Clinic effectiveness	ML can help improve both clinic management per se (logistics, economy, human resources, admissions, etc.) and adherence to evidence-based treatment program and other routines, which increase the efficacy of applied treatments	Valid clinical or pharmacogenetic predictors of response are needed to tailor specific algorithms to individual patients	Algorithm research has evolved as a new branch of clinical research that evaluates the clinical and economic impact of algorithm-guided treatment in primary and psychiatric care of patients with depressive disorders	[69]	Treatment algorithms and collaborative-care systems are systematic treatment approaches that are designed to improve outcomes by enhancing the quality of care; e.g., such systems for treatment of depression
	Operational tasks	ML will boost primary healthcare management, with effects on, e.g., planning, waiting lists, scheduling, length of stays, workload, quality of care, etc.	E.g., a simulated annealing algorithm to optimize the patient admission sequence towards minimizing the total completion and total waiting of patients	Operational tasks in primary healthcare which can be augmented with ML include workflow, diagnostic imaging when expected in primary setting, personnel staffing and scheduling, process assessments, organizational case studies, and patient admission and referral routines	[70]	The example ML model have demonstrated to be effective in the evaluation of diagnostic imaging workflows
	Risk prediction	A tangible ML advantage for a primary healthcare clinic is naturally risk prediction	Random forest on QRISK3 risk prediction algorithms	Encapsulated a long list of risk factors and has identified potential new risk factors	[71]	Development and validation of QRISK3 risk prediction algorithms to estimate future risk of cardiovascular disease
	Task automation	Digital AI-embedded primary healthcare will enable thorough task automation	Achieving automation in the task delegation process can use several ML methods; neural networks, evolutionary algorithms, or swarm intelligence algorithms	ML can positively and negatively affect job resources (autonomy/control, skill use, job feedback, relational aspects) and job demands (e.g., performance monitoring)	[72]	Work design improvement – with consequences for employee well-being, safety, and performance

(continued)

Table 2 (continued)

	Area	Action	Machine learning algorithm	Explanation	Example	Reference
	Individual treatment	Treatment based on a person's specific setup of genes, proteins, environment, medical history, and other conditions	Error-bound for estimating individual treatment effect, and creation of learning CNN algorithms	Family of algorithms for predicting individual treatment effect (ITE) from observational data, under the assumption known as strong ignorability	The bound relates ITE estimation to the classic machine learning problem of learning from samples, along with methods for measuring distributional distances from samples	[73]
	Precision medicine	Precision medicine (PM) for a long range of conditions, will be become omnipresent in primary healthcare	Key points to be addressed for a reproducible treatment algorithm: technology, thresholds, quality controls, validation of molecular alterations identified, interpretations of the results, molecular alteration/target relation, prioritization	Also called “personalised medicine,” is defined by the National Cancer Institute as “a form of medicine that uses information about a person’s genes, proteins, and environment to prevent, diagnose, and treat disease”	Treatment algorithms based on tumor molecular profiling in oncology	[74]
	Clinical trials	Design and recruitment of clinical trials, with many new possibilities as a result of AI, also interacting to closer with primary healthcare and the electronic health records and other databases	Both supervised and semi-supervised learning, cluster analysis, reinforcement learning (RL), in which the algorithm learns from previous experience and adjusts its behavior in response to what it has learned and causal inference	Machine learning will provide important insights into (1) ongoing clinical trials for non-COVID-19 drugs, (2) clinical trials for repurposing drugs to treat COVID-19, and (3) clinical trials for new drugs to treat COVID-19	Clinical trials have adapted significantly to new conditions during the SARS-CoV-2 pandemic – many times with the help of machine learning	[75, 76]
	Drug development	Deep drug development, individual precision medicine will move closer to the AI-rich future primary healthcare	A plethora of deep learning algorithms have been implemented in several drug discovery processes. ML is active on several levels; with DL, meta learning, general adversarial networks (GAN) reinforcement learning, support vector machines, symbolic learning, and convolutional neural networks (CNN)	Active in stages such as: (1) peptide synthesis, (2) dosage/delivery, (3) active/inactive ligand classification, (4) protein folding prediction, (5) structure based virtual screening, (6) drug repurposing (QSAR), (7) biomarker discovery and preclinical development, (8) bioactivity prediction,	Used in, e.g., peptide synthesis, structure-based virtual screening, ligand-based virtual screening, toxicity prediction, drug monitoring and release, pharmacophore modelling, quantitative structure–activity relationship, drug repositioning, polypharmacology, and physicochemical activity	[77]

			(9) molecular pathway identification, (10) mode-action prediction and ADMET, and (11) primary/secondary drug screening	The same authors have also shown how several other values, e.g., blood sugar, temperature, and HbA1c can be detected with this methodology; see their publication list [40]	[46, 78]
	Transdermal optical imaging	Smartphones scanning faces with the camera, and can give accurate blood pressure, pulse, and other vital figures	Advanced machine learning algorithm to create computational models that predict reference systolic, diastolic, and pulse pressure from facial blood flow data	With this technique, all essential vital sign can be given to the patient or doctor anywhere	
	Monitoring	Continuous monitoring of diseases moving out of hospitals and to the patient's homes and also closer to the primary healthcare	<i>ICU</i> : e.g., trend detection and curve fitting (e.g., the change in the average heart rate between the current and the previous minute is more than a specified value). Also, multivariate statistical methods. Various machine learning approaches were applied in this field. Deep neural networks with recurrent architecture are effective in speech recognition	Alarm algorithms were previously seen only in critical care monitoring. The alarms of medical devices are a matter of concern in critical and perioperative care with a high frequency of false alarms. Smartphones are now also capable monitoring tools allowing for continuous monitoring of many diseases reserved for the ICU	In the <i>ICU</i> , there is a new for more relevant alarms, with new, e.g., alarm algorithms using statistical approaches. Smartphones are increasingly used to monitor everything from diabetes, bipolar disorder, vital signs, etc., and start to mimic many of the tools, which were previously reserved for the ICU
	Symptom checker	Tools that use computer algorithms to help patients with self-diagnosis or self-triage	Eg., the DocBot clinical decision support algorithm	Symptom checkers (23 publicly available, and free checkers tested) have yet deficits in both triage and diagnosis. Triage advice from symptom checkers is generally risk averse, encouraging users to seek care for conditions where self-care is reasonable	[16]

Table 2 (continued)

	Area	Action	Machine learning algorithm	Explanation	Example	Reference
	Dermatology	Assortment, triaging, guidance, and auto-diagnosis dermatological photos	Several common types of machine learning approaches used in dermatology: convolutional neural network (CNN), natural language processing (NLP), support vector machine, and random forest. Notably, there are many other possible machine learning approaches	Recent advancements in access to large datasets (e.g., electronic medical records, image databases, omics), faster computing, and cheaper data storage have encouraged the development of ML algorithms with human-like intelligence in dermatology	Potential to improve the dermatologist's practice from diagnosis to personalized treatment and speed up the connection with primary healthcare	[18]
	Pathology	Analysis of pathology slides, moving the speciality close to primary healthcare	Pathology image analysis using segmentation deep learning algorithms with convolutional neural networks	Full image scanning techniques and visualization software, whole slide imaging (WSI) has become routine	Acceleration of clinical diagnosis from pathology images and automating image analysis efficiently and accurately	[79]
	Medical photos	To categorize, diagnose, triage, and evaluate a wide range of medical imagery. Potential basis of computer vision systems	Multiple instance learning (MIL)	Suitable for image processing applications and based on a mixed integer nonlinear optimization problem	The algorithm has been preliminarily applied to a set of color images, with the aim to identify images containing some specific color pattern, and successively to a medical dataset, containing photos of melanoma and common nevi	[79]
	Radiology assistant	Virtual assistant in radiology for both radiologists and GPs. E.g., chest X-ray evaluation	An application using a convolutional neural network (CNN) model to operate as a predictive model for diagnosis support as a virtual assistant	This model of artificial intelligence (AI) provides seamless integration with the preexisting workflow without disrupting the regular procedure of the physicians	ToraxIA: Virtual assistant for radiologists based on deep learning from chest X-ray	[80]

	Medical decisions and guidance Patient guidance	<p>Meta-algorithm. The meta-algorithm represents the backbone of the multimorbidity guideline of the German College of General Practitioners and Family Physicians</p>	<p>Meta-algorithm for guiding primary care encounters for patients with evidence-based and case-based guideline development methodology</p>	<p>Patients with comorbidity [81]</p>
	Smartphone retinal camera 	<p>Smartphone-enabled retinal camera could make otherwise costly ophthalmologist technology more accessible</p>	<p>Retinal image analysis is a challenging problem due to the precise quantification required and the huge numbers of images produced in screening programs</p>	<p>Brain-inspired algorithms for automated retinal image analysis, recently developed for the RetinaCheck project. Many of these algorithms outperform state-of-the-art techniques. With deep residual networks diabetes can be diagnosed directly from retinal images, without using any blood glucose information</p>

Precision Medicine and Frontiers for AI

Precision medicine stems from identifying new patterns within the genetics of an individual and tailoring treatments to their disease. It is based on the premise that under all the identical genetic information, individuals have unique differences that distinguish them. Machine learning and AI are facilitating this process allowing tailored therapies through pharmacogenomics that can reduce issues with medication side effects and treatment failures [21, 22]. Emerging frontiers for AI in medicine are already entering primary care with the spread of apps via “passive diffusion.”

Legal and Regulatory Aspects

Social and legal considerations must be considered where medicine borders artificial intelligence, together with regulatory and political hindrances that surround aspects relating to who should own patient data [9, 23]. This will require public, policy-maker, and regulator engagement before AI could be accepted in the public eye for primary care. The speed at which newer and emerging technologies are incorporating AI into patient diagnostics using the patient’s data also present their own ethical challenges for primary healthcare. Questions such as who is to blame if an AI system misclassifies a disease fail to alert a physician or fail to follow specific instructions due to a bug or cyberthreat and become important discussions for the policy-maker, the family physician, and the patient. Another, perhaps more intrinsic, problem arises if patients do not perform self-tests in the proper ways, people screw the system by sending other’s people’s data or data get lost by a hack, etc.

Privacy Concerns

Additionally, privacy preservation when AI and the data used to build it is out of the owner’s control and into the hands of industrial giants like Google, Microsoft, and Facebook. Such corporations want access to patient data and argue in favor of utilizing the data to train AI algorithms in order to benefit

and improve patient healthcare. However, some patients feel that their data should not be used by these companies who do not incentivize patients or compensate them from the advertising revenue they generate from the use of such patient data. This adds a layer of scrutiny regarding safeguarding concerns, data ownership, and data security. The primary care physician and the patient themselves may not benefit from the applications being created by these platforms building AI systems while unethically compromising patient privacy.

Patient Safety

The above point raises a case for the consideration of patient safety and hence reducing the risk to patients especially the vulnerable with safeguarding concerns who attend primary care. Machine learning algorithms for prediction of risk and risk mitigation systems could also benefit primary care physicians and their patients. Patients will need education about risk and risk mitigation practices, and AI platforms analyzing the knowledge about a particular risk-factor determinant can link these patients to the right knowledge base.

Medical Imaging Diagnostics and Radiology

AI for medical diagnostics has also come a long way since developments, and arguments were first made for its use in medical image pattern recognition. Clinicians and radiologists are able to utilize machine learning for medical image diagnostics in secondary care. So, its use would be especially practical in primary healthcare systems where radiology support is usually limited. However, there is also the innate sense of superconservatism within medicine at various technology readiness levels. Technological innovation and its implementation post-regulation can take more than a decade to reach the clinical environment as this usually requires extensive clinical trials. On the other hand, wearable technologies were introduced over a very short period of time

and have now become part of the lives of many patients. Wearables with AI capabilities are needed to analyze and alert primary care clinicians. Diagnostic laboratory investigations usually require interpretation for the patients to understand what their tests mean. This can occur offline and through mHealth systems.

Explainable methods in medical imaging and diagnostics are also benefiting from AI. There are newer primary care systems such as those proposed by Prof. Lord Darzi's GP-led Polyclinics, which were set up in 2008 and had self-contained services with clinical imaging facilities such as X-ray, CT, and ultrasound [24]. These would benefit from augmentations from AI-based infrastructures that support specialist-guided auto-interpretation achieved through supervised learning approaches.

Medical Informatics and Clinical Decision Support

Evidence-based practice is promoted across the globe for medical informatics and evidence-backed treatment. The difficulty is that time pressures preclude effective appraisal of the literature. Medical informatics and augmented evidence-based medicine in primary care are becoming more feasible using artificial intelligence platforms that are reducing the time needed to appraise the evidence. AI-powered platforms that can aid in systematic literature searches and appraisals are now available or are being proposed, and this can support evidence-based information discovery.

As described by Tversky, clinical decision-making utilizes cognitive heuristics for recall or to understand knowledge, and GPs may usually generate a range of likely differential diagnoses that often require evidence-based methods to rule in or out [5, 25]. There is seemingly an expectation bias, which can lead to the dismissal of important information that is deemed less relevant. Areas identified to be affected by this methodology of diagnostics are geographically variable. For instance, in the UK and many other parts of the world, earlier diagnosis of cancer continues to remain a challenge, and this might reflect the use of heuristics. Sheringham et al. conducted a factorial experiment that showed that

GPs are not more likely to initiate cancer investigations for individuals with higher-risk symptoms and, also, do not investigate everyone with the same symptoms equally [5, 26]. There was a potential 42% rate of omission to seek further information from their patients perhaps because of underlying cognitive biases.

AI could assist GPs in recognizing and overcoming cognitive biases, but only if the system has been trained on the correct data and from the appropriate population. An AI diagnostic tool developed using clinical information from the UK might not provide the correct clinical guidance to a primary care clinician in India. Moreover, the AI outputs need to support GP decision-making where, for example, precise diagnostic labels are less important than deciding on an appropriate course of action.

In enhancing a GP's diagnostic abilities, it is also important to appreciate that AI systems do not get tired or irritable, which can affect a GP's ability to communicate and work effectively. Moreover, AI might have a key role in assessing and improving GP communication skills [27]. It must clearly be mentioned that there is a rapid improvement of AI systems over time by continuous self-learning. These systems are not static. AI systems of just a few years ago are considered primitive nowadays.

Patient's Perspective

Patients prefer rapid and easy access to specialist services through primary care, extended consultation times, a clinician (usually their GP) to be available to support their queries at a moment's notice and control over their data. Some of these aspects, such as their own GP being available around the clock, are impractical. However, most patient-centered systems in some developed economies deliver this to a large extent as out-of-hours services, but this can be a challenge in other emerging healthcare economies. Some of these challenges can be overcome using AI. In fact, chatbots and robotic process automation systems are being used to support out-of-hours practice and

triaging. Given the growing globalization of healthcare, this network of primary care support will continue to evolve; however, challenges still exist in this regard [28, 29].

Software bots perform precise, preset workflows to reduce the potential for errors and the associated costs, and they can do this around the clock, without a drop-off in efficiency or quality [29]. Systems like robotic process automation have the potential not only to cut operating costs by streamlining workflows but also to ensure greater compliance, which in turn feeds through into higher levels of patient satisfaction.

Gender Aspects

Gender differences in disease usually affect the management of patients, and AI can support evidence-based guidance identifying where differences could influence treatment outcome and identify at-risk diagnoses to enhance primary care treatment of chronic diseases [30]. Initially, the design of these algorithms did not take these differences into consideration, but this is changing, and chapter two of this handbook demonstrates how AI is being implemented to study gender differences in areas such as reproductive medicine.

Point-of-Care Dermatology and Ophthalmology

By using machine learning platforms as point-of-care diagnostic tools to diagnose skin lesions, patients are able to take photos of skin lesions that can be classified using artificial intelligence and triaged for dermatological input [18, 31]. Primary care physicians with specialist interest in dermatology can leverage these platforms to manage skin lesions, together with specialist dermatologists. Dermatological diagnosis before a patient attends a clinic has its limitations, but also offers possibilities with AI augmentation to rapid diagnostics and referral for early surgical intervention [31]. AI has also shown potential in interpreting many different types of image data including retinal scans (discussed below), radiographs, and ultrasound [32, 33]. Many of these

images can be captured with relatively inexpensive and widely available equipment.

Public Health Aspects on Primary Healthcare

In the context of public health management of epidemics and for contact tracing, AI systems were developed to support viral epidemic and pandemic tracking for flu, human immunodeficiency virus (HIV), and now SARS-COV-2. Monitoring of HIV and other sexually transmitted infections requires a concerted multidisciplinary effort by virologists with primary care physicians who may have specialist interest in public health or sexually transmitted infectious diseases, and the cooperation of patients. AI tracking systems designed to track symptomatic individuals were developed during the SARS-COV-2 pandemic in most countries including the USA and South Korea. This adds an additional layer of privacy concerns that makes it difficult for regulators and policy makers. Although rules seemed relaxed during SARS-COV-2 pandemic.

SARS-Cov-2 has also amplified the increasingly important role of primary care especially in managing mental health, chronic disease management, and SARS-COV-2-related issues. From a health system perspective, primary care is essential to the Triple AIM of healthcare reform [34]:

1. Population health
2. Experience of care
3. Per capita cost

An AI system to support or improve these aims is desired.

AI for General Practice Management

AI can also automate repetitive clerical tasks. Eligibility checks, insurance claims, prior authorizations, appointment reminders, billing, data reporting, and analytics can all now be automated using AI, and some companies have developed AI-powered category auditors to help optimize coding for quality payment programs.

Endocrinology and Diabetes

Endocrinological diseases can be highly complex, and specialist knowledge is required to manage patients presenting with these conditions. Patients usually require adjustments to medications and routine biochemical investigations to check their thyroid, adrenal, and hypothalamic function [35]. For diabetics, blood sugar and HbA1c check-ups are required to optimize diabetic management and identify poor blood glucose control, and diabetic ophthalmic complications from micro- and macro-angiopathic changes [32]. Current implantable platforms for AI-based continuous monitoring of diabetes have been designed to support primary care management of diabetic disorders [36, 37].

Selection of the right combination of drugs carries combinatorial complexities with over 11 factorial possibilities for optimal drug class combinations with added pharmacogenomic complexity [21]. This may benefit from artificial intelligence systems that take into account poly-medication that the patient is already taking, clinical information, investigations, follow-up, patients' life style choices, and risk assessment.

The federal Food and Drug Administration approved IDx, a convolutional neural network-centered diagnostic system that uses AI to detect diabetic retinopathy [32]. IDx does not require a specialist to interpret the images or results, making it the first such system cleared for use by the FDA. Physicians and their care teams, even those not normally involved in eye care, can use the technology to screen their patients for the condition during routine office visits.

Cardiovascular and Respiratory Management

Cardiac

Wearable devices like the Apple watch that can remind patients to take their cardiac medications and to monitor irregular heart rhythms can send data to the general practitioner and ensure timely treatment or early warning about an impending cardiac arrest. Automated implantable

defibrillating systems have algorithms that can detect an arrest to activate a defibrillator and that can predict electrical storms [38]. The management of these devices if they malfunction is not routinely in the control of the primary care physician, but patients are expected to troubleshoot any issue independently to inform the specialist. Assistive AI technologies could support the primary care physician in troubleshooting a device malfunction. The physician can be alerted to provide support and could also prompt a direct referral to the specialist team or alert the specialist-interested primary care physician and keep them in the communication loop. AI systems for remote diagnostics including ultrasound scans for a cardiologist's remote ECG interpretation, remote ultrasound, and remote diagnostic reporting will all become beneficial for the patient and primary care physician [39]. Cardiogenic and neuro-syncopal events usually need to be differentiated from each other, and these are areas that diagnostic machine learning could also support.

Hypertension

Hypertension management can require regular and ambulatory monitoring. Its management utilizes six main classes of drug types and can also benefit from pharmacogenomics and drug choice prediction, and hypertensive complication management using artificial intelligence [21]. Follow-up systems would benefit from continuous machine-learning-based systems monitoring with smartphone apps, transdermal optical imaging to monitor yearly fluctuations in blood pressure as a determinant to cardiovascular risk [40].

Respiratory

Several chronic respiratory disorders require medical and rehabilitation support such as chronic obstructive pulmonary disorders and asthma are benefiting from artificial intelligence [41]. Other respiratory pathologies such as cystic fibrosis and other restrictive pathologies, together with those that are associated with neuromuscular junction and neurodegenerative disorders leading to

respiratory complications, are areas that will see increasing support from artificial intelligence. Machine learning models deployed through m-Health platforms and smartphone apps are helping to support patient rehabilitation and management of their disease as well as decision support for the primary care physicians managing complex respiratory patients [42].

Chronic Neurological and Neuropsychiatric Disease Monitoring

Neurological diseases like Parkinson's disease and various other diseases can affect gait, fine motor dexterity, and other systems [43, 44]. Others such as epilepsy and associated neuropsychiatric conditions like depression, schizophrenia, eating disorders are also managed by primary care physicians, etc. [44–46]. Artificial intelligence systems through wearables have been designed to support the diagnoses of diseases through assessment of subtle gait disturbances [43]. Seizure monitoring systems are available that either enable alerts for the physician to be made aware of changes in a patient's seizure activity or for predictors of an impending seizure to be differentiated from black-out events. Other conditions such as alcohol and drug dependence are also utilizing AI to support rehabilitation. Autism is also an area that AI will continue to develop to support. Cerebrovascular disease support for rehabilitation, diagnostics, and at-risk prediction of strokes have all benefitted from machine learning models. Relevant chapters in this handbook have discussed these areas in depth, and the reader is referred to the AIM in neurology, stroke, and neurodegenerative disorders sections for more insights.

Obstetrics, Pregnancy, and Pediatrics

Pregnancy monitoring and the monitoring of physiological parameters for the developing baby's fetal heartrate interpretation, dating scans, Down's syndrome ultrasound prediction, supporting detection for neonatal infections, and identifying

developmental abnormalities in children. Others are developing AI applications for screening for adverse perinatal outcomes [47]. Such abnormalities including speech deficits are usually incorporated in the screening undertaken by health visitors and some primary care physicians with specialist interest in obstetrics and pediatrics. Unsurprisingly, these areas stated above will also be benefitting from artificial Intelligence, and machine learning methods have been used to support medication choices, etc. [48, 49].

Oncology

Oncology remains a highly complex and challenging disease carrying a large global financial burden where diagnostics and treatment choice is limited. As such early involvement of the specialist oncologist and surgeon is necessary for diagnostics, surgical management, neoadjuvant chemoradiotherapy, and adjuvant therapy.

AI-powered algorithms for diagnosing disease are outperforming physicians in detecting skin cancer, breast cancer, colorectal cancer, and brain cancers [32]. Numerous tools, such as IDx-DR, Aysa, and Tencent that can reduce the need for unnecessary referrals, increase continuity with patients and enhance mastery for primary care physicians [32, 50].

Newer AI platforms combining symptom checkers with clinical pattern recognition algorithms could facilitate remote oncological diagnostics, which will monitor clinical features and identify patients at risk of cancers for primary care physician referral, direct specialist referral, or predict cancer risk for early detection and management. This will be facilitated by wearable technologies, AI-powered implantable devices, and point-of-care diagnostic set-ups. Further developments of these technologies will be crucial for specialties such as neuro-oncology in brain tumor detection for at-risk groups, etc. AI-powered radiogenomic diagnostics will also enable and facilitate early screening and pharmacogenomic interventions leading to early referral processes and

selections for immediate appropriate medical and surgical therapies. It would also facilitate engagement with specialist teams of oncologists allowing earlier information flow between them and the primary care physician.

Many other primary care-related conditions from other body systems and subspecialties will continue to benefit from artificial intelligence as summarized in Tables 1 and 2 together with the type of machine learning models that have been developed to solve the issues. Table 1 also provides a summary overview (June 2021) of some of the companies that are helping to innovate within this space.

Conclusion

In conclusion, primary healthcare is potentially where AI in medicine will be most visible to most people. Developments will include AI empowering independence, patient ownership, and responsibility for their data with the general practitioner being able to access this data easily.

Primary healthcare will not necessarily mean a physical clinic that we are used to – it can take place online, in the street, in a clinic, on the go, in the patient's pocket or in the body, over the phone or webcam, or at home supported by machine learning algorithms to secure the interaction.

A suite of AI tools will be developed for the patient and their primary healthcare network, where a plethora of apps, clinical decision support, transparent and two-way educative electronic health records. This may utilize a cloud-based infrastructure constructed in such a way that the patient has independent access to their data under the guiding principles of what is legal and within that particular country's ethico-legal remit.

Moreover, the shift of balance of care may edge closer towards the primary care physician as we are seeing in some developed economies. Some proponents seem to believe that the Scandinavian model of pluripotent healthcare centers, at least in remote areas, may be easier to establish with embedded AI. However, other systems are bound to evolve to meet the challenge of incorporating AI into their

primary healthcare systems. This will also bring new opportunities for emerging economies.

The traditional limitations of homes, hospitals, primary clinics, and cyberspace will be increasingly blurred. The locations of treatment and also that of diagnostics will evolve. Most management methods may be moved to the home setting to meet the demand for excellent care of patients with special needs, the elderly, and patients with conditions after stroke or with neurodegenerative diseases. The use of AI will enable advanced medical monitoring at home, even in critical cases with available multidisciplinary primary care physician support for managing complex cases. A benefit of primary healthcare is its cross-disciplinary nature. This chapter has also demonstrated how AI can be used to triage the patient, far in advance and far away. Multiple medical specialties can be tied into this chapter, and in some ways this chapter concludes the impact of AI in medicine as a whole, but readers are referred to relevant chapters for added inspiration and in-depth overview. We have also highlighted some of the major trends, recognizing that a summary of such a vast field is a real challenge. Primary healthcare will be a key outlet for effective design and delivery of AI in medicine, since it has a central role of coordinating and involving specialties.

Abstract

Global emergence and exponential growth of artificial intelligence (AI) is becoming seamlessly integrated in our lives. By definition, AI describes a set of advanced technologies enabling machines to perform highly complex tasks effectively otherwise requiring intelligence that can't be matched if human beings were to perform them. How this reflects on the human mind is certain to continue being an area of ongoing research. This said, science fiction books and the numerous AI-induced apocalyptic scenarios presented to us in films and television series depicting AI gone wrong have cultivated a sense of fear and apprehension. However, to date, the healthcare industry does not evoke Orwellian concerns. Instead, the impact of this technology is particularly evident in the healthcare sector where this innovation promises transformation of the landscape of nursing practice along with the process involved in the delivery of collaborative, compassionate, ethically sound, and evidence-based patient care. In so doing, AI will likely resolve the current problem of global staff shortage and the decline in funding growth driven by an aging baby boomer generation living with multiple complex chronic health conditions.

During this transformative time, nurses must reflect on how healthcare technologies can ensure the patient's experience of care is embedded with understanding and compassion. The loss of these essential characteristics may lead patients to feel that in an AI-driven world their rights become an after-thought in the relentless pursuit of efficiency. To address this, formal and informal educational programs need to be reviewed. Besides enhancing the educators' AI knowledge, it would be

logical to include AI-related professionals to create a truly collaborative approach to training nurses.

Keywords

Artificial intelligence · Nursing · Education · Robotics · Technological competence

Chapter Introduction

The implications of artificial intelligence (AI) as the fourth industrial revolution (IR) on healthcare cannot be discussed without making any reference to the previous and related innovations. To this end, this chapter will outline the emergence of the preceding three IRs and their impact on society. It will then proceed to examine some of the key moments in AI. After defining AI and explaining the subsets of AI, this chapter will discuss how AI in healthcare can further influence a seamless quality of nursing practice care.

Introducing the IRs

During eighteenth-century England, modernity was conceived by technology. The resulting innovations which started the industrial revolutions fostered modern democracy together with the foundation of modern economies. Furthermore, society was disrupted when new buildings replaced the old structures. Similarly, institutions, industry, and demography were all to change course so that very little about life in Britain could be said to have been untouched by the revolution.

Today then we are witnessing an era of a technological revolution predicted to fundamentally change our lives as never seen before. To avoid

any confusion, it is perhaps appropriate to clarify what is being meant by the term “revolution.” The Cambridge Dictionary, for example, defines the term industrial revolution as “[...] the period of time during which work began to be done more by machines in factories than by hand at home” [1]. To this end, there is no doubt that advances in science and technology (S&T) have had a positively profound effect on the development of global industrialisation [2].

At this juncture, it is also noteworthy that the word revolution itself, as in the American Revolution and the French Revolution, implies the notion of suddenness, lasting for a few years. The industrial revolution, on the other hand, was not a sudden historical event but one which, although fast-paced, lasted for many years. Such phenomenon has been described as revolutionary while occurring over a long period of time. The scientific revolution of the sixteenth and seventeenth centuries, for example, is a case in point. The fact is that the term “industrial revolution” is so ingrained in our thoughts; it seems pointless to jettison it.

Despite such a historical achievement, a universal agreement on what constitutes an industrial revolution is still lacking [3]. However, from the perspective of the technological evolution [4], four fundamental general phases have been identified. In historical context, for example, the first industrial revolution in the early eighteenth century led to the discovery of the steam power and water which significantly increased the productivity of human labor by replacing manual handmade production. Furthermore, this innovation transformed society with trains, mechanization of manufacturing, a degree of automation, and of course smog. Almost 100 years later, the second industrial revolution evolved when electricity was notably a key driver. Mass industrial production led to productivity gains and opened the way for individualized mass consumption. Some 70 years later, the third industrial revolution led to the era of information technology (IT) resulting in the development and rise of computers and computer networks (WAN, LAN, MAN, etc.), the manufacturing of robotics, connectivity, and of course the birth of the Internet.

The fourth IR also referred to as industry 4.0 (4IR), which was coined by Klaus Schwab, started 30 years later and is arguably ongoing [5]. This specific industrial revolution combines technological and human capacities in an unprecedented way through self-learning algorithms, self-driving cars, human-machine interconnection, and big data analytics [6]. Differences between the fourth industrial revolution and the aforementioned three are clearly noticeable. In its scale, scope, and complexity, the transformation will be unlike anything humankind has experienced before. The fourth industrial revolution is not merely a prolongation of the third industrial revolution but rather a new and distinct revolution.

Brief History of AI

Why include the history of AI? This question is best answered by outlining its importance in any intellectual pursuit. History enables us to understand society of the past, thereby increasing our mastery over today's society [7]. This would lead to the views held by Tosh when he asserted that “To know about the past is to know that things have not always been as they are now, and by implication that they need not remain the same in future” [8, p2]. Thus far and based on the writings of these two authors, it would be relevant to conclude with what the renowned Spanish American philosopher, George Santayana, is famously quoted to assert that “Those who cannot remember the past are condemned to repeat it” [9].

Made not Born: The Beginning

Scholars can be forgiven for thinking that AI is the creation of modern minds. In fact, AI is not an innovation of current time. Its history can be traced back to Greek antiquity when such intellectuals from the time of Homer to Aristotle pondered over the idea of mechanical men and automatons. For example, nearly 3000 years ago in the *Iliad*, Homer described how Hephaestus created golden handmaidens and endowed them with reason and learning. Hephaestus also created

a bronzed automaton colossus tasked with defending the Minoan Kingdom of Crete against invaders and hurl boulders to sink any foreign vessels approaching Crete's shores [10]. It is said that Talos was killed by the attacked and killed by the Argonauts who removed the nail from around his ankle that sealed the outflow of blood. In so doing, the flow of his blood comprising of the "molten lava" was drained from his body leading to his death.

Greek mythology also cites the craftsmanship of Greek engineer Daedalus as being the first mortal to create "living statues" of bronze sculptures capable of demonstrating human characteristics whereby they could move their eyes, form tears, bleed, move, and speak. It is also said that Daedalus created a cow made of wood which on mating gave birth to the half-man and half-bull Minotaur. It is also suggested that Daedalus also made wings out of wax for himself and his son Icarus so they could escape from their prison in Crete. Icarus ignored warnings of flying close to the sun which melted his wings, thereby drowning in the sea.

Another noteworthy historical marking was the mythical Greek sculptor known as Pygmalion who created the beautiful statue of Galatea. Her beauty was such that Pygmalion fell so deeply in love with her that the gods brought Galatea to life. Later on, George Bernard Shaw reenacted in his theater play *Pygmalion* which became the famous musical *My Fair Lady*.

Moving forward to 1495, Leonardo Da Vinci is reputed to have designed an automaton robot with an anatomically correct jaw. The robot could stand, raise its visor, and independently move its arms. It is said that the operation of the entire system was based on a series of chains and pulleys. The discovery of his sketchbook in 1950 led to the successful replication of a fully functional robot.

In 1739, of his many creations, Jacques de Vaucanson of Grenoble, France, was well-known for the creation of the "robotic" duck known as the Vaucanson's Duck. This simulacrum of life was crucial for the enlightenment of automata construction. The use of perforated gold-plated copper plate used to build this life-sized duck

permitted a view of the functioning of the internal components. When activated, this creation moved like a duck, wiggled its beak in water, quacked, and readjusted its position. It was renowned for eating pellets and following a period of "digestion"; the pellets were excreted as fecal matter. Voltaire was most impressed and labeling him as the "new Prometheus" added: "sans le canard de Vaucanson, vous n'auriez rien qui fit ressouvenir de la gloire de la France" [11] (Without Vaucanson's Duck, you have nothing to remind you of the glory of France). Whether he was being sarcastic or not is left to the individual's thinking.

The intellectual legacies of early thinkers, philosophers, mathematicians, and logicians created the foundation for the development of "mechanized" humans. As a notable example, in 1928, Professor Makoto Nishimura, a Japanese biologist and botanist, built the first robot in Japan called *gakutensoku* which translates as "learning from the law of nature." This would imply that the robot could learn from people and nature.

The earlier thinkers were instrumental in ensuring that AI became increasingly more tangible throughout the 1700s and beyond. It became a time when philosophers contemplated how human thinking could be artificially mechanized and manipulated by intelligent nonhuman machines. The 1950s marked a momentous era when progress in AI underpinned by research findings truly came to fruition. The first major success in this decade was led by Alan Turing, a British mathematician among other things who proposed a test, the Turing test [12], that measured a machine's ability to replicate human actions to a degree that was indistinguishable from human behavior. The Turing test became a key component in the philosophy of AI as it discusses intelligence, consciousness, and ability in machines. However, the greatest success is arguably credited to John McCarthy, a British computer scientist who coined the phrase "artificial intelligence" in 1956 at the Dartmouth Conference. In 1958, McCarthy also developed a popular programming language called Lisp which became important in advancing machine learning (ML).

Following the conference and interest in AI, scientists were excited and began to make bold

statements and promises about the future findings of AI research. Consequently, sizeable research funding was received from governments and other organizations. Research and innovations in the field of AI began to flourish between 1957 and the 1960s when computers were faster and were able to store more information, thus demonstrating its impact on many real-world applications. However, a scientific discipline often encounters different challenges as it evolves and matures. With AI, it soon became evident that computational power was limited to solving small problems only. To progress it needed to overcome the challenges of AI research and to make the transition from being a “cool technology” to a “real-life presence” in human society [13]. Unfortunately, the promised outcomes failed to live up to the unreasonable hype, and the field of AI experienced intense critique. From the mid-1970s to the mid-1990s, the exuberance of AI soon gave way to a slump known as an “AI winter” when disillusionment set in and funding declined. After this phase of low point in the 1990s, optimism has since increased in AI and AI research funding.

Definition

The complexity involved in the development of synthetic intelligence as being comparable with human intelligence has led to varying interpretations of this technology. Some writers even seem reluctant to use the term AI preferring “computational intelligence” instead [14].

However, the possibilities of creating intelligent technologies have intrigued humankind since the inception of computers. Even the meaning of the word intelligence including AI has been central to much discussion and a source of confusion. Although a definition aims to influence the way forward, to date a universally agreed definition of “intelligence” or “intelligence” of AI is not in evidence [15]. However, Alan Turing, the founding father of AI, defined this technology as “the science and engineering of making intelligent machines, especially intelligent computer programs that can act as intelligently as human

beings” [12]. This would suggest that AI technologies resemble processes associated with human intelligence, such as reasoning, learning and adaptation, sensory understanding, and interaction—a concept popularized in such films as *The Terminator*; *I, Robot* (2004); *The Matrix*; *2001: A Space Odyssey* (1968); and *Ex Machina* (2015), which portrayed the fictive worlds profoundly altered by AI and automata. On the other hand, in the public discourse, AI is often characterized as sentient machines having human-like capabilities [16]. By inference, it describes a set of advanced technologies that enable machines to perform highly complex tasks effectively which would otherwise require intelligence that can’t be matched if a human being were to perform them [17].

Subsets of AI

Terminology surrounding AI technologies continues to evolve and can be a source of confusion particularly to a noncomputer scientist. In general terms, AI is broadly classified into machine learning (ML) and deep learning (DL) (Fig. 1). ML, a subset of AI, has been defined as the process of building computer systems that learn by analyzing huge amounts of data, apply algorithms to the data, and thereafter train themselves to make accurate informed decisions based on these underlying datasets rather than following pre-programmed rules [18]. As a rule, the operating process of a computer is underpinned by algorithms. This comprises a series of step-by-step instructions written by a programmer for software to follow verbatim. Algorithms, the building blocks for ML and AI, are almost everywhere around us. They comprise of a series of precise step-by-step instructions to do something or solve a problem. Following a cake recipe for making a cake or a nurse following a step-by-step procedure when undertaking a venepuncture is some of the many examples of algorithms. Another familiar example relates to nurses inputting keywords for a search strategy. The computer then processes the data in its database for items relevant to the words in the query. The results are the output which is

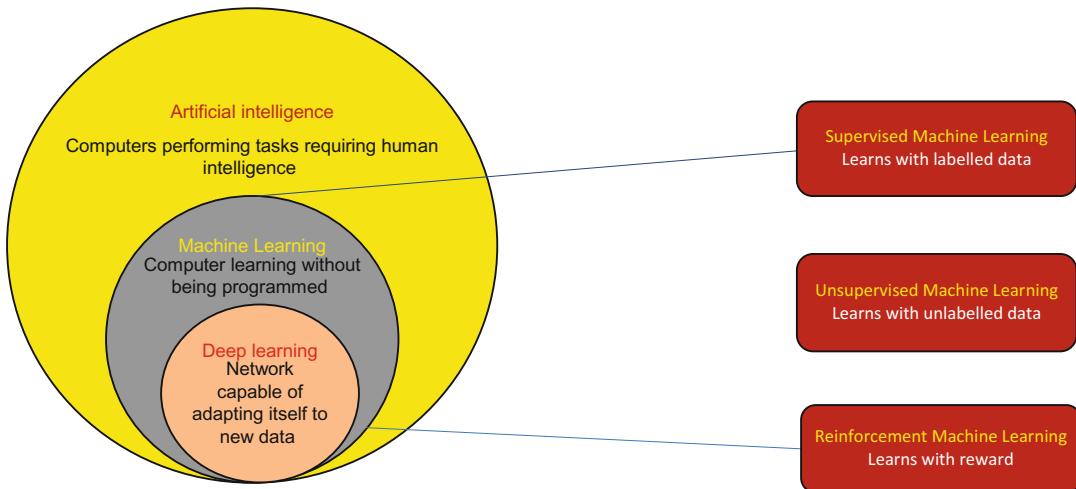

Fig. 1 Subsets of artificial intelligence

yielded through the ability of the computer to recognize patterns in the data.

Supervised Machine Learning (SML)

Based on Thomas Bayesian theorem and as the names suggest, SML (Fig. 2) involves machine learning algorithms (hereafter called the model), i.e., learning under the presence of a supervisor. The formal supervised learning process can be depicted by a simple formula, $Y = f(X)$, whereby the input variable is (X) and an output variable called (Y). The algorithm is used to learn the mapping function from the input to the output. In its basic mathematical context, the output (Y) is a dependent variable of input (X) represented by $Y = f(X)$. The ultimate aim is to approximate the mapping function (f) in order to predict the output variables (Y) during the input of new data. In reality if the mapping process is deemed correct, the algorithm has successfully learned; otherwise, necessary changes need to be made to the algorithm, thereby enabling it to learn correctly. SML algorithms are created to make predictions from future new unseen data.

The predicted labels can be both numbers and categories. For instance, if house prices are being predicted, then the yielded output will be a

number thus referred to as a regression model. If an email is being predicted as being spam or not, then the output is a category and falls under the rubric of a classification model.

A basic principle of SML can be exemplified with a scenario from the student nurse and teacher relationship in a university setting whereby the learning experience of the former is facilitated via the medium of textbooks, independent learning, and skill laboratory. If a test is set, then hopefully the student nurse will pass; otherwise, the marker's feedback will enable the student nurse to learn from his/her mistakes in order to successfully achieve the outcome.

Assuming you have a child who after graduating from learning the words mummy and daddy you decide to teach her what a dog or cat is. You could either show her/him videos of dogs and cats or related pictures or introduce her/him to a real-life dog and cat with the aim that the child also learns the differences and attributes between the two animals. If after a while the child can differentiate between the dog and the cat, then teaching has been successful. If the outcome was not achieved, then you will no doubt undertake some more coaching until a successful outcome is reached. In this example, you acted as a supervisor, and the child was the algorithm that needed to learn. This constitutes the basic principle of supervised learning.

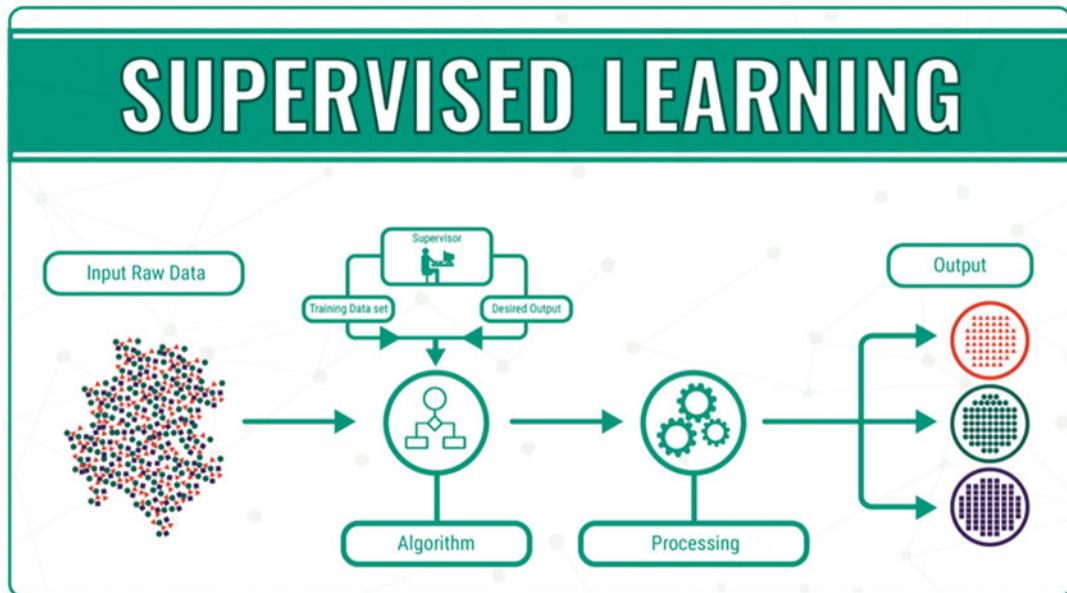

Fig. 2 Supervised machine learning (SML). (Source: With kind permission from Ronald van Noon)

Unsupervised Machine Learning (UML)

On seeing such movies as *The Terminator* or *Ex Machina*, it is probable that people have spoken about computers and machines possessing the ability to “teach themselves” in a seamless manner without the input from humans. In fact, this example suggests that in a way people are alluding to the processes involved in UML. Simply put, in UML (Fig. 3), a set of unlabeled data (raw data) is provided enabling a model to independently learn important structure relating to the dataset. Thereafter, the raw data is interpreted to identify and recognize hidden patterns in the dataset. This is followed by the application of a relevant algorithm which separates the data objects into groups based on similarities and differences between the objects and represents that dataset in a compressed format. The objective of UML is achieved through clustering when data are divided into distinct clusters based on distance to the centroid of a cluster or by association when the rules are used to discover interesting patterns.

Reinforcement Machine Learning (RML)

RML (Fig. 4), which is managed by a plethora of different algorithms, is a goal-oriented learning tool where a computer agent (algorithm), mapping and acting as an independent decision-maker, analyzes available data within its defined environment (task or simulation), derives a rule for taking actions (moves by agent), and maximizes long-term rewards or punishment (numerical values) through a trial-and-error system [19]. As a rule, the RML agent’s performance, which is not based on prior information, is rewarded or punished during each time step, thus allowing it to improve the performance of subsequent actions by trial and error [20].

A Case for ICU

It has been suggested [21, 22] that given the voluminous amount of data recoded from the complex comorbid nature of conditions experienced by

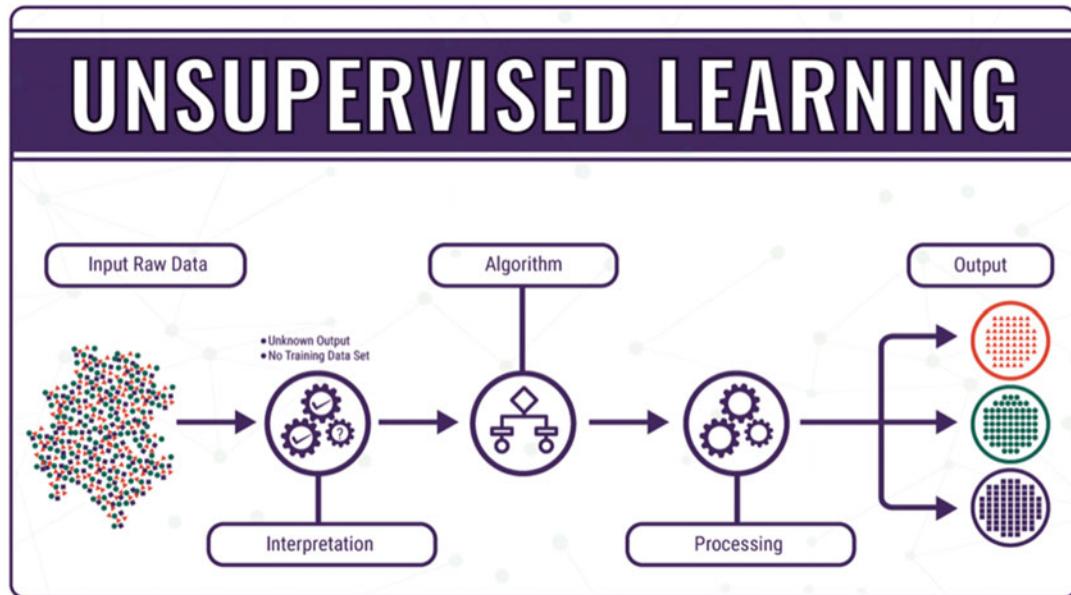

Fig. 3 Unsupervised machine learning (UML). (Source: With kind permission from Ronald van Noon)

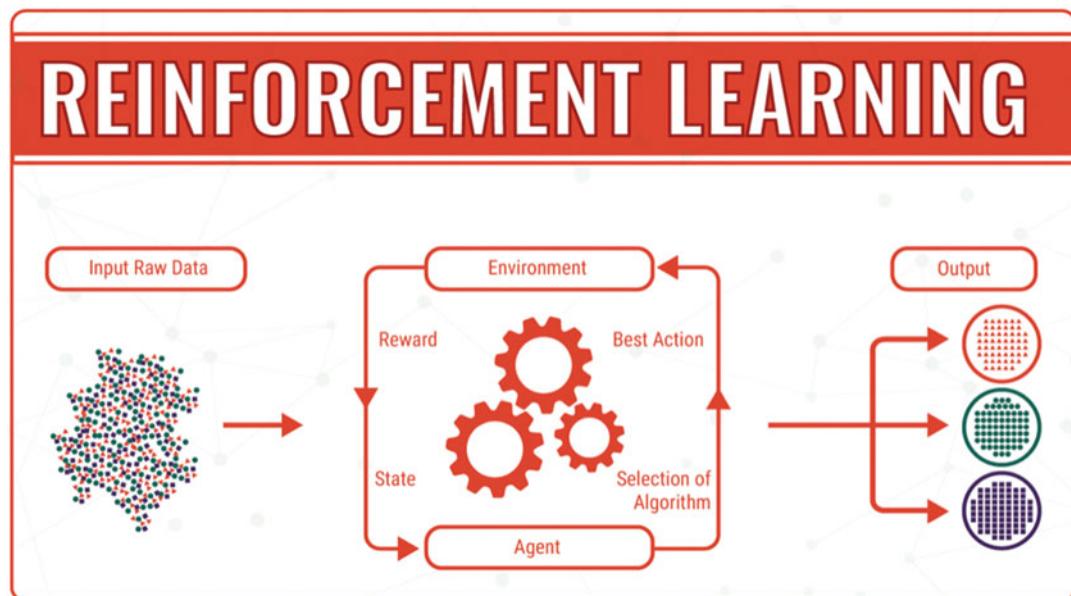

Fig. 4 Reinforcement machine learning (RML). (Source: With kind permission from Ronald van Noon)

patients admitted to ICU means that they are likely to benefit more from an RML approach system than by evidence-based clinical guidelines or best practices defined by physicians. Consequently, although nascent in nature, RML is still a well-

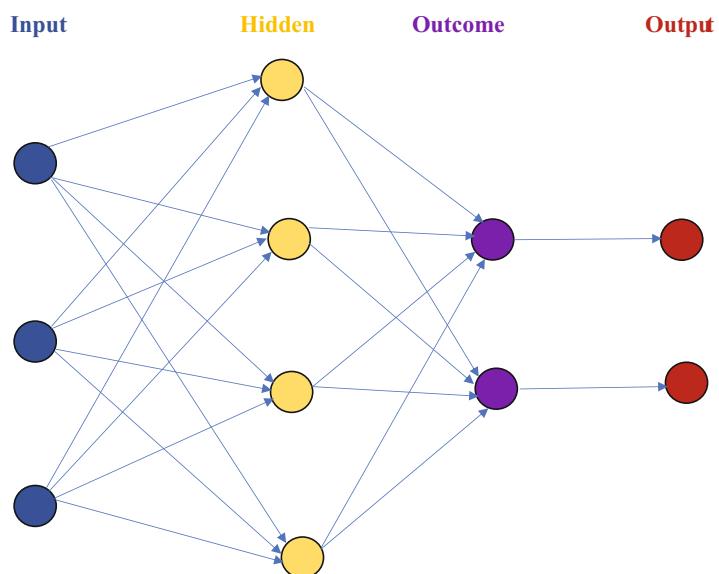

suited model for ICU since it can optimize treatment and patient outcome. Similarly, it can expand healthcare professionals' understanding of protocols and the potential to apply various treatment options.

The application of RML in ICU could be outlined with a simple example when evaluating a patient's state (demographics) and vital measurements (laboratory test results). After securing these data, a therapeutic intervention would be actioned followed by further tests to determine outcome. A reward would be assigned to the RML agent if the patient's state improves; otherwise, punishment would be assigned if the condition remains unchanged. In the latter instance, the physician would take another action reflective of the state. This state-action pairs for a patient which would roll out over time would represent the patient's condition, thus resulting as being fixed (first 24 h stay in ICU) or dynamic (when patient could be discharged at different times from ICU).

Deep Machine Learning (DML)

DML is, for example, a key technology behind driverless cars, enabling them to recognize a stop sign or to distinguish a pedestrian from a lamp-post. This technology is a subfield of ML with functional capabilities similar to ML. However, its functional properties are different. DL is concerned with algorithms inspired by the biological neural network and function of the human brain called artificial neural networks (ANNs). ANNs work by constructing layers upon layers

Fig. 5 Illustration of a simple neural network.
 (Source: Jiang et al. 2017)

of simple processing units (often referred to as “neurons”), interconnected via many differentially weighted connections [23] (Fig. 5). A key difference between the two technologies could be explained: thus, if ML algorithm returns an inaccurate prediction, then an engineer needs to step in to make necessary adjustments. But with a DL model, the algorithms can determine on their own if a prediction is accurate or not. As an example, ML could be programmed to recognize a hypoglycemic event based on the blood glucose parameters inputted. Eventually it could also pick up any phrase relating to a low blood glucose values reflecting the inputted parameters for hypoglycemia. However, a program with a DL model could recognize other variables, such as infection, stress, insufficient insulin or medication intake, and unscheduled strenuous physical exercise to mention a few, which can also contribute to hypoglycemia. This makes DL far more capable of carrying out complex tasks and making accurate predictions autonomously than machine learning.

Nursing

History informs us that the nursing profession evolved using the basic scientific principles of the nineteenth century [24], thus enabling nurses to have a critical role to be full-time hands-on care

providers. Throughout this time, nurses have also witnessed the influx of technological innovations. These have ranged from the “test-tube” babies, medical lasers, the artificial heart, genome mapping, CT and MRI imaging, angioplasty, dialysis, endoscopic procedures, bionic prosthetics, the Internet and health information technology (IT), the electronic health record (EHR), and robotic surgeries.

Despite nurses being the largest group of health professionals, the global healthcare system is experiencing a turbulent time. For example, staff shortage compounded by the continued decline in funding is unlikely to meet the ever-increasing demand driven by an aging population with multiple chronic conditions [25]. Bridging this gap between supply and demand will require changes rather than “simply throwing more resources at healthcare” [26]. Achieving this change means that a reform within the healthcare system is necessary if it is to continue delivering high-quality care underpinned by cutting-edge research. Reformation should also consider the implementation of a continued educational program for healthcare providers who face a huge knowledge challenge as the pace and complexity of medical knowledge now “exceeds the capacity of the human mind” [27]. Knowledge acquisition becomes a particularly important mechanism for nurses to strategically position themselves to remain relevant in the twenty-first century when healthcare is being ushered toward telemedicine and AI. This era of nursing-AI interface will potentially change the traditional approach to the nurse-patient relationship and the person and family-centered compassionate care. The success of this significant paradigm shift will invariably necessitate a strong and powerful nursing leadership to open discussion that will inform healthcare providers about opportunities and challenges for patient care and the profession.

Nursing Practice

Nursing is based on a framework known as the nursing process [28], comprising of a five-stage cyclical process known as assessment, nursing

diagnosis, planning, intervention, and evaluation [29]. Established in the early 1960s, this cutting-edge brainchild of Ida Orlando was depicted as a product that defined the nursing profession’s unique contribution to patient care. This interactive problem-solving approach became one of the signature roles of nurses in performing and achieving outcomes of nursing care. In practice, the nurse practitioner uses a degree of critical thinking to gather data, analyze and interpret the data, select, and apply appropriate intervention measures, concluding the process by evaluating the efficacy of the plan [30]. Thereafter, the development within the nursing profession led to nurses’ discovering and understanding the essence of evidence-based practice, defined as the “the conscientious, explicit and judicious use of current best evidence in making decisions about the care of the individual patient. It means integrating individual clinical expertise with the best available external clinical evidence from systematic research” [31]. Such an approach to care enabled the practitioner to apply a holistic approach to care that incorporated such elements as best research evidence, clinical expertise, the patient’s individual values, and circumstances, together with the characteristics of the practice in which the health professional works [32] and without excluding the use of experience, skills, training, patient’s values, and support [33]. The current process involved in the implementation of nursing interventions or actions to achieve a predictable outcome will arguably transcend within a technologically advanced future. Unless the present approach to care management which is underpinned by prescribed procedures is reviewed urgently, then the probability of such tasks being performed by humanoid nurse robots (HNRs) cannot be ignored. To avert this potentially likely scenario, it will be necessary that the future role of the nurse will be reviewed.

Societal Change

Arguably, advancements in the current exponential growth in robotics are being fuelled to also mitigate international shortage of nurses and to

support the current growing aging population in society brought about by the baby boomers [34]. It has been estimated that the current baby boomer generation in the United States, generally defined as the cohort born between 1946 and 1964 [35, 36], will reach 78 million by 2035, peaking to 100 million by 2060 compared to 76.4 million people under 18 [37]. As such this category of the elderly population will place greater demand on the healthcare system [38]. The consequences of an aging society, also known as Society 5.0, is more extreme in Japan as it is the only country in the world with the highest number of elderly people [39] and with a decrease in the birth rate, thereby negatively impacting on the figures entering the workforce [40]. The result of an aging Japanese society (*chokoreika*) combined with a reduced birth rate has led Japan to rely heavily on technology to provide human-centered care for the elderly people. It would therefore seem realistic and prudent to think that like Japan, the inclusion of humanoid nurse robots within the workforce could potentially resolve the strain being experienced in all sectors of the global healthcare system.

AI and Nursing Education

Historically the healthcare industry has always implemented machineries to complement care strategy. However, none of these technological innovations would be comparable with the capabilities and impact of the rapidly evolving AI in the care industry. Consequently, consideration should be given to the possibility that the integration of AI in healthcare is a likely cause of consternation among nurses. To address this state, it will be important to consider how the formal and informal educational programs and curricula could be re-examined to meet the needs of the existing and future nurses. The acquisition of new AI nursing competencies is most likely to be assured through the inclusion of such topics as basic health informatics knowledge and skills, concepts of data literacy, technological literacy, and AI algorithms together with a sound grasp of the ethical implications of using AI technology in the clinical context [41, 42]. The availability of

robots alongside the existing cadre of high-fidelity simulators in the school of nursing simulation laboratories is considered important in enabling nursing students to confidently gain hands-on experience with the technology [41].

The successful outcome of programs will also depend on the enhanced AI knowledge base of nurse educators teaching nurses in higher education [42]. Further, the desired outcome of any AI educational programs will also be underpinned by the involvement of a multidisciplinary approach to teaching that include information technologists, robotics engineers, and computer programmers. Such a collaborative approach which includes engineering principles will enhance nurses' understanding of technologies to be encountered in real-world clinical settings [34, 43]. The fact that nurses possess key insights into continually evaluating care to optimize outcomes makes them ideal candidates in co-designing technologies that address patients' needs and preferences programmed in nontechnical jargons that eliminates misunderstanding by patients [44]. The outcome likely to emerge from the co-creation of robots will enable the partnership between nurses and human nurse HNRs to deliver optimal patient care in a safer and a more effective and efficient manner.

Enhancing Holistic Care

This collaborative nurse-robot interface is more likely to strengthen nursing practice [45] rather than fearing that technology will replace nurses [46]. In welcoming innovation, nurses need to understand that both technology and the human nurse can each make a unique contribution in the delivery of competent of care. For example, AI technology can provide continuous real-time feedback about a patient's status than the moment-in-time assessment undertaken by the nurse. This combined data collation will provide a more accurate analysis of the patient's status, therefore a well-informed and approach to care. As nurses become more proactive in learning about AI technologies, HNRs in nursing will be valued as key members of the multidisciplinary care team. In turn, automation of repetitive tasks

will enable human nurses to focus more on the art of caring by building relationships, exercising empathy, and using human judgment to guide and advise.

Robots to the Rescue

Today society is witnessing an unprecedented rate of evolutionary and incremental as well as revolutionary and transformative technological development within nursing and the healthcare industry. For example, it is becoming evident that AI-driven robots are increasingly prevalent in the clinical settings worldwide. These robots (Table 1) have improved tasks and the procedural functionalities that are being performed in a more efficient and safer manner.

Table 1 Examples of technological innovations with functional properties

Robotic technology	Function
Paro	Nuzzles those who stroke or talk to it
Robear and RIBA	Capable of transferring patients from a bed to a chair
da Vinci surgical robot	Used in various types of surgeries where surgeons control the system and directs procedure
Cody	Gives bed baths to patients
Veebot	Has an 83% accuracy in selecting the best vein
Robotic prescription dispensing systems	Made the dispensing of pharmaceuticals more accurate and safer. Decreases the responsibilities of nurses in medication administration
Lynx Autonomous Intelligent vehicles	Capable of moving goods in a large facility and can self-navigate in dynamic environments
Swisslog RoboCourier	Used for transport of specimens, medications, and supplies in hospitals, clinical laboratories, and pharmacies
Xenex	Uses high-intensity ultraviolet light to disinfect any surfaces of the healthcare facility
Aibo	A friendly pet for the elderly
Pepper	Specializes in customer service, monitors corridors at night, and communicates with patients
Chapit	Engages in elementary conversations
Palro	Able to lead a group of elderly people in an exercise routine
Tug	Autonomous mobile delivery system that transports equipment weighing up to 450 kg
Ribo and Buddy	Other than being a friend, recognize individual family members of a household, take photos, read books to children, assist in the kitchen, relay messages, and share weather forecast
SARA	A Dutch design robot to support nursing staff in taking care of the elderly. SARA can also, for example, assist the elderly with their exercises, tell them stories, or warn the nurses if something goes wrong
Baxter	A British-built robot that can detect if a human needs help moving or dressing and use its sensors and dexterous fingers to lend a hand
ElliQ	California, a robotic companion for the elderly
Dinsow	Assists with mood, improving activity, and acts as a reminder to take medication

The Future of Robotics

Just like the rise of robotics in nursing, technology is developing at a fast rate within the medical arena. In a continued effort to improve healthcare, the future of surgery is gradually experiencing a radical change. For example, some of the robotics which are in their early stage of development hold the promise to assist in surgery (Table 2), thus improving direct patient care.

Conclusion

A noticeable decline in funding growth in a challenging global economy along with an international shortage of healthcare workforce is unlikely to meet the increasing demand driven

Table 2 Robotics of the future

Robotic technology	Function
Medrobotic's Flex Robotic System	This robotic technology has shown some success in assisting in the visualization in general surgical, gynecological, and thoracic procedures in the United States
Hansen Flex Robotic System	This technology is used during electrophysiology procedures by remotely navigating a robotic catheter in the cardiac atria and can also provide 3D catheter control including 3D visualization during these procedures
Medtech – ROSA Spine	Can perform minimally invasive spinal surgery
Atheon – TUG	This autonomous mobile delivery robot is capable of transporting racks, carts, or bins weighing up to 543 kg

particularly by an aging baby boomer generation living with multiple complex chronic health conditions. To resolve the problem, attention has focused on AI technology to contribute toward delivering healthcare as well as to boost productivity and bring about significant economic and social benefits.

Today, our world has entered a period of truly transformative change propelled by the pace and scale of technological developments that was simply not anticipated. Such an avalanche of technological advances will undoubtedly reshape the very essence of humanity and touch every aspect of life on the planet. In the context of healthcare, nurses should not simply focus on how technology detracts from humanistic care. Instead, it will be more appropriate for them to explore how healthcare technology and compassionate care play key roles in the provision of compassionate nursing practice. Further, nurses need to reconsider their roles by analyzing how the inclusion of AI in care can enhance critical thinking and the nursing process. This collective approach to delivering care underpinned by evidence will lead them to support the patient's journey adding value through expedited, more precise, and enriched decision-making. As nurses' knowledge of AI increases, they will be able to delegate technical roles and repetitive tasks to HNRs, thereby enabling them to spend more time with patients and families. To summarize, it is only through gaining AI knowledge that nurses will realize the potential of this technology within the healthcare settings. So rather than alienating themselves from this technology, nurses should infuse AI to optimize healthcare outcome in a safer and more efficient manner. Irrespective of whether AI

singularity will come to pass or not, AI in healthcare sectors will continue to improve by overcoming challenges, and these improvements which are continually being achieved appear to be accelerating.

The notion that AI might create existential risk to humanity has certainly fuelled currency by prominent thinkers [47] and public intellectuals [48] as well as the creation of a dystopian society as portrayed by Hollywood movies. Although the age of AI has arrived, the question of whether people should fear this technology remains. The AI-induced apocalyptic scenarios presented to us in many films and television series depicting AI gone wrong have certainly cultivated a sense of fear and apprehension. Moving away from the cinematic space, AI is revealing endless possibilities of serving humanity in all its enterprises [49]. Finally, whether the depiction of a dystopian society is motivating, frightening, or discouraging is difficult to assert, but at least they have posited the ethical dimension of technology on the agenda. On a final note, while celebrating the present and future success of AI, we should take heed of the cautionary wisdom of Eliezer Yudkowsk [50] (2008) when he said that "By far the greatest danger of Artificial Intelligence is that people conclude too early that they understand it."

Historically, the field of respiratory medicine has been a breeding ground for pioneering applications of artificial intelligence (AI). Recently, the field has seen an explosion of interest in AI applications that has been primarily driven by advances in computing power, algorithmic innovations, and availability of large datasets. In this chapter, we examine the applications of AI across different modalities of respiratory medicine, such as chest imaging,

lung function testing, telemedicine, sleep medicine, etc. We provide a historical context of these applications as well as highlight the latest trends, including the remarkable successes of deep neural networks (DNNs). Finally, we share our future perspective while pointing out the existing barriers to the implementation of AI systems in routine clinical practice.

Introduction

Technological advances have always pushed the boundaries of what is possible in respiratory medicine. Since the development of spirometry and chest radiography in the nineteenth century, the diagnosis, treatment, and management of respiratory diseases have radically improved over the last century. Today, we are witnessing the genesis of another technological revolution brought about by artificial intelligence (AI).

Specifically, we define AI as computer algorithms simulating intelligence for tasks that seem intuitive to humans, such as reasoning, knowledge representation, learning, natural language processing, perception, and the ability to manipulate physical surroundings [1]. Machine learning (ML) is a subset of AI in which the computer automatically learns a task from predefined data features. Within ML, deep learning (DL) is a class of algorithms where the computer extracts the necessary features from raw input data. Deep learning models or deep neural networks (DNNs), such as convolution neural network (CNN) and recurrent neural network (RNN), have become very popular lately due to the availability of large labeled datasets, efficient training algorithms, and advances in parallel processing [2].

The field of respiratory medicine has been a breeding ground for many pioneering applications of AI in healthcare. It has been part of the

formative years of AI as expert systems to interpret pulmonary function tests (PFTs) and in its transformation to the first machine learning and deep learning applications on medical imaging data [3, 4]. In the last several years, there has been an explosion in interest in medical AI applications, a trend also observed in the field of AI in respiratory medicine. The number of articles published in just the last year alone constituted 90% of all articles published since 2000 [5].

In this chapter, we review the advances in ML and DL as applied to respiratory medicine. We will describe the history and illustrate the latest trends across different clinical modalities such as imaging, lung function testing, critical care monitoring, sleep monitoring, and telemedicine. Finally, we discuss the future perspective of AI in relation to respiratory medicine.

Imaging

Almost half a century back in 1966, Gwilym S. Lodwick introduced the term “computer-aided diagnosis” in scientific literature. He emphasized, “there is scarcely any repetitive function in which the computer cannot be of help to us, in radiology” [6]. Three years earlier, he had developed a visually descriptive system to convert X-ray images into numerical sequences, which in today’s ML terminology are called feature vectors. He postulated that these sequences could be manipulated by a digital computer to predict a diagnosis [7] and further demonstrated a relationship between these features and one-year survival of advanced lung cancer patients.

Scanning and processing radiographic images in the computer memory finally became possible in the 1970s. Image processing typically involved low-level operations such as filtering for detecting edges and lines, fitting simple mathematical structures, etc. [4]. At that time, rule-based methods that employed step-by-step procedures on low-level imaging features for finding lungs, heart, ribs, and, finally, abnormal regions were in fashion [8, 9]. However, these methods were often too brittle, similar to expert systems.

To address these challenges, the trend shifted to textural analysis, which marked the entry of the modern ML paradigm in chest imaging [10]. In textural analysis, a discrete region of interest (ROI) within the lung field is selected and a feature extraction algorithm based on structural [11], statistical, or binary patterns is applied [12]. Then a supervised learning algorithm is used to classify the textures. The group of Kunio Doi at the University of Chicago published many seminal studies in this field [13], and until recently, this was the dominant approach. A major weakness of such approaches is that it is impossible to determine which features are optimal. This makes them strongly application-dependent as it requires prior knowledge of the characteristics of the texture [4].

This is where deep learning entered the scene by completely taking over the task of both learning the features and classifying the problem. By removing the human element altogether, it marks a paradigm shift in the history of computational medical imaging. The trend started precisely in 2012 when Krizhevsky et al. trained a CNN with an error rate that was less than 10.8 percentage points than the runner-up in the ImageNet challenge, an annual computer vision competition organized by Stanford University [14]. Until then, training DNNs were computationally expensive, but it became feasible due to the development of a parallel processing framework with graphical processing units (GPUs). Today, the application of DNNs to chest radiographs and CT scans has resulted in a step change in diagnostic accuracy when compared to ML algorithms on semantic features such as tumor speculation or quantitative features such as shape and texture [5].

In this section, we will review the latest applications of DNNs within different medical imaging modalities.

Chest X-ray

Chest X-ray is the most commonly requested radiologic examination. Analysis of chest X-rays is formulated as a computer vision

problem in which CNNs have become state of the art. CNNs have been trained to detect abnormal findings on plain chest X-rays and specific pathologies, including tuberculosis [15, 16], pneumonia [17], and malignant pulmonary nodules [18]. Rajpurkar et al. developed a CNN to detect the presence of 14 different pathologies, including pneumonia and pulmonary masses and nodules [19]. While no significant differences in the area under the receiver operating characteristics curve (AUROC) was observed between radiologists and the AI, the time to interpret the images was significantly longer for the radiologists (240 min vs 1.5 min).

In a similar study, Hwang et al. developed a parallel network of CNNs to detect abnormalities associated with major diseases like lung cancer, tuberculosis, pneumonia, and pneumothorax on chest radiographs, as well as to localize the abnormalities. While the AI consistently outperformed thoracic radiologists and physicians in identifying disease abnormalities ($AUROC = 0.983$ vs $0.814\text{--}0.932$, $p < 0.05$) [20], the humans significantly improved their diagnostic performance when they assessed the radiographs with the assistance of the AI. Further, the same group demonstrated that the same AI improved the sensitivity of radiology residents in the detection of clinically relevant abnormalities in emergency room settings [21].

A common application of AI is to triage chest X-rays in clinical workflows. Annarumma et al. trained a CNN to triage chest radiographs as “normal,” “non-urgent,” “urgent,” and “critical” using a dataset of 329,698 images [22]. With a sensitivity and specificity of 71% and 95%, respectively, the AI further resulted in a fourfold reduction in the time to report radiographs with critical findings and a twofold reduction in the time to report urgent findings. During the COVID-19 pandemic, triaging of patients using AI on chest X-rays to detecting pneumonia-related abnormalities received a lot of attention [23, 24]. As this is a rapidly evolving situation, these results should be considered with a lot of caution due to uncertainties in data reporting and the high risk of bias [25].

Computed Tomography (CT)

CT is an advanced imaging technique that provides an insight into the lung structure in vivo. It is an ideal tool for the assessment of airway diseases and for screening lung cancer. DNNs have been extensively used in CT-based diagnostic workflows in respiratory medicine. Gonzalez et al. trained a CNN on 7983 CT scans from COPDGene, a large well-characterized cohort of airflow obstructed subjects, to stage the severity of chronic obstructive pulmonary disease (COPD) [26]. The same model was also used in predicting acute respiratory disease (ARD) events and mortality in smokers. Using the same cohort, Humphries et al. developed a CNN to classify the presence and severity of emphysema, which concurred well with visual scores of emphysema [27]. The CNN scores also contributed to the prediction of mortality and lung function parameters in COPD.

The availability of public CT datasets has precipitated a growing interest in applying DNNs to identify patterns associated with interstitial lung disease (ILD) such as fibrosis, consolidation, ground glass opacity, etc. [28]. In 2018, Walsh et al. published a seminal study in the application of DNNs for diagnosing ILD [29]. The group trained their model on 420,096 unique four-slice montages created from 929 CT scans. In the internal test set with 139 scans, the model demonstrated an accuracy of 76.4%. In another test dataset ($N = 150$ CT scans), the model outperformed 60 out of 91 thoracic radiologists in the diagnosis of fibrotic lung disease with a diagnostic accuracy of 73.3%. A recent study by Bermejo-Pelaez et al. developed a DNN to detect subtle interstitial changes that precede the development of ILD [30].

DNNs have also been used in the detection of pulmonary embolism. Tajbakhsh et al. carried out a comparative investigation to detect pulmonary embolism using a pretrained CNN with fine-tuning (transfer learning), which outperformed a CNN built from scratch, even at its worst case [31]. DNNs have also been applied to detect and calculate clot burden of acute pulmonary embolism on CT pulmonary angiography, which further correlated with measures of ventricular function [32].

There has been accumulating evidence that the implementation of low-dose CT can reduce mortality in lung cancer. An important limiting factor in this implementation is the availability of radiologists to report the large volume of screening CT scans. There has therefore been substantial interest in developing AI systems that can detect and accurately diagnose malignant pulmonary nodules on CT imaging. While the traditional approach involved applying ML on radiomics features from CT [33, 34], the trend has mostly shifted toward the application of DNNs for end-to-end screening [35–37]. Ardilla et al. developed a DNN using cases from the National Lung Cancer Screening Trial, which outperformed six board-certified radiologists when the current CT scan was available and was equivalent to the radiologists when both current and past scans were available for review [35]. Shen et al. developed an interpretable model that provided low-level semantic features often reported by radiologists with representations learned by the model, to explain predictions of nodule malignancy [37].

Researchers have also shown that DNNs can be used to predict prognosis and tumor type based on CT images. Hosny et al. trained a DNN to predict survival based on CT appearances in patients with non-small cell lung cancer undergoing surgery or radiotherapy [38]. The DNN distinguished between early (<2 years) and late (≥ 2 years) mortality in patients undergoing surgery and radiotherapy. Wang et al. reported that a DNN could predict epithelial growth factor receptor mutation status in patients with lung adenocarcinoma based on CT images [39]. The accuracy of the DNN significantly exceeded that of predictive models using clinical, semantic, or radiomics features.

During the COVID-19 pandemic, several researchers used DNNs to differentiate COVID-19 pneumonia from common pneumonia on CT scans [40, 41], and to quantify lung abnormalities [42]. The premise was that COVID-19 pneumonia lungs present with pronounced ground glass opacities that can be identified by a DNN [43]. These methods were mostly developed to identify high-risk patients with poor prognosis for early

intervention or for optimizing medical resources in emergency room settings.

Histopathology

Visual inspection of histopathology slides is one of the main methods used by pathologists to assess the stage, type, and subtype of lung tumors. Many AI-based diagnostic systems that provide an automated assessment of tissue images have been explored to aid diagnostic workflows in histopathology. Couدرay et al. trained a CNN on whole slide images from the Cancer Genome Atlas to automatically classify tumor types into adenocarcinoma (LUAD) and squamous cell carcinoma (LUSC), which showed a comparable performance to expert pathologists [44]. Further, the model also predicted ten most commonly mutated genes in LUAD. Similarly, Shia et al. developed a DNN to predict tumor programmed ligand 1 (PD-L1) status from whole slide images of non-small cell lung cancer [45]. DNNs have also been applied to differentiate between lung adenocarcinoma growth patterns (acinar, micro-papillary, solid, lepidic, and cribriform) [46, 47], as well as to detect lung cancer metastases in lymph node slides [48]. Courtiol et al. developed a CNN on whole slide images to predict the overall survival of mesothelioma patients, without any pathologist-provided locally annotated regions [49]. They explained the predictions by highlighting regions that were mainly located in the stroma and are histological features associated with inflammation, cellular diversity, and vacuolization.

Bronchoscopy

Bronchoscopic inspection, as a follow-up procedure after radiological imaging, plays an important role in the diagnosis and treatment of lung disease patients. Bronchoscopy is followed by a biopsy, which requires the pulmonologist to be very selective as it may cause life-threatening haemorrhage. In this regard, DNN techniques on bronchoscopic images could provide objective recommendations on lung pathology and enable clinicians to be

more selective. However, the lack of large datasets prohibits the training of DNNs from scratch. Tan et al. fine-tuned an existing DNN (transfer learning) on a small sample of lung bronchoscopic images to differentiate between cancer, tuberculosis, and normal cases with an overall accuracy of 82% [50]. Feng et al. extracted textural features from bronchoscopic images and fed them into an ML classifier to distinguish between LUAD and LUSC [51].

Point-of-Care Ultrasound (PoCUS)

Emergency physicians often have access to PoCUS, a portable diagnostic tool that helps in minimizing the delay between the onset of symptoms and the initiation of definitive therapy [52]. Although literature on the application of AI on PoCUS imaging remains limited, some researchers have applied DNNs to detect the presence of B-line artifacts and further classify its severity [53]. More recently, Roy et al. used a DNN that scored and localized the severity of COVID-19 on PoCUS images [54].

Lung Function Testing

Pulmonary function tests (PFTs) are considered an important tool for the evaluation of the respiratory system and for diagnosing obstructive diseases such as asthma, chronic obstructive pulmonary disease (COPD), and lung fibrosis. Traditionally, we refer to complete PFT as the combination of spirometry, whole-body plethysmography, and diffusion capacity test, although tests like forced oscillation test (FOT) and nitrogen washout also fall under the purview of lung function testing. The interpretation of lung function testing has been considered as an important aspect among respiratory physicians.

There are several guidelines to aid in the differential diagnosis of common respiratory diseases [55, 56]. Although guidelines seem to be helpful in defining the typical patterns based on strict cutoffs, many cases have mild and varying disturbances that do not fit in any of the predefined boxes. As a result, the interpretation of PFT

requires expert knowledge, which is expensive and not always available at all levels of healthcare. Moreover, additional tests are often requested to confirm a diagnosis.

The potential of AI was recognized as a tool to provide an automated interpretation of PFTs by reproducing the cognitive abilities of a physician. Early attempts were made in the 1980s using rule-based expert systems such as PUFF and Pulmonary Consult [3, 57], which could model the interpretation pattern of an individual. However, such systems were brittle, and coupled with the limitations on computing power at the time, they never gained any widespread adoption.

After a long hiatus, there has been a resurgence of AI for PFT interpretation in the recent years. This has been largely motivated by the recent successes of machine learning in various applications across the medical domain. It was realized that machine learning can assist in providing a faster and more accurate diagnostic interpretation of PFT because of its ability to find patterns in a high-dimensional feature space [28].

In this section, we summarize the applications of AI and ML across different lung function testing methods.

Pulmonary Function Tests

Topalovic et al. developed an ML model using 1430 PFT cases that could differentiate between eight types of respiratory disease. In a head-to-head comparison using 50 test cases, the model demonstrated an accuracy of 82% and outperformed 120 European pulmonologists by a wide margin [58]. Machine learning has also been applied to detect ILD in systemic sclerosis patients using PFT [59].

Spirometry

Spirometric forced expiration lies at the foundation of PFT testing, and several researchers have applied ML techniques on spirometry data to extract clinical biomarkers. Bodduluri et al. developed a DNN to identify quantitative CT-based structural phenotypes

on the COPDGene cohort [60]. The model was more accurate in differentiating emphysema/small-airway phenotypes than traditional spirometric measures like forced expiratory volume in 1 s (FEV₁) and Tiffeneau index. Kaplan et al. explored different ML models and clinical features to differentiate asthma, COPD, and very subtle asthma-COPD overlap syndrome [61]. The group utilized a very large cohort of around 400,000 subjects extracted from US electronic health records covering primary care, specialist care, and hospital medical records. The best model featured spirometry measurements with BMI, pack years, symptoms, and history of allergic and chronic rhinitis as input features. Recently, Das et al. trained a CNN to automate the process of visual evaluation spirometric flow-volume loops, which is a source of large intertechnician variability in spirometric quality control [62].

Forced Oscillation Tests

The forced oscillation test (FOT) is a noninvasive and effort-independent method to measure respiratory impedance using sound waves. It offers a more accurate measurement of central and peripheral airway obstruction than spirometry [63]. FOT generates many frequency-dependent measurements, and an ML approach may help in uncovering different phenotypes in such a rich feature set. The group of Amaral et al. have been extensively involved in applying ML techniques in detecting COPD and categorizing severity in COPD patients [64, 65]. They also developed an ML approach to assist in the early diagnosis of smoking-induced respiratory changes [66]. Recently, they compared several classifiers to detect airway obstruction in asthma patients using FOT data, and interestingly, the simple k-nearest neighbor classifier achieved the best performance [67].

Telemedicine

Telemedicine originally emerged as a way to treat and manage patients who were located in remote places, far away from local health

facilities or in areas with shortages of medical professionals. As the affordability and accessibility to smartphones and sensors become widespread, telemedicine has become an important tool for the monitoring, self-management, and intervention of respiratory diseases. By monitoring clinical outcomes at an individual level, such technologies facilitate preventive and pre-emptive care remotely.

However, generating insights into the plethora of signals gathered by telemonitoring devices necessitates the development of ML algorithms. In the past, several researchers have applied predictive algorithms to monitor COPD and asthma exacerbations on data from telemonitoring devices [68]. Orchard et al. developed an ML model that considered daily reported clinical symptoms, physiological measurement of pulse and oxygen saturation, and medication to predict hospital readmissions and decision to start corticosteroids in COPD patients [69]. The ML model demonstrated a superior performance when compared to a traditional scoring model ($AUC = 0.74$ vs 0.60). Shah et al. carried out a similar study where they utilized a telemonitoring system consisting of a tablet computer with a customized application and a Bluetooth-enabled pulse oximeter [70]. The group trained a finite state ML model on the collected data to predict exacerbation events in COPD patients. An interesting mobile platform was developed by Chamberlain et al. [71], which consisted of an electronic stethoscope, peak flow meter, and a patient questionnaire. An ML algorithm was utilized to screen patients for COPD or asthma based on this data. ML methods such as naïve Bayes classifiers and support vector machines have been applied to home peak expiratory flow measurements and symptom scores to predict exacerbations a week early in adults [72] and children [73].

Miscellaneous

In this section, we highlight several applications of AI in miscellaneous applications of respiratory medicine.

Sleep Monitoring

Sleep monitoring or polysomnography (PSG) is a type of test to diagnose sleep disorders like obstructive sleep apnea [74]. Traditionally, PSG is performed in a sleep laboratory in which different sleep variables are monitored continuously overnight. One of the most cumbersome processes in polysomnography data is manual scoring of different sleep stages. To tackle this, many researchers have applied ML methods on PSG signals to automatically classify sleep stages [75–77]. Alloca et al. developed an automated sleep-stage classification program called “Somnivore,” which achieved a high F1 score (0.84–0.90) with manual visual scoring in humans, rodents, and pigeon polysomnography data [75]. Nikkinen et al. developed an DNN that accurately determined the oxygen desaturation index (ODI) and apnea–hypopnoea index (AHI) using only the oxygen saturation signal as input [78].

Breath Analysis

Breath analysis offers an excellent potential to phenotype respiratory disorders because exhaled breath contains a mixture of gases and traces of many volatile organic compounds (VOCs) that emanate from the respiratory tract itself. Several techniques exist to measure VOCs in the breath, such as gas chromatography–mass spectroscopy, electronic nose, and chemical sensors, each of which requires advanced pattern recognition methods to identify abnormal signatures in measured VOCs [79].

One of the generally accepted exhaled biomarkers is nitric oxide (NO), of which increased levels are associated with pulmonary inflammation in asthma patients. Machine learning models utilizing exhaled NO data have been used to discriminate between asthma and healthy individuals [80], to monitor asthma control in children [81], and to phenotype severe asthma [82]. ML methods on VOC data have been used to discriminate COPD and healthy individuals [83] and to detect lung cancer [84]. One study reported ten

new COPD-related VOCs, which was discovered using a data-mining approach [85].

Lung Sound Analysis

Computerized lung sound analysis involves discriminating between normal and adventitious lung sounds obtained during auscultation. Although ML has become a standard method for classifying adventitious sounds, these sound events are intermittent and highly variable from one person to another, presenting a challenge in generalizing these algorithms to a general population [86]. In the past, ML approaches have been applied to classify adventitious sounds associated with asthma [87], COPD [88], and ILD [89] and to detect common respiratory disorders in children using cough sounds [90]. Bardou et al. reported that DNNs outperformed traditional ML techniques in the classification of lung sounds into seven categories (normal, coarse crackle, fine crackle, monophonic wheeze, polyphonic wheeze, squawk, and stridor) [91].

Conclusions and Future Perspectives

We summarize our observations in Table 1. The application of artificial intelligence in respiratory medicine has created a very optimistic trend with new discoveries being reported at a breathtaking rate. DNNs are emerging as a key tool for developing imaging biomarkers for diagnosis, prognosis, and prediction of response to therapy. However, a major limitation for such computational approaches is the lack of large training datasets, which is characteristic of the medical field. An effective solution to this problem is transfer learning, an approach that entails pre-training a DNN on large nonmedical image datasets and then fine-tuning it in on an outcome specific dataset. Research has shown that transfer learning can outperform state-of-the-art ML models with manually engineered features in medical imaging [92].

There is also a need to develop open-source platforms to benchmark and bolster further deep learning research in respiratory medicine. The recent formation of open-source imaging consortium, a collaboration between academia and

Table 1 An overview of the applications of artificial intelligence across different modalities of respiratory medicine

Modality	Application	Main outcomes
Chest imaging	Plain chest X-ray	Common respiratory disease diagnosis [15–21], triaging [22], COVID-19 [23, 24]
	Computed tomography	Detecting COPD [26, 27], ILD [29, 30], pulmonary embolism [31, 32], identifying nodule malignancy [35–37], tumor prognosis [38, 39], COVID-19 [40–42]
	Histopathology	Tumor classification [44, 45], tumor growth pattern [46, 47]
	Bronchoscopy	Lung cancer diagnosis and classification [50, 51]
	Point-of-care ultrasound	Detecting B-line artifacts [53], COVID-19 [54]
Lung function testing	Spirometry	Obstructive airway disease differentiation and phenotyping [60, 61]
	Pulmonary function testing (spirometry, body plethysmography, and diffusion capacity)	Common respiratory disease diagnosis [58, 59]
	Forced oscillation test	Obstructive airway disease differentiation and phenotypes [64–67]
Telemedicine	Telemonitoring diagnostics	Predicting exacerbations in COPD and asthma [68–73]
Miscellaneous	Sleep monitoring	Scoring sleep stages
	Breath analysis of volatile organic compounds	Obstructive airway disease differentiation and phenotyping [64–67]
	Lung sound analysis	Classifying pathological lung sounds [86–91]

industry to develop imaging biomarkers for idiopathic pulmonary fibrosis (IPF), ILD, and other respiratory diseases using AI, is definitely a welcome sign [93]. There remains an enormous potential for DNNs to embrace domains outside of imaging, such as PFTs, FOTs, biosignal monitoring, etc. Since these applications involve the collection of raw data characterized by high dimensionality, DNNs may be employed to find specific patterns. The only bottleneck is the lack of sufficient sample sizes for training coupled with the diversity of the input data type that hinders transfer learning approaches. Finally, large clinical databases of multicenter randomized controlled intervention trials are another underexplored domain. DNNs on these detailed datasets carry the potential to predict treatment effects for individual patients. At this stage, the raw data of commercial datasets are highly protected and only available for internal use [94]. Merging raw data of similar studies for AI approaches may boost the field of personalized treatment.

We believe that the future has a lot in store for applications of AI. The recent trend of smartphones serving as general practitioners is only poised to grow with advances in Chabot capabilities that rely on natural language processing (NLP) [95]. This will make healthcare more accessible, especially in low-income countries, while bringing down overall costs [96]. Advances in NLP will also be deployed to extract clinical insights from the vast pool of unstructured electronic medical records (EMR), such as documents or notes [97]. The final frontier will lie in leveraging extremely large sets of data (or “big data”) that would integrate clinical, physiological, imaging, genomic sequence, and sensor data. DNNs would be used to explore quantitative biomarkers in big data and to develop personalized treatment and management strategies [98].

A criticism that is often directed at DNNs, and any other form of AI, is their lack of explainability, which can be defined as an ability to provide reasons for its output. Explainability is critical for gaining trust, especially if a physician plans to take action based on the prediction of a DNN. An explanation must be interpretable; therefore, revealing the mathematical operations of a DNN is hardly interpretable to the user. Several techniques currently exist today

that can generate explanations by estimating how the input features or different regions within an input image contributed to the output [99]. This may be useful in cases where the user could overrule the decision of a DNN by inspecting its faulty or biased explanations. However, there remains another technical impediment, that is, these systems are not sufficiently interrogated for robustness. It has been shown that DNNs can break down with small perturbations in input data [100]. For example, a DNN model trained on imaging data from the latest machine at an advanced care facility may malfunction at a rural hospital with older machines. However, this may not be the case for a human radiologist who can easily interpret data from both machines.

Lastly, we would like to highlight an “inconvenient truth” that while many AI algorithms have produced remarkable success in carefully selected cohorts (“laboratory conditions”), they are not yet ready to be deployed at the frontiers of clinical practice (“in the wild”) [101]. First, we should also consider updating our clinical guidelines and standards of care by incorporating AI, when it is evidence based, as it is done in the entire field of medicine [102]. Second, we would like to point out that the fragmented nature of our healthcare system, determined by a complex web of political, social, and commercial interests, provides very little incentive for AI applications. Thorny issues relating to data ownership, sovereignty, and transfer need to be resolved to allow AI innovations. At present, while the physician retains the final decision-making power, questions on liability arises as AI systems become more powerful and autonomous. Finally, the ethical implications of employing AI are poorly understood. AI models are prone not only to biases of the researchers or the institutions funding their development but also to spurious associations relating to gender or ethnicity in the datasets [103].

Abstract

Rheumatology is a discipline to manage clinical conditions in joints, soft tissue, connective tissue, and autoimmune diseases. Rheumatoid arthritis, systemic lupus erythematosus and other connective tissue diseases, gout and metabolic bone diseases, osteoarthritis, and spondyloarthritis are well-known multi-organ rheumatic diseases. The application of artificial intelligence (AI) in rheumatology is relatively

rare; however, an increase in AI research in rheumatology is apparent, especially in the recent 2 years. AI has been applied in prediction of disease or outcome using electronic health records (such as for axial spondyloarthritis), deciphering of genetic or other high-dimensional biological data (such as for erosive arthritis, juvenile idiopathic arthritis), image classification (such as for anti-nuclear antibody, joint space narrowing, fractures), and miscellaneous AI applications in mixed types of data (such as for inflammatory synovial). This book chapter summarizes recent AI research in rheumatology and provides a perspective on the potential of AI in clinical or research aspects of rheumatology.

Introduction

Rheumatology is a unique discipline to manage patients with rheumatic diseases, medical conditions that primarily affect the bone, joint, and soft tissue, and connective diseases. Many of these diseases have autoimmunity in pathogenesis; therefore, newer therapeutics target specific immunological proteins to remedy aberrant immune function. The diagnosis of rheumatic diseases is not straightforward, often requiring multiple clinical tools to help rheumatologists decide. The application of artificial intelligence (AI) in rheumatology is still in infancy, but some research has documented the potential to transform the practice of rheumatology.

The major rheumatic diseases include rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), metabolic bone diseases (e.g., gout and osteoporosis), spondyloarthritis (e.g., ankylosing spondylitis and psoriatic arthritis), and other connective tissue diseases (e.g., systemic sclerosis). RA is an inflammatory polyarthritis primarily affecting small joints, which often causes disability if left untreated. Efforts to diagnose RA early include the use of *machine learning* (ML) to identify disease cases from electronic health records (EHRs) and assist the classification of RA. SLE is a prototypic autoimmune disease characterized by the presence of multiple autoantibodies and a myriad of clinical presentation. AI/ML has been used to identify or classify SLE patients based on genetic or immunophenotyping data. Gout is a urate deposition disease that often causes acute arthritis. The prediction of acute flare is a challenge to clinicians and the patients since the prophylactic medication is effective and can be safely administered prior to the flare. ML has been used to automate the identification of acute flare from clinical notes that can further accelerate the development of a predictive model. Spondyloarthritis is a group of inflammatory arthritis affecting axial (ankylosing spondylitis) or peripheral joints (psoriatic arthritis). The diagnosis of these conditions

heavily relies on bone and joint radiography. AI has been applied to assist in interpreting X-rays and tracing the radiographic progression of the diseases. Osteoporosis results from a decrease in bone mineral density, which reduces bone strength and increases the risk of fractures. Since many of the affected patients are asymptomatic, effective screening to identify patients at risk is essential, where AI algorithms are helpful.

AI is a set of algorithms and technologies used to imitate or augment human intelligence. Figure 1 depicts the research disciplines in AI that include, but are not limited to, planning, reasoning, knowledge representation perception, robotics, and machine learning. In machine learning, various algorithms are developed to detect patterns in sampled data for prediction or decision-making. Among these machine learning algorithms, the artificial neural network technique has received much attention in recent years due to its success in many applications (e.g., macular degeneration detection, self-driving car, or virtual assistant). The technical breakthroughs of neural network training and design become an emerging subdiscipline, deep learning. Different types of neurons and various layer connectivity styles form numerous deep learning models.

Machine learning, as an important subfield of AI, is characterized by its ability to identify clinically relevant patterns among an abundance of medical data by different learning strategies. Supervised learning is the most popular machine learning strategy where the model is trained on a labeled dataset to recognize the patterns associated with specific classes. This type of learning strategy is commonly used for classification and regression. To date, many of the machine learning studies in rheumatology have used supervised learning models such as support vector machine (SVM), logistic regression, random forest, or artificial neural network (ANN) to perform disease classification or detection. Supervised learning is often used in tasks with a clear reference label, such as the prediction of patient outcomes using electronic medical charts.

On the contrary, unsupervised learning is another learning strategy using unlabeled data to detect the underlying relationships or patterns of

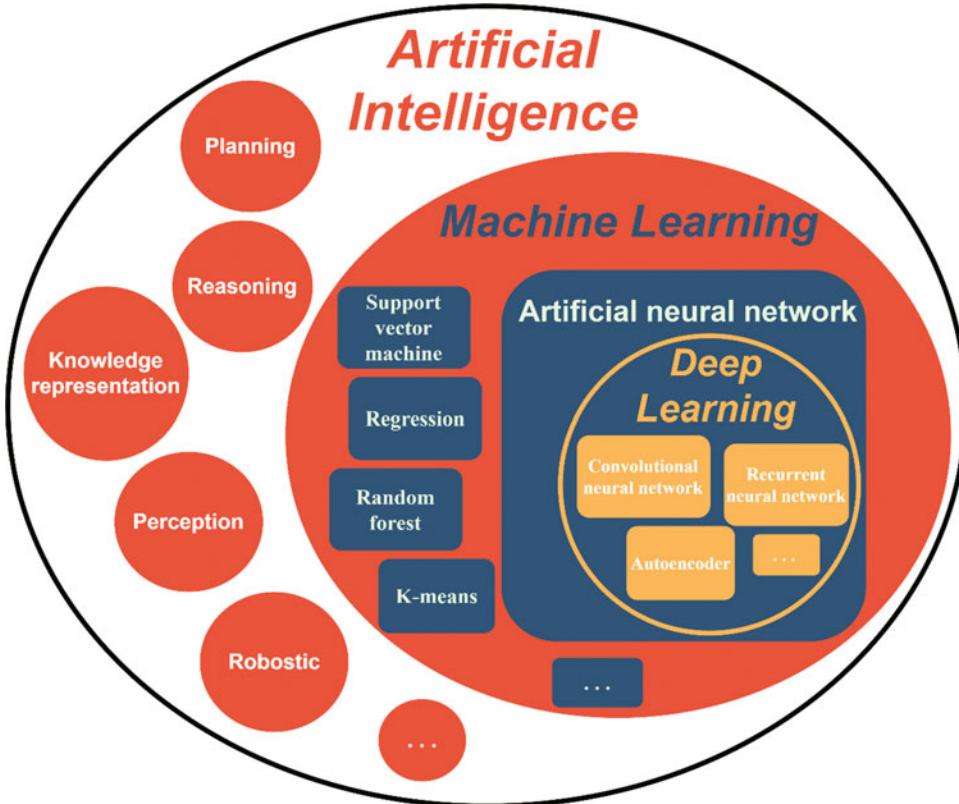

Fig. 1 The Venn diagram of different artificial intelligence disciplines

the dataset. The unsupervised learning algorithm can be a useful data analytics tool for clinicians to gain a better understanding of the medical data because it can reduce the dimensionality of the given data (e.g., t-SNE and autoencoder) or cluster similar data points (e.g., k-means and DBSCAN). These algorithms delineate the inherent data structure and provide insight into complex data such as genetic or high-dimensional flow cytometric data.

As a specific class of machine learning algorithms, deep learning has received much spotlight in recent years and has already been successfully used in many medical disciplines such as ophthalmology, radiology, and pathology. Deep neural network (DNN), a type of ANN with multiple designed layers, is an essential form of deep learning. In contrast to classic machine learning algorithms that still require feature engineering with prior knowledge, DNN automatically extracts features from the raw data by nonlinear

transformations of neurons (hidden layers). Convolutional neural network (CNN) is one of the prevalent DNN architectures. CNN has been mainly applied in medical imaging tasks. It recognizes feature patterns by the convolutional layer, learning different phenotypic signatures of a medical image. Recurrent neural network (RNN) is another famous DNN architecture. RNN is specialized for processing sequential data by allowing previous outputs to be used as inputs while having hidden states that make it more suitable for longitudinal data analysis.

Application of Artificial Intelligence in Rheumatology

AI is reshaping rheumatology in both basic research and clinical practice since it can perform tasks that usually would require medical expertise

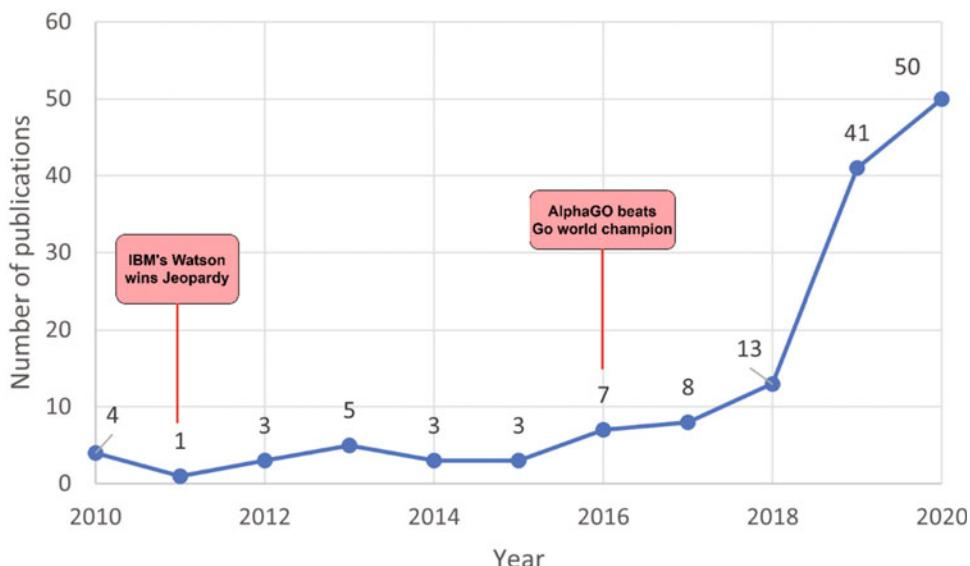

Fig. 2 Number of studies of artificial intelligence in rheumatology on PubMed (between 2010 and 9 November 2020). Search query: ((“rheumatology”[Title/Abstract] OR “rheumatic”[Title/Abstract] OR “rheumatoid”[Title/

Abstract]) AND (“machine learning”[Title/Abstract] OR “artificial intelligence”[Title/Abstract] OR “deep learning”[Title/Abstract]))

such as diagnosis, prognosis prediction, or medical image analysis. Research and clinical applications of AI, including machine learning and deep learning, in rheumatology, are rare, but the number and diversity of AI research in the field has been raised during the last decade (Fig. 2).

In the following paragraphs, we discussed recent publications in the field relevant to AI. We categorize the publications according to the data types: electronic health records, genetic data or biomarkers, medical images, and mixed types of data (listed in Table 1).

Application in Electronic Health Records

The EHRs can be a valuable tool for conducting research studies on rheumatology patients’ disease, treatment, and outcomes since EHRs contain a tremendous amount of patient information. AI models that trained from EHRs have been increasingly adopted as a disease detector or a predictor. For instance, Lötsch et al. [1] assemble machine learning algorithms to identify the predictors

associated with the development of persistent pain in RA. A Gaussian mixture model (GMM) was applied to identify the three distinct pain intensity subgroups (low, median, and high persistent). After the unsupervised clustering, a random forest was used to select predictive parameters from clinical data to train machine learning classifiers. Classifiers trained with selected parameters provided pain group assignment at a balanced accuracy of 70%. Identification of RA patients in primary care EHR is clinically essential for prompt treatment. In order to diagnose RA at an early stage, the eDRAM (early disease risk assessment) framework was proposed for finding important risk factors from a large-scale EHR database by nonnegative matrix factorization (NMF) and performing SVM for disease risk assessment [2]. The eDRAM was evaluated in a cohort of 1,007 RA-diagnosed patients and 921,192 control patients. The result shows that the eDRAM had an accuracy of 72% with 200 risk factor inputs. The other study applied the random forest model to identify the most informative predictors to detect RA patients from primary care EHRs [3]. The model identified eight predictors,

Table 1 Artificial intelligence studies in rheumatic diseases

Input type	Applications	AI methods	Optimal result	Ref.
Electronic health records	Identify the predictors associated with the development of persistent pain in rheumatoid arthritis	Gaussian mixture model	Balanced accuracy: 70%	[1]
	Diagnose rheumatoid arthritis at an early stage	Nonnegative matrix factorization, support vector machine	Accuracy: 72%	[2]
	Identify the most informative predictors to detect rheumatoid arthritis patients	Random forest model	Eight predictors were identified	[3]
	Identify systemic lupus erythematosus cases from electronic health record data	L1-regularized logistic regression	AUROC: 0.97	[4]
	Detect the occurrence of osteoarthritis from health behavior survey data	Deep neural network	AUROC: 0.768	[5]
	Mortality prediction	Random survival forests	Specificity: 0.8, sensitivity: 0.48	[6]
	Predict radiographic progression in patients with axial spondyloarthritis	Support vector machine	Average AUROC: 0.78	[7]
	Predict readmission risk to an outpatient rheumatology clinic	Random forest	AUROC: 0.653	[8]
	Forecast the state of disease activity of rheumatoid arthritis patients	Recurrent neural network	AUROC: 0.91	[9]
	Predict hospital readmission for lupus patients	Long short-term memory network	AUROC: 0.7	[10]
Genetic and biomarker data	Identify evidence of gout flares from the medical records	Natural language processing and support vector machine	Sensitivity, 82.1%; specificity, 91.5%	[11]
	Identify rheumatoid arthritis cases from medical records	Support vector machine	AUROC: 0.966	[12]
	Identify systemic lupus erythematosus cases from medical records	Penalized logistic regression	Specificity, 97%, sensitivity, 60%	[13]
	Identify key biomarkers to discriminate between healthy people and seropositive rheumatoid arthritis patients	Artificial neural network	Accuracy: 83.3%	[14]
	Identify biomarkers associated with ultrasonography-detected erosive arthritis	Logistic regression, decision trees	Six biomarkers were identified	[15]

(continued)

Table 1 (continued)

Input type	Applications	AI methods	Optimal result	Ref.
	Stratify patients with systemic lupus erythematosus based on gene expression signatures	k-means clustering, support vector machine	Accuracy: 88%	[19]
	Stratify patients with juvenile-onset systemic lupus erythematosus	Balanced random forest	Accuracy of 90.9%	[20]
	Distinguish methotrexate therapeutic nonresponders from responders	L2-regularized logistic regression	AUROC: 0.78	[21]
	Predict systemic lupus erythematosus disease activity	Random forest	Accuracy: 83%	[22]
Medical images	Detect and estimate geometric and texture features of synovium thickening and bone erosion	Support vector machine	Accuracy: 92.50%	[23]
	Rheumatoid arthritis image grading	Convolutional neural network	Accuracy: 92.50% and 95% in two datasets	[24]
	Osteoarthritis image severity grading	Assembled DenseNet	Sensitivity, 86.0%; specificity, 99.1%	[25]
	Scoring of rheumatoid arthritis activity from Doppler ultrasound images	Convolutional neural network	Accuracy: 75.0%	[26]
	Diagnose hip osteoarthritis from X-ray images	Convolutional neural network	Accuracy of 92.8%	[27]
	Diagnose knee osteoarthritis from X-ray images	Siamese convolutional neural network	AUROC: 0.93	[28]
	Detect cartilage lesions at MRI for osteoarthritis diagnosis	Convolutional neural network	AUROC: 0.91	[29]
	Distinguish between eroded and not eroded joints	Convolutional neural network	Balanced accuracy of 47.5%	[30]
	Quantify the difference between healthy and eroded image patches	U-net, Siamese convolutional neural network	–	[31]
	Detect low bone mineral density using plain hip radiographs	Deep texture encoding network	Sensitivity, 91.11%; specificity, 86.08%	[32]
Mixture data	Assess the radiographic bone texture in the distal metacarpal bone relevant to rheumatoid arthritis	Graph convolutional network, deep texture encoding network	AUROC: 0.68	[33]
	Detect radiographic osteoarthritis	Deep texture encoding network, ResNet18	Positive predictive value: 81.37% for deep-TEN, 87.46% for ResNet18	[34]
	Identify synovial subtype, and determine the synchrony between synovial histologic features and their genomic subtypes	k-means clustering, support vector machine	AUROC: 0.88 for high inflammatory subtype, 0.71 for high inflammatory subtype, 0.59 for mixed subtype	[35]
	Predict treatment responses in rheumatoid arthritis patients	Gaussian process regression	AUROC: 0.66	[36]
	Predict osteoarthritis progression	Multimodal machine learning	AUROC: 0.79	[37]

including diagnostic codes for RA, medication codes, and absence of alternative diagnoses. Murray et al. [4] trained an L1-regularized logistic regression with the EasyEnsemble method on a noisy labeled dataset to automatically identify SLE cases from EHR data. The final model achieved an AUROC of 0.97. In addition to image-based deep learning algorithms on automatically detecting osteoarthritis (OA), Lim et al. [5] used a DNN with scaled principal component analysis (PCA) to detect the occurrence of OA from health behavior survey data. Their experiments show that the DNN with scaled PCA resulted in 76.8% of AUROC and minimized the effort to generate features.

In terms of prognosis or outcome prediction, a mortality prediction model using the random survival forests (RSF) was developed by Lezcano-Valverde et al. [6]. The RSF model identified five mortality risk groups and has a specificity of 0.8 and a sensitivity of 0.48 in the validation cohort. Joo et al. [7] carried out a retrospective and hospital-based study to evaluate seven machine learning-based models on predicting radiographic progression in patients with axial spondyloarthritis (axSpA). The SVM was the top best-performing models (average AUROC was over 0.78) in their study. Prevention of readmission is an important task in RA patient management. Madrid-García et al. [8] developed a random forest model from departmental EHR data for predicting readmission risk to an outpatient rheumatology clinic between 2 and 12 months after discharge. The final model's performance was AUROC of 0.653 on a chronologically split test dataset. Additionally, to leverage longitudinal data in EHR, the RNN has been widely adopted in recent years. Norgeot et al. [9] assessed the ability of an RNN to forecast the state of disease activity of RA patients at their next clinical visit. The predictive model reached an AUROC of 0.91 in a test cohort of 116 patients. Another example is applying long short-term memory (LSTM), a type of RNN, to predict hospital readmission for lupus patients. The LSTM has a better performance compared to traditional ANN (0.7 AUROC vs. 0.66 AUROC) [10].

Most of the clinical information in EHRs is unstructured narrative; therefore, various studies explored the integration of natural language processing (NLP) and ML techniques to unleash the power of EHRs in rheumatology research. Zheng et al. [11] developed an automatic tool that combines NLP and ML algorithms for identifying evidence of gout flares from the EHRs. This tool was evaluated using over 590,000 clinical notes; it identified 18,869 clinical notes as gout flare positive with a sensitivity of 82.1% and a specificity of 91.5%. Carroll et al. [12] trained an SVM model based on a refined set of EHR features containing ICD-9 codes, medication exposures, and NLP-derived information for identifying RA cases. Their study demonstrated that compared to naïve collections of EHR features, using a refined set of features to train an SVM can achieve slightly better performance (AUROC of 0.966 on refined dataset vs. AUROC of 0.956 on naïve dataset) and required relatively fewer cases (50–100 training samples are required) on RA patient identification. Jorge et al. [13] used penalized logistic regression to identify SLE cases from EHRs. However, it is worth noting that, as a result, adding SLE-related concepts extracted from unstructured data via NLP did not improve the model's performance.

Application in Genetic and Biomarker Data

Much research effort has been focused on the discovery of biomarkers that enable early diagnosis of RA. Nowadays, artificial intelligence has become a powerful tool in biomarker discovery. Chocholova et al. [14] performed data mining using ANN on serum sample data to identified key biomarkers, which can discriminate between healthy people and seropositive RA patients with an accuracy of 83.3%. In another study, logistic regression and decision trees with the forward wrapper feature selection method were applied to a cohort of 120 SLE patients to identify biomarkers associated with ultrasonography-detected erosive arthritis. There were six features selected by the machine learning models,

including anti-CarP, ACPA, arthralgia, Jaccoud's arthropathy, anti-Sm, and neurological manifestations. Their further analysis reveals that ACPA and anti-CarP antibodies have a relatively higher importance in developing erosive damage [15].

Next-generation sequencing (NGS) and transcriptomics provide an unprecedented genome-wide view of gene expression in rheumatology research. Poppenberg et al. [16] trained four different machine learning models with transcriptomes from peripheral blood mononuclear cells (PBMCs) for predicting juvenile idiopathic arthritis stage. Random forest outperformed other models with an AUROC of 0.94 on an independent testing cohort of 14 samples. To predict psoriatic arthritis (PsA) risk among psoriasis patients by genetic signature, Patrick et al. [17] adopted machine-learning techniques for genetic architecture subtype prediction and risk assessment. The PsA prediction model achieved > 90% precision with a specificity of 100%. Supervised machine learning classifiers were also employed to aid clinical decision-making. For example, Franks et al. [18] conducted a study on identifying four intrinsic gene expression subsets of systemic sclerosis (SSc). They built multinomial elastic net (GLMnet), SVM, and random forest classifiers with gene expression data of 297 skin biopsy samples that merged from three independent cohorts. The external validation shows that GLMnet achieved the best accuracy of 85.4%. In a study of stratification of patients with SLE based on gene expression signatures derived from whole-blood transcriptomic data, machine learning methods including k-means clustering and SVM with error-correcting output code (ECOC) framework were performed as a new stratification scheme. The classifier was trained to learn the transcriptomic signatures of each cluster and accurately classify new patients with an accuracy of 88% [19]. Another study related to SLE stratification was conducted by Robinson et al. [20]. This retrospective study collected 67 patients with juvenile-onset SLE and 39 healthy controls. A balanced random forest (BRF) model was built for discriminating patients with juvenile-onset SLE from healthy

controls with a prediction accuracy of 90.9%. A highly predictive classifier of methotrexate (MTX) nonresponse was developed by Plant et al. [21] using L2-regularized logistic regression. This predictive model has an AUROC of 0.78 on distinguishing therapeutic nonresponders from responders using whole-blood transcript expression data. The high degree of SLE gene expression heterogeneity among patients and study cohorts is challenging SLE disease activity prediction. Kegerreis et al. [22] established a random forest classifier to integrate gene expression data from three SLE datasets and used it to predict SLE disease activity. The classifier achieved a peak classification accuracy of 83% under tenfold cross-validation.

Application in Medical Images

Medical imaging is essential in the diagnosis and staging of RA disease. There is a long history of classic machine learning methods in rheumatology imaging, and recently there have been many studies adopted deep learning approaches to solve more complex problems. The grading evaluation of metacarpophalangeal (MCP) RA ultrasonic images heavily relies on trained sonographers' expertise. Yang et al. [23] proposed a computer-aided grading method for detecting and estimating geometric and texture features of synovium thickening and bone erosion. They extracted quantitative feature metrics and texture features from the region of interest (ROI) of RA ultrasound images. The SVM classifier, trained with ROI feature descriptor, provides the highest accuracy of 92.50% on classifying four grading MCP RA ultrasonic images.

In contrast to feature engineering and classic machine learning, deep learning automatically learns texture and image context features from training data. Tang et al. [24] developed an automatic RA grading method using deep CNN architecture. The model takes gray-scale ultrasound images of MCP and proximal-interphalangeal (PIP) joints as inputs and then outputs the corresponding RA grading results. The deep CNN-based RA grading model achieves

satisfactory accuracy (90.3% in MCP dataset and 95% in PIP dataset, respectively), comparable to RA experts in four-grade classification.

Radiographic scoring systems play an important role in the evaluation of the progression and treatment of RA. Kellgren-Lawrence (KL) grading system is widely used for clinical assessment and diagnosis of OA. Norman et al. [25] grouped KL grades into four degrees of OA severity (KL 0–1 are no OA; KL 2–4 represent mild, moderate, and severe OA, respectively) and developed an assembled DenseNet with over 4,000 bilateral PA fixed-flexion knee radiographs to make OA assessments. This assembled DenseNet's testing sensitivity and specificity of no OA were 83.7% and 86.1%; mild OA was 70.2% and 83.8%; moderate OA were 68.9% and 97.1%, and severe OA was 83.7% and 99.1%, respectively. In addition, the saliency map analysis showed that the assembled DenseNet could correctly identify relevant features within a radiographic image that are used to make OA assessments, such as joint space narrowing and osteophytes. In another example of AI application in the radiographic scoring system, a study conducted by Andersen et al. [26] showed that CNN could be used in the scoring of RA activity from Doppler ultrasound images according to the OMERACT-EULAR Synovitis Scoring (OEES) system. A total of 1,694 Doppler ultrasound images were used in this study. The CNN model achieved an average per class (OEES scores of 0–3) accuracy of 75.0%.

With the advantage of machine learning, various studies developed the computer-aided diagnosis tool of OA in medical imaging in rheumatology. A deep CNN was trained and tested on 420 hip X-ray images to diagnose hip OA. The CNN model performance is comparable to an attending physician with 10 years of experience with an accuracy of 92.8% [27]. Knee OA is another common musculoskeletal disorder in RA patients. Tiulpin et al. [28] trained a deep Siamese CNN using 18,376 plain radiographs and validated it on 5,960 images from another independent cohort. The images in both cohorts were graded according to the KL grading system. The model yielded an AUROC of 0.93 for OA

diagnosis ($KL \geq 2$). Developing standardized computer-based methods for detecting cartilage lesions at MRI would be beneficial to OA diagnosis because cartilage loss is relevant for OA. A fully automated deep CNN-based cartilage lesion detection system was developed by Liu et al. [29]. The result from two individual evaluations showed that the AI-based diagnosis tool has an overall diagnostic AUROC of 0.91 and good intraobserver agreement with a k statistic of 0.76.

Recently deep learning has been adopted to detect bone erosions. Bone erosion is a peri-inflammatory destructive bone lesion that is associated with RA severity and poor functional outcome. As RA progresses, the marginal erosions become visible on X-ray images. A deep CNN model was leveraged by Rohrbach et al. [30] to distinguish between eroded and not eroded joints. A limited accuracy (balanced accuracy of 47.5%) was achieved due to the high data imbalance. Besides the X-ray images, the high-resolution peripheral quantitative computer tomography (HRpQCT) is a promising tool to quantify the shape, volume, and surface area of erosions. Ren et al. [31] employed deep neural networks on HRpQCT scans to do segmentation of bone surface boundary and classification of the difference between healthy and eroded image patches. Patients with RA are at increased risk of developing osteoporosis. Kuo et al. investigated the potential of a deep texture encoding network (Deep-TEN) model for the low bone mineral density (BMD) estimation [32]. The Deep-TEN model was also used to assess the radiographic bone texture in the distal metacarpal bone [33] relevant to RA and knee OA [34].

Application in Mixture Data

Some studies in machine learning using integrated multi-type data for rheumatology research, instead of using a single type of data along. Orange et al. [35] employed k-means clustering and SVM on synovial histologic feature data and RNA sequencing data to identify three distinct molecular subtypes of RA synovial tissue correlated with specific clinical

phenotypes. To accurately predict treatment responses in RA patients, based on clinical profiles with additional genetic information, the Gaussian process regression model was shown to be the best performer that was correctly predicting 78% of 680 subjects' treatment response, with an AUROC of 0.66 [36]. In addition to multi-type data integration, multimodal machine learning is an alternative way to analyze the mixed data types. Tiulpin et al. [37] developed a multimodal machine learning-based OA progression prediction model. The model fused the predictions of KL grade, and disease progression from a CNN model and patient's characteristics, surgery history, and symptomatic assessment results by a gradient boosting machine classifier. The model yielded an AUROC of 0.79, which is better than a reference logistic regression (AUROC of 0.75).

Future Perspectives and Challenges

In general, the adoption of new technology such as AI in rheumatology lags behind the popularity of AI in other industries and subspecialties. Despite this, the introduction of AI to the field has produced much interesting research proving that AI can positively impact rheumatology. The application of AI focuses on the extraction and interpretation of EHRs, medical imaging, and handling of genetic and immunophenotyping data, and only selected disease categories have been exposed to AI/ML. In the coming years, AI will inevitably have a greater impact on rheumatology's research and clinical practice. However, unique challenges will emerge in the process of applying AI/ML models in rheumatology.

First, the diagnoses of rheumatic diseases are notoriously difficult owing to the need for multiple diagnostic modalities and dependence on physicians' or patients' subjective observations. For example, EULAR/ACR classification criteria for RA include the number of joint involvement and duration of symptoms, both of which are subject to detailed medical history-taking; however, the validation studies of the criteria found the

sensitivities from 0.50 to 0.60 and specificities from 0.88 to 0.97 [38]. This caveat needs to be considered for AI applications based on subjective data or those designed to assist the diagnosis of rheumatic diseases.

Second, many rheumatic diseases are relatively rare compared to common diseases. Systemic sclerosis, for example, has a prevalence ranging from 3.8 to 50 per 100,000 population [39]. Therefore, it is difficult to obtain enough high-quality data to support AI/ML models' training. In this regard, applying specific techniques to overcome the paucity of data is needed, such as fine-grained annotation, few-shot learning, or data augmentation.

Third, rheumatic diseases often have multi-organ involvement, so many patients need multidisciplinary care. For instance, patients with psoriatic arthritis need collaborative care by rheumatologists and dermatologists. The design of AI-assisted systems for these diseases need to consider the gaps in patient management between different subspecialties. The clinical heterogeneity may require researchers/developers to collect data from involved subspecialties, consult relevant experts, or update the model before applying it in a new clinical context.

Conclusions

The clinical application of AI/ML is still in infancy despite a growing number of high-quality research demonstrating the potential to support research and clinical work in rheumatology. The adoption of new technology needs to consider the general medical and subspecialty-specific caveats to maximize the benefits of AI/ML that may impact rheumatology care.

Abstract

In this chapter, we explore and evaluate methods for trabecular bone characterization and osteoporosis diagnosis with increased interest in sparse approximations. We first describe texture representation and classification techniques, patch-based methods such as Bag of Keypoints, and more recent deep neural

networks. Then we introduce the concept of sparse representations for pattern recognition and we detail integrative sparse analysis methods and classifier decision fusion methods. We report cross-validation results on osteoporosis datasets of bone radiographs and compare the results produced by the different categories of methods. We conclude that advances in the AI and machine learning fields have enabled the development of methods that can be used as diagnostic tools in clinical settings.

Fracture risk

Introduction

Osteoporosis is a skeletal disorder characterized by decreased bone strength that may lead to susceptibility of fracture [1]. There are more than 3 millions of people diagnosed with osteoporosis in the USA per year. The risk is increasing with age, especially the people who are over 40. Timely diagnosis of osteoporosis can effectively predict fracture risk and allow for effective treatment.

Trabecular bone characterization and automated and accurate diagnosis of bone osteoporosis is significant for improving public health. Aerial Bone Mineral Density (BMD) is computed in dual-energy X-ray absorptiometry (DXA) scans to diagnose osteoporosis [2]. However, BMD can predict fracture with only 60% accuracy. Analysis of trabecular bone micro-architecture can significantly improve the prediction rates, but this information requires bone biopsy with histomorphometric analysis. The task of obtaining trabecular bone micro-architecture information by noninvasive methods is a nontrivial scientific problem [3]. Diagnosis of osteoporosis using bone radiograph scans presents some challenges, mainly because images of osteoporotic and healthy subjects are visually very similar. Previous approaches to evaluating bone structure on radiographs by 2D texture analysis were reported in [2, 4, 5]. Moreover, in [6, 7] the authors propose to use 2D texture analysis to characterize 3D bone microarchitecture.

Here we present and evaluate mathematical methods and algorithms for computer-aided diagnosis. The application domain is osteoporosis diagnosis in radiographs of the calcaneus bone. We will explore the use of sparse modeling and classification for classifying diseased from healthy subjects. Then we will present ensemble sparse techniques to find more accurate solutions than individual classification techniques. We will also test other classification techniques based on texture features, or patch-based techniques such as the Bag of Keypoints and deep learning methods.

Methods

Nonsparse Classification Techniques: Texture-Based, Patch-Based, and Deep Learning

Introduction to Texture-Based Classification

Texture is an image property that can be used for segmenting and classifying images into different objects. We can define texture as a structure consisting of a group of related elements [8]. The pixels in this group are called texture primitives, texture elements, or texels.

Texture analysis techniques are mainly applied to texture recognition and texture-based shape analysis [8]. Generally, people consider texture as fine when the texture element is small and there are large differences between elements, and coarse when the element is large and there are only few elements in the image, grained and smooth. For scientific applications of texture, we use more precise characteristics such as tone and structure [9]. Tone is more about pixel intensity and structure is about the spatial relationship between texture elements. There are many methods for texture extraction, such as wavelet analysis, Gabor filters, co-occurrence matrices, intensity histogram-based, and spatial frequency domain descriptors.

We present texture-based methods for computer-aided diagnosis of diseased and healthy subjects [10]. Our premise is that the deterioration of disease can be captured by textural features. We first computed texture features based on wavelet decomposition, discrete Fourier and Cosine transforms, fractal dimension, statistical co-occurrence indices, and structural texture descriptors. We employed feature selection techniques that consider the individual feature predictive ability and inter-feature redundancy to find the most discriminant feature set. In the classification stage, we employed Naïve Bayes, Multilayer Perceptron, Bayes Network, Random Forests, and Bagging models for diagnosis.

Feature Computation The purpose of this stage is to compute texture descriptors that can be used for separation between groups of healthy and diseased subjects. This is usually performed

in a high-dimensional feature space to reduce the Bayes error rate. Next, we describe frequently used feature sets.

Fractal Dimension These features have shown promise in texture classification applications. A fractal is defined as a mathematical set whose Hausdorff dimension exceeds the fractal's topological dimension [11]. It has been shown that fractal dimension correlates well with a function's roughness. Therefore, we used fractal dimension to measure the roughness and granularity of the image intensity function. The topological dimension of this function is equal to 3, consisting of 2 spatial dimensions plus the intensity.

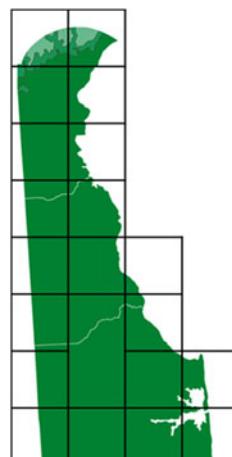

The method of box counting can be utilized to compute the fractal dimension. Assuming a fractal structure with dimension D , we let $N(\epsilon)$ be the number of nonempty boxes of size ϵ required to cover the fractal support. Using the relation $N(\epsilon) \simeq \epsilon^{(-D)}$, we can numerically estimate D from

$$D = \lim_{\epsilon \rightarrow 0} \frac{\log N(\epsilon)}{-\log \epsilon} \quad (1)$$

by least squares fitting. We display an example of application of box counting in Fig. 1.

For the case of grayscale images or continuous functions, we generated eight binary sets using multiple Otsu thresholding, then computed the fractal dimension, area, and mean intensity for each point set as in [12].

Fig. 1 Box counting to compute the fractal dimension of Delaware state boundary

Wavelet Texture Descriptors A multiscale texture descriptor is usually very useful for classification. Gabor filter banks and wavelet transforms are both multiscale spatial-spatial frequency filtering techniques. The discrete wavelet transform is frequently applied using tree or pyramid hierarchies for texture representation. Multiband analysis offers advantages over the traditional discrete Fourier transform, but wavelet transform does not produce as exact a result as the Fourier transform.

Discrete Wavelet Frames Discrete wavelet frames employ a filter bank for multiscale decomposition. The Haar wavelet with a low-pass filter

$$H(z) = (1 + z^{-1})/2 \quad (2)$$

and a corresponding high-pass filter

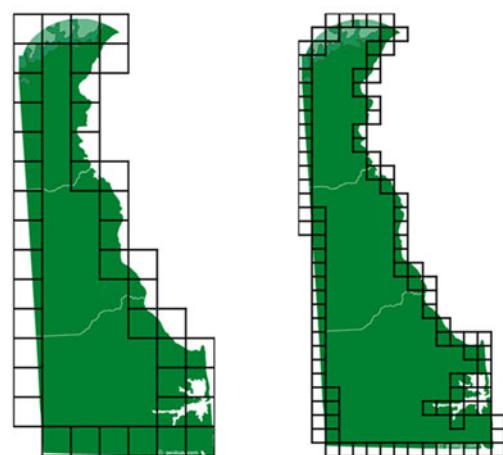

$$G(z) = (1 - z^{-1})/2 \quad (3)$$

is frequently used because of its efficiency and computational simplicity.

The largest filter kernels will have size $2^{maxlevel}$, where the $maxlevel$ is the number of multiresolution levels. At each level, we filter the image by using the filter combinations:

$$H_x H_y, H_x G_y, G_x H_y, G_x G_y, \quad (4)$$

where H_x is the low-pass filter along the x direction and G_y is the high-pass filter along the y direction.

To produce the wavelet frame representation, we compute the discrete wavelet transform for all possible signal shifts at multiple scales. The filters are used to decompose the image into subbands. We compute the orthogonal projections and residuals for a full discrete wavelet expansion. We then compute energy, variance, entropy, contrast, skewness, and kurtosis signatures to form the texture descriptor. These characteristics are calculated as follows.

Contrast It measures the intensity contrast between a pixel $p(i, j)$ and its neighbors in an image by

$$\sum_{i,j} |i - j|^2 p(i, j) \quad (5)$$

Energy It is expressed by the sum of squared elements

$$\sum_{i,j} p(i, j)^2 \quad (6)$$

Skewness It measures the lack of symmetry. For a random variable x , the skewness is the third standardized moment γ_1

$$\gamma_1 = E\left[\left(\frac{X-\mu}{\sigma}\right)^3\right] = \frac{\mu_3}{\sigma^3} = \frac{E[(X-\mu)^3]}{\left(E[(X-\mu)^2]\right)^{3/2}} = \frac{k_3}{k_2^{3/2}} \quad (7)$$

where μ is mean, σ is standard deviation, μ_3 is central moment, E is expectation operator, and k_i is the i th cumulants.

Kurtosis It measures the degree to which data points follow a heavy-tailed or light-tailed distribution. Higher kurtosis values correspond to heavier-tailed distributions.

$$Kurt[X] = E\left[\left(\frac{X-\mu}{\sigma}\right)^4\right] = \frac{\mu_4}{\sigma^4} = \frac{E[(X-\mu)^4]}{\left(E[(X-\mu)^2]\right)^2} \quad (8)$$

Entropy It presents the state of a system, such as the disorder and randomness of the system. The wavelet entropy is defined in [13] as

$$S(p) = -\sum_j p_j \ln p_j \quad (9)$$

Wavelet Gabor Filter Bank The Gabor filter is a linear filter that can extract relevant characteristics for multiple frequencies and orientations (Fig. 2), similarly to the human visual system.

Gabor functions form a complete but non-orthogonal basis. In the spatial domain, a 2D Gabor filter is a Gaussian kernel function modulated by a sinusoidal plane wave. Gabor filters are often used for texture identification, and good results have been achieved. The filter is represented in complex form as follows:

$$g(x, y; \lambda, \theta, \psi, \sigma, \gamma) = \exp\left(-\frac{w^2 + \gamma^2 v^2}{2\sigma^2}\right) \exp\left(i\left(2\pi\frac{w}{\lambda} + \psi\right)\right) \quad (10)$$

and

$$w = x \cos \theta + y \sin \theta \quad (11)$$

$$v = -x \sin \theta + y \cos \theta \quad (12)$$

where λ is the wavelength of the sinusoidal factor, θ is the orientation of the normal to the parallel stripes of a Gabor function, ψ is the phase offset, σ is the standard deviation of the Gaussian envelope, and γ is the spatial aspect ratio.

The filter dictionary can be produced by dilations and rotations of the mother Gabor wavelet.

Local Binary Patterns (LBP) For each pixel pix in the image, we compare the intensity of pix to the intensities of its eight neighbors. If the intensity of pix is greater or equal to its i th (where $i = 1, 2, \dots, 8$) neighbor, we set $b_i = 0$, otherwise $b_i = 1$. From these eight neighbors, we construct an eight-digit binary number $b_1 b_2 b_3 b_4 b_5 b_6 b_7 b_8$. We use the histogram of these numbers as a texture descriptor [14].

Discrete Fourier and Cosine Transforms The Discrete Fourier transform and the Discrete Cosine transform coefficients aim to capture characteristics of texture in the spatial frequency domain. For example, fine texture has greater high frequency components, whereas coarse texture is represented

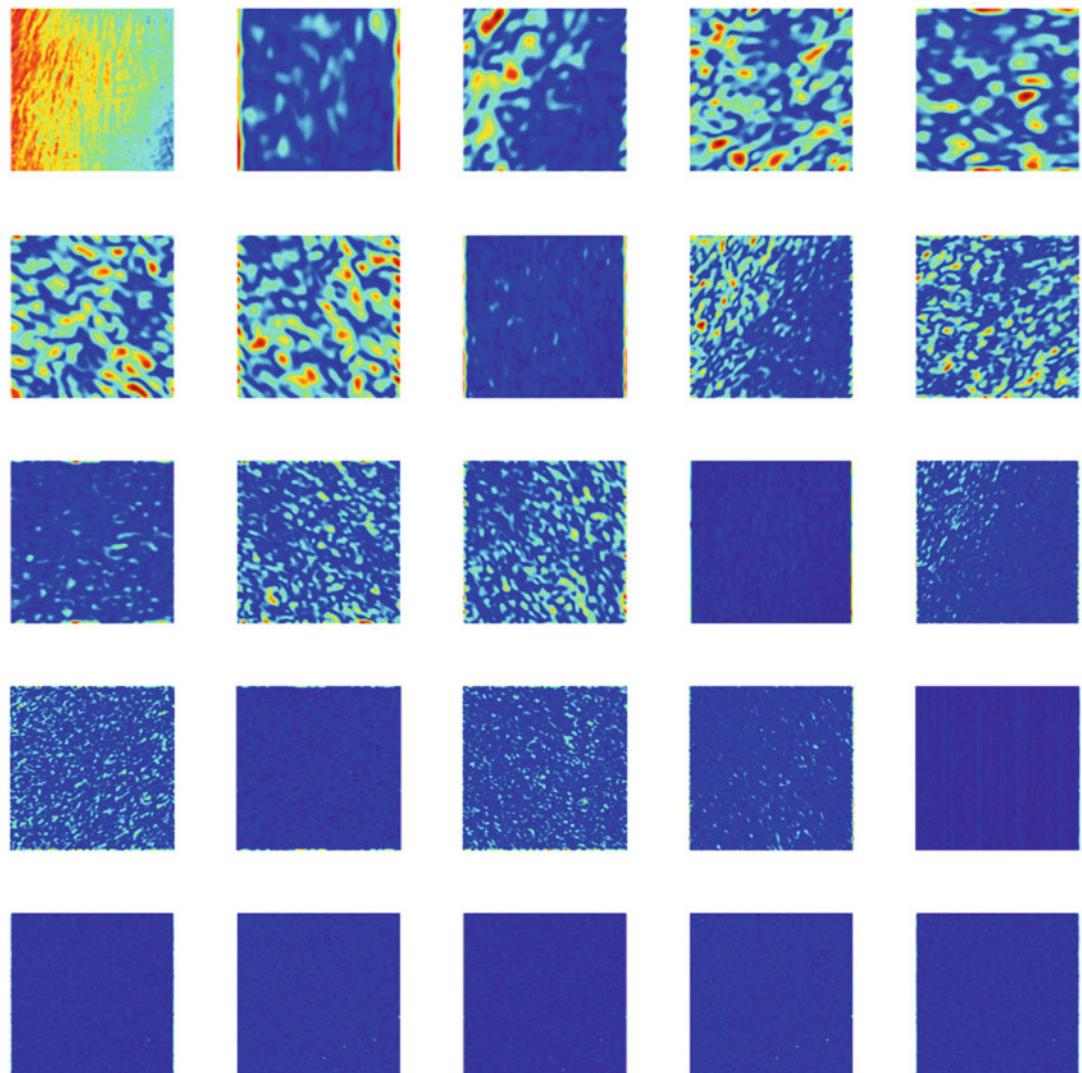

Fig. 2 The original bone radiograph and the Gabor texture components of a healthy subject using four scales and six orientations. The 24 components are calculated on the original image in top left. While these maps pronounce

by lower frequencies. The Discrete Fourier and Cosine transforms are defined as follows,

Discrete Fourier transform (DFT):

$$F(k, l) = \frac{1}{MN} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} f(m, n) \cdot e^{-j2\pi(\frac{mk}{M} + \frac{nl}{N})}, \quad (13)$$

where $f(m, n)$ is the pixel intensity at (m, n) , and $k = 0, 1, 2, \dots, N-1, l = 0, 1, 2, \dots, M-1$.

the texture characteristics, visual interpretation is still particularly challenging. Therefore, a machine learning technique is needed to distinguish healthy from osteoporotic subjects

Discrete Cosine Transform (DCT) uses only cosine basis functions:

$$C(k, l) = \sqrt{\frac{\alpha}{MN}} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} f(m, n) \cdot \cos \frac{\pi(2m+1)k}{2M} \cos \frac{\pi(2n+1)l}{2N}, \quad (14)$$

where $\alpha = 1$, if $k = l = 0$; $\alpha = 4$, if $1 \leq k \leq M-1, 1 \leq l \leq N-1$.

We use the 8×8 coefficients corresponding to lower frequencies for classification.

Law's Texture Energy Masks The texture energy is computed by a set of 5×5 convolution masks (level, edges, waves, spots, and ripples) to measure the amount of variation within a fixed-size window. We use the average level (intensity) feature to normalize intensity range and then we use the remaining 24 components to form the texture vector. Next, we calculate the mean, variance, energy, skewness, kurtosis, and entropy for each component.

Edge Histogram We compute the intensity gradient magnitude $|\nabla f|$ and then calculate its histogram by

$$p_{|\nabla f|}(|\nabla f| = r_k) = \frac{n_k}{N}, k = 0, \dots, L - 1 \quad (15)$$

$$\nabla f = \left(\frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial x_2}, \dots, \frac{\partial f}{\partial x_N} \right)^T \quad (16)$$

Gray Level Co-Occurrence Matrix (GLCM)

The GLCM calculates how the frequency of occurrence of gray-level pairs (i, j) in horizontal, vertical, or diagonal pixel adjacencies on the image plane, displayed in Fig. 3. Horizontal (0°), vertical (90°), and diagonal (-45° , -135°) dimensions of analysis are denoted by P_0 , P_{90} , P_{45} , and P_{135} , respectively. After we create the GLCMs, we compute contrast, correlation, energy, and homogeneity measures.

Feature Selection This classification component aims to select relevant and informative

features for classification. It is applied to improve classification performance, to reduce computational complexity, and to interpret data.

Correlation-based Feature Selection (CFS)

This method selects features that are highly correlated with the pattern classes, but have low correlation with the remaining features. The subset evaluation function is given by:

$$Merit_S = \frac{\bar{k}_{rf}}{\sqrt{k + k(k-1)r_{ff}}} \quad (17)$$

where $Merit_S$ is the merit of the selected feature set S , \bar{k}_{rf} is the mean correlation between the features and class with $f \in S$, and r_{ff} is the mean pairwise feature correlation. The numerator expresses predictive capacity, while the denominator expresses feature redundancy.

Best First Search (BF) Searches the space of feature subsets by greedy hillclimbing that may include backtracking. Best first may search forward, or backward, or, consider all possible single feature additions and deletions at a given point using a bi-directional strategy.

Genetic Algorithm-based Search (GA) Genetic search works by having a population of variables representing feature sets and performs the operations of reproduction, cross-over, and mutation in each generation to get the offspring that optimizes a feature set-related objective function.

Information Gain (IG) This function measures the information gain with respect to the class:

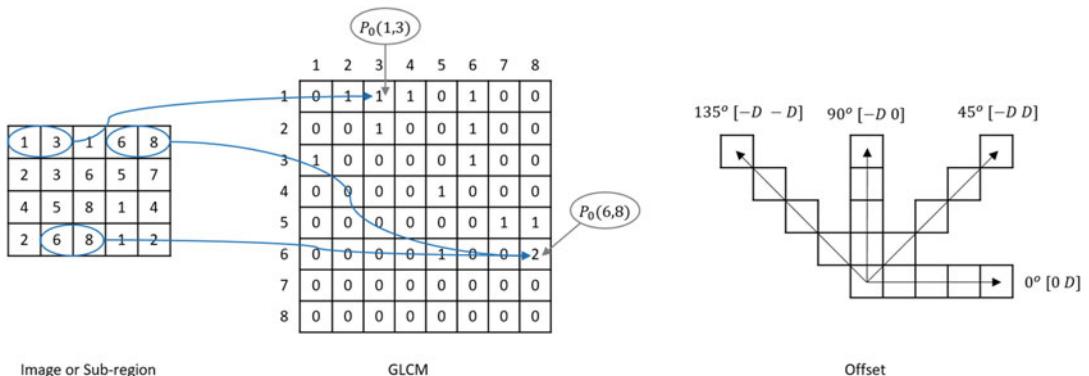

Fig. 3 Process used to create the GLCM (left) and Offset of GLCM (right)

$$\begin{aligned} \text{InfoGain(Class, Attribute)} \\ = H(\text{Class}) - H(\text{Class}|\text{Attribute}) \end{aligned} \quad (18)$$

where H is the entropy of each class given by $H(\text{Class}) = -p_{\text{Class}} \log p_{\text{Class}}$. We select the attributes by individual ranking evaluation.

Ranker Using Ranker as a search means that we will rank the features based on the features' individual evaluations. A threshold can be set in Ranker, and features that are smaller than this threshold will be removed from the feature set. Ranker is used with attribute evaluators, such as Information Gain (IG), feature selection and entropy, etc.

Classifiers and Discriminant Functions

Naïve Bayes (NB) This model assumes conditional statistical independence $p(x|\omega_j) = \prod_{k=1}^D p(x_k|\omega_j)$ where $x = (x_1, x_2, \dots, x_D)^T$ and D is the dimensionality of the feature space. The posterior probability is based on Bayes' formula:

$$p(\omega_j|x) = \frac{p(x|\omega_j)P(\omega_j)}{p(x)}.$$

The MAP decision rule is typically used for classification. Suppose we have two categories ω_1 and ω_2 with discriminant functions $g_1(x)$, $g_2(x)$, where

$$\begin{aligned} g_i(x) = -\frac{1}{2}(x - \mu_i)^T \sum_i^{-1} (x - \mu_i) + \frac{D}{2} \ln 2\pi \\ - \frac{1}{2} \ln \left| \sum_i \right| + \ln P(\omega_i). \end{aligned}$$

Then we can define a single discriminant function by

$$g(x) = g_1(x) - g_2(x).$$

The decision rule is:

$$\begin{cases} \omega_1, & \text{if } g(x) > 0 \\ \omega_2, & \text{if } g(x) < 0 \end{cases}.$$

Multilayer Perceptron (MLP) A multilayer perceptron is a feedforward artificial neural

network system that maps input patterns onto class labels. An MLP has multiple layers of nodes that are fully connected to the next layer. Each node is a neuron with a nonlinear activation function. MLP utilizes backpropagation for supervised learning [15, 16]. Because MLP has multiple layers of logistic regression models, it can distinguish data that are not linearly separable. In learning by backpropagation that can be considered as an extension of the LMS algorithm, we adjust the connection weights, according to the amount of error in the output compared to the expected result.

Bayes Network (BN) A Bayes network is a probabilistic graphical model that uses a directed acyclic graph to represent a set of random variables and their conditional dependencies. In a Bayesian network, the joint probability density function can be written as the product of univariate conditional density functions dependent on their parent variables:

$$p(x) = \prod_{v \in V_p} (x_v | x_{pa(v)}) \quad (19)$$

where $pa(v)$ denotes the parents of v . In the graph, the parents are vertices directly connected to v by a single edge.

Bagging For a training set S with size k , Bagging generates j training subsets denoted as S_i with size $k' < k$, by sampling from S uniformly and with replacement. We denote the original set as A . In the training stage, we first have $D = \emptyset$ and j is the number of classifiers to train. Then for $p = 1, 2, \dots, j$, we take a bootstrap sample S_p from A to train classifier D_p . Then the classifier D_p is added to the current ensemble, $D = D \cup D_p$. The class label prediction for the input x is obtained by majority voting on the individual classifier decisions produced by D_1, \dots, D_j [16].

Random Forests (RF) Random forests is an ensemble learning method that constructs multiple decision trees from subsets of the training set and uses random feature selection for node splitting. RF decides the class after applying voting to the predicted classes by the individual trees for classification, or by calculating the mean prediction for regression. Random forests address

the overfitting tendency of the decision trees and have shown robustness with respect to noise [17].

Bag of Keypoints

Bag of Keypoints (BoK) [18] is a patch-based technique that originates from Bag of Features methods. These methods have been applied to image recognition and classification and have produced very good results. They apply feature detection, extraction, and clustering for finding the most representative features in the training database. In the next step, they build a vocabulary that consists of the frequency of occurrence of these features. In the testing stage, features are extracted from the unlabeled image and encoded using the vocabulary that was built during training. Then a learning method is applied to classify the test pattern into one of the classes.

We employed the support vector machine (SVM) classifier for learning a discriminant function from the encoded features and classifying unlabeled samples. In the SVM module, we evaluated the use of linear or radial basis function kernels. We utilized radial basis function kernels for our experiments to address possible non-linearity of the decision boundary.

Deep Neural Networks

Deep learning methods and more specifically convolutional neural networks have recently re-emerged as powerful techniques for image segmentation, object recognition, and classification [19–23]. These techniques simultaneously learn the set of features and the decision function. In contrast to traditional texture-based techniques, deep networks do not need to receive a hand-crafted feature set as input. Deep learning methods have been applied to biomedical image datasets and have produced very good results.

We employed sequential and residual networks of varying complexity such as Alexnet [19], Googlenet [20], Resnet18 [23], and Inceptionv3

[21]. Because our datasets are small, we employed transfer learning techniques to adjust the weights of pretrained networks, instead of learning the decision function from the beginning as described in [22, 24]. All networks were pretrained on Imagenet that is a database of 1.2 million natural images.

We applied transfer learning to each network in slightly different ways. To adjust Alexnet to our data, we replaced the pretrained fully connected layers with three new fully connected layers. We set the learning rates of the pretrained layers to 0 to keep the network weights fixed, and we trained the new fully connected layers only. In the case of Googlenet, we set the learning rates of the bottom 10 layers to 0, we replaced the top fully connected layer with a new fully connected layer, and we assigned a greater learning rate factor for the new layer than the pretrained layers.

To provide the networks with additional training examples, we employed data resampling using randomly centered patches, followed by data augmentation by rotation, scaling, horizontal flipping, and vertical flipping. Finally, we applied hyperparameter tuning using Bayesian optimization to find the optimal learning rate, mini-batch size and number of epochs.

Sparse Representation and Classification

The concept of sparsity has been used in many methods of mathematics, computer science, and engineering and plays an important role in machine learning and pattern recognition. Next, we introduce the standard sparse technique, the details of this method, and other related sparse techniques.

Overview of Sparse Modeling Methods Tissue classification is typically achieved by supervised machine learning approaches. Among numerous techniques that proposed generative or discriminative models, use of kernels, and linear or nonlinear approaches, sparse classification techniques have shown promise and applicability for characterizing visual patterns in region of

interest (ROI)-based analyses. Sparse representation techniques have been applied to extensive fields including coding, feature extraction and classification, superresolution [25], and regularization of inverse problems [26]. Exploration of signal's sparsity may provide insight into the important patterns of prototyping of objects category. The sparse representation is more concise for compression and naturally discriminative for classification [27]. Sparse representation techniques calculate a sparse linear combination of atoms for describing a vector sample using an overcomplete dictionary of prototypes. If the representations of these linear combinations are sufficiently sparse, then they can be used for object recognition and classification of imaging patterns.

The authors in [27] proposed the sparse representation classification (SRC) method to recognize 2,414 frontal-face images of 38 individuals of Yale B Database and over 4,000 frontal images for 126 individuals of AR Database, producing recognition rates greater than 90% for both databases. Another notable face recognition application of sparse coding was published in [28] reporting high levels of classification accuracy. Dictionary learning techniques have also emerged as solutions for sparse representation in the recent years. The utilization of K-SVD, where SVD denotes singular-value decomposition, for dictionary learning has been studied to produce a dictionary aiming for more accurate representation [29]. In [30], the K-SVD technique has been used for color image restoration to handle non-homogeneous noise and information missing problems. The authors in [31] observed that K-means may yield as good precision rate as K-SVD when we use the same number of atoms. The SRC method with dictionary learning was applied to classification of pulmonary patterns of diffuse lung disease in [32]. Additional algorithms such as matching pursuit (MP), orthogonal matching pursuit (OMP), and basis pursuit (BP) have been proposed for codebook design [29].

Sparse Representation and Classification

Sparse representation or approximation techniques construct a dictionary from labeled training samples to calculate a linear representation of a

test sample. This representation can be used to make a decision for the class of the test sample. Assuming that a dataset has k distinct classes, s samples, and for i th class, there are s_i samples, so that $s = \sum_i s_i$, we define a dictionary matrix M from the training set as

$$M = [v_{1,1}, v_{1,2}, \dots, v_{k,s_k}]. \quad (20)$$

where $M \in \mathbb{R}^{l \times s}$, and $v_{i,h}$ is a column vector for the h th sample from i th class. In image classification applications, a $p \times q$ grayscale image forms a vector $v \in \mathbb{R}^l$, $l = p \times q$ using lexicographical ordering.

A new test sample $y \in \mathbb{R}^l$, can be represented by a linear combination of samples $y = \sum_{i=1}^k \beta_{i,1} v_{i,1} + \beta_{i,2} v_{i,2} + \dots + \beta_{i,s_i} v_{i,s_i}$, where $\beta_{i,h} \in \mathbb{R}$ are scalar coefficients. Hence, the test sample y can be rewritten as:

$$y = Mx_0 \in \mathbb{R}^l. \quad (21)$$

where x_0 is a sparse solution. If there are sufficient training samples, the components of x_0 are equal to zero except for the components corresponding to the i th class. Then $x_0 = [0, 0, \dots, \beta_{i,1}, \beta_{i,2}, \dots, \beta_{i,s_i}, 0, 0, \dots, 0]^T \in \mathbb{R}^s$.

In [33], it was proved that whenever $y = Mx$ for some x , if there are less than $l/2$ nonzero entries in x , x is the unique sparse solution: $\hat{x}_0 = x$. Finding an accurate sparse representation of an underdetermined system of linear equations is an NP-hard problem [34]; therefore, only approximate solutions can be found. The authors in [35] supported that if the solution x_0 is sparse enough, it is equal to the solution \hat{x}_1 of the l^1 -minimization problem:

$$(l^1) : \hat{x}_1 = \arg \min \|x\|_1 \text{s.t. } Mx = y. \quad (22)$$

In sparse representation classification, we define a characteristic function $\delta_i : \mathbb{R}^s \rightarrow \mathbb{R}^s$ that has nonzero entries, only if x is associated with class i . Then the function $\hat{y}_i = M\delta_i(\hat{x}_1)$ represents the given sample y using components from class i only. To classify y and determine the class label $\hat{\omega}_i$, we minimize the residual between y and \hat{y}_i [27]:

$$\hat{\omega}_i = \arg \min_i r_i(y) \doteq \|y - M\delta_i(\hat{x}_1)\|_2. \quad (23)$$

This technique also adopts the sparsity concentration index (SCI) to measure the efficiency of class-conditional representation of a sample. The SCI of a coefficient vector $x \in \mathbb{R}^s$ is $SCI(x) = \frac{k \times \max_i \|\delta_i(x)\|_1 / \|x\|_1 - 1}{k-1} \in [0, 1]$ as defined in [27]. For a solution \hat{x} , if $SCI(\hat{x})$ is 1, y is only represented by images from a single class, and if $SCI(\hat{x}) = 0$, the components of β are spread evenly over all classes.

Algorithms for Solving the Sparse Representation Problem Earlier in this section, we mentioned that finding an accurate solution of sparse representation is an NP hard problem and described a method for finding an approximate solution to Eq. (22). Here we outline three common methods for solving (22). One is the matching pursuit (MP) method. MP selects atoms, one at a time, to minimize the approximation error. This is done by finding the atom with the largest inner product of the signal, subtracting the approximation from the signal using only that atom, repeat this step until it finds the satisfying residual. In [36] the authors proposed an algorithm as orthogonal matching pursuit (OMP). OMP modified MP to achieve full backward orthogonality of residuals (errors) at each step, resulting in improved convergence. Another optimization method for this problem is basis pursuit (BP) [37]. This method optimizes a joint expression of the constraint and the objective function and is equivalent to the LASSO method.

Second Order Cone Programming Formulation The second order cone (SOCP) programming problems are convex optimization problems. The SOCP can be used to implement linear programming (LP), convex quadratic programs (QPs), and convex quadratically constrained quadratic programs (QCQPs) [38]. The standard form of SOCP is defined as following:

$$\min u_1^\top x_1 + \cdots + u_n^\top x_n \quad (24)$$

$$s.t. A_1 x_1 + \cdots + A_n x_n = b \quad (25)$$

$$x_i \geq 0 \text{ for } i = 1, 2, \dots, n \quad (26)$$

SOCP can be used for solving problems of the form,

$$\min_x f(x) \text{ s.t. } \begin{cases} c(x) \leq 0 \\ ceq(x) = 0 \\ A \cdot x \leq b \\ Aeq \cdot x = beq \\ lb \leq x \leq ub \end{cases} \quad (27)$$

where $f(x)$ is an objective function, lb and ub are lower bound and upper bound respectively, A is a matrix and b is a vector for inequality, Aeq is a matrix and beq is a vector for equality, and $c(x)$ and $ceq(x)$ are constraint functions that return vectors. Especially, $f(x)$, $c(x)$, and $ceq(x)$ can be nonlinear functions.

Integrative Ensemble Sparse Analysis Techniques

This method builds an ensemble of sparse representation classifiers based on block decomposition of the input ROI to address shortcomings caused by high dimensionality and to introduce spatial localization in sparse approximations [39]. Figure 4 summarizes the main stages of our method that may be divided in block-based learning and Bayesian model averaging to form decision functions.

Block Decomposition We first divide each training ROI into non overlapping blocks of size $m \times n$. Thus, each ROI image is expressed as $I = [B^1, B^2, \dots, B^{NB}]$, where NB is the number of blocks in an image. The dictionary D^j , where $j = 1, 2, \dots, NB$ corresponds to the block B^j at the same index within the image ROI. The dictionary D^j for all the s images can be represented as follows:

$$D^j = [bv_{1,1}^j, bv_{1,2}^j, \dots, bv_{k,s_k}^j], \quad (28)$$

where $bv_{i,h}^j$ is the column vector denoting the h th sample, i th class, j th block B^j .

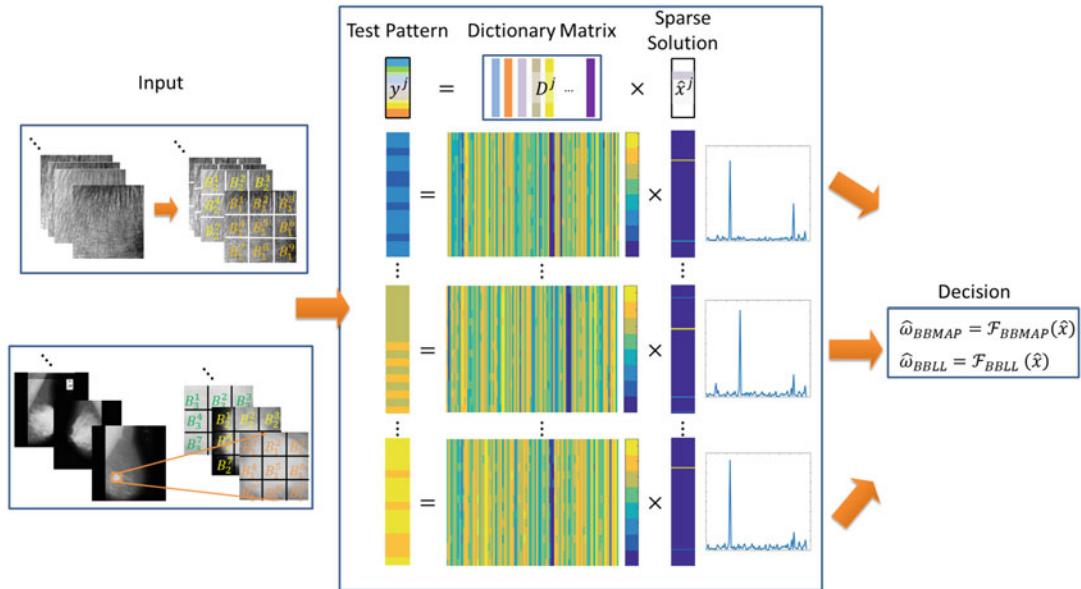

Fig. 4 Main stages of our integrative sparse modeling system: block-based analysis, sparse solutions, and decision functions

Ensemble Classification In this stage, each test sample is classified by constructing ensembles of classifiers that solve a set of sparse coding and classification problems, or hypotheses corresponding to the block components. Given a test sample y^j in j th block, we find the solution x^j of the regularized noisy ℓ^1 -minimization problem:

$$\hat{x}^j = \arg \min \|x^j\|_1 \text{ subject to } \|D^j x - y^j\|_2 \leq \epsilon \quad (29)$$

where $j = 1, 2, \dots, NB$. The test sample y^j will be assigned to the class ω_i^j , which has minimum approximation error calculated by (30).

$$\omega_i = \arg \min_i r_i(\hat{x}) \doteq \arg \min_i \|y - \hat{y}_i\|_2. \quad (30)$$

We utilize ensemble learning techniques in a Bayesian probabilistic setting as weighted sums of classifier predictions. We employ a function that applies majority voting to individual hypotheses (BBMAP) and an ensemble of log likelihood scores computed from relative sparsity scores (BBLL).

Maximum a Posteriori decision function (BBMAP) The class label for each test sample is determined by voting over the ensemble of $N B$ block-based classifiers. The predicted class label $\hat{\omega}$ is given by

$$\hat{\omega}_{BBMAP} = \mathcal{F}_{BBMAP}(\hat{x}) \doteq \arg \max_i pr(\omega_i | \hat{x}), \quad (31)$$

where \hat{x} is the composite extracted feature from the test sample given by the solution of (29). The probability for classifying \hat{x} into class ω_i is

$$pr(\omega_i | \hat{x}) = \sum_j^{NB} ND_{\omega_i^j} / NB \quad (32)$$

$$ND_{\omega_i^j} = \begin{cases} 1, & \text{if } \hat{x}^j \in i\text{th class} \\ 0, & \text{otherwise} \end{cases}, \quad (33)$$

where $ND_{\omega_i^j}$ is an indicator function whose values are determined by the individual classifier decisions.

Log likelihood approximation residual-based decision function (BBLL-R) We define a

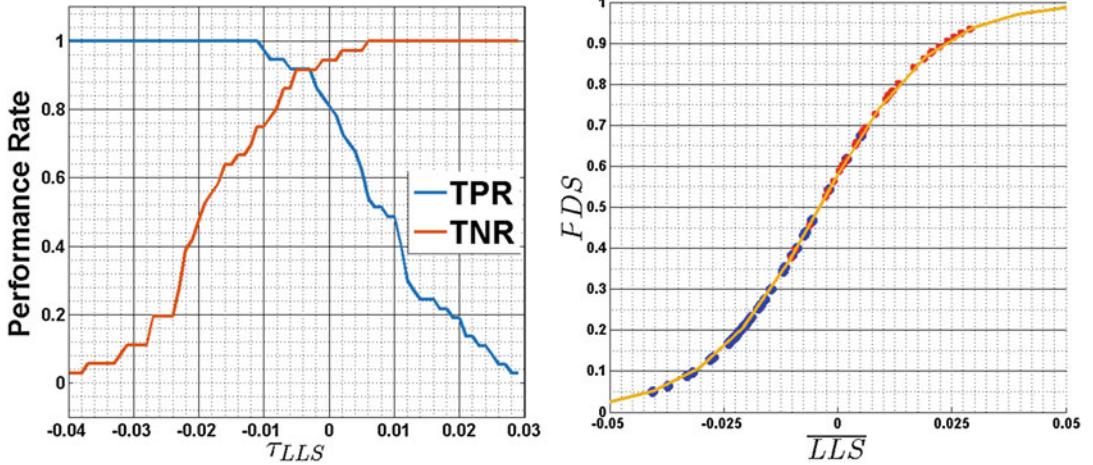

Fig. 5 An example of TPR and TNR curves versus τ_{LLS} for determining $\tau_{LLS}^* = c$ (left) and the sigmoid probability decision score PDS after calculating the parameters m, c for (38) (right)

likelihood score based on the residuals r_m ; r_n calculated in the sparse representation stage of each classifier. We calculate the expectation of $\overline{LLS(\hat{x})}$ over all individual classifiers:

$$\begin{aligned} \overline{LLS(\hat{x})} &= -\frac{1}{NB} \\ &\times \left[\sum_j^{NB} \log r_m^j(\hat{x}) - \sum_j^{NB} \log r_n^j(\hat{x}) \right], \end{aligned} \quad (34)$$

where $r_\omega^j(y)$ is the approximation residual for class ω and j is the block index:

$$r_\omega^j(y) = \|y - M\delta_\omega(\hat{x}_1)\|_2 \text{ for } j = 1, \dots, k. \quad (35)$$

Log likelihood sparsity-based decision function (BBLL-S) We define a likelihood score based on the relative sparsity scores $\|\delta_m(\hat{x}^j)\|_1$, $\|\delta_n(\hat{x}^j)\|_1$ calculated in the sparse representation stage of each classifier. We calculate the expectation of $LLS(x)$ over all individual classifiers:

$$\begin{aligned} \overline{LLS(\hat{x})} &= -\frac{1}{NB} \left[\sum_j^{NB} \log \|\delta_m(\hat{x}^j)\|_1 \right. \\ &\quad \left. - \sum_j^{NB} \log \|\delta_n(\hat{x}^j)\|_1 \right], \end{aligned} \quad (36)$$

The introduction of the log-likelihood score accommodates the definition of a decision function for the state $\hat{\omega}$. To determine the class, we apply a decision threshold τ_{LLS} to $\overline{LLS(\hat{x})}$.

$$\begin{aligned} \hat{\omega}_{BBLL} &= \mathcal{F}_{BBLL}(\hat{x}) \\ &\stackrel{.}{=} \begin{cases} m\text{th class}, & \text{if } \overline{LLS(\hat{x})} \geq \tau_{LLS} \\ n\text{th class}, & \text{otherwise} \end{cases}. \end{aligned} \quad (37)$$

This threshold is expected to be equal to 0, if there is no estimation bias, but may be experimentally determined as the minimizer of a Bayes-type risk function. Hence, the optimal τ_{LLS}^* value can be determined by sampling the domain of τ_{LLS} and calculating true positive and true negative rates. Next, the optimal value is determined by the intersection of TPR and TNR curves. An example of this procedure for determining τ_{LLS}^* is displayed in Fig. 5.

In the next stage, we aim to convert the log likelihood decision scores to bounded posterior probability values using a sigmoid function. This function is denoted by Probability Decision Score (PDS) and is expressed by

$$PDS(\overline{LLS}) = \frac{1}{1 + \exp[-m(\overline{LLS} - c)]} \quad (38)$$

To calculate the model parameter c , we require that this function be equal to 50% probability for τ_{LLS}^* , hence $c = \tau_{LLS}^*$. To estimate m , we set a fixed probability level PDS_{min} (e.g., 5%, 10%) for the smallest value \overline{LLS}_{min} .

$$m = \frac{1}{\tau_{LLS}^* - \overline{LLS}_{min}} \ln \left(\frac{100 - PDS_{min}}{PDS_{min}} \right) \quad (39)$$

In Fig. 5, we display the graph of PDS versus LLS for one experiment. We can use PDS to express margins of uncertainty for classification in percentiles.

Results

The main goal of the presented experiments is to test the hypothesis that ensembles of block-based sparse classifiers improve the classification performance of conventional sparse representation. The second goal is to compare the proposed technique to classifiers based on texture, Bag of Keypoints, and deep learning. Finally, we compare the performances of the two decision functions BBMAP and BBLL. We describe the application of our system to osteoporosis diagnosis, report the classification results produced by leave-one-out cross-validation experiments, and discuss our findings.

Data Description The objective is to distinguish between healthy and osteoporotic subjects. The TCB challenge dataset contains labeled digital radiographs of 87 healthy and 87 osteoporotic subjects for training and testing (available online in <http://www.univ-orleans.fr/i3mto/data>, last access in 05/2018). The calcaneus trabecular bone images in the dataset have an ROI size of 400×400 pixels. A more detailed description of the dataset is provided in [40]. The experimental procedures involving human subjects were approved by the Institutional Review Board of the institution that provides the data.

Texture-Based Classification In the performance evaluation of conventional texture-based techniques, we calculated 723 texture-related features [10]. We selected features using correlation-based feature selection with best first search (CFS-BF), correlation-based feature selection with genetic algorithm

search (CFS-GA), information gain (IG), and no-feature selection as described in section “[Non-sparse Classification Techniques: Texture-Based, Patch-Based, and Deep Learning](#).” CFS-GA yielded an overall better performance than CFS-BF, IG, and no-feature selection on leave-one-out cross-validation (Table 1). This implies that CFS-GA effectively selects distinguishing features from the entire set. Among the tested classifiers, Bagging accomplished the highest performance with an ACC of 67.8% on leave-one-out cross-validation.

Bag of Keypoints Classifier The main parameters that we tuned were the fraction of features to keep for building the vocabulary, the vocabulary size, the penalty coefficient for misclassification of training samples in SVM, and the kernel scale. The results showed that BoK was able to separate successfully healthy from osteoporotic subjects with an ACC of 99.3% leave-one-out cross-validation as displayed in Table 2. This very high accuracy may be attributed to the extraction of discriminant features from the textured areas. Also, the employed SVM model is known to address data complexity caused by nonlinearity and high dimensionality.

Deep Neural Networks We evaluated the performance of the networks described in section “[Bag of Keypoints](#).” We set the learning rates of the convolutional layers to much lower values than the final layers. In this way, we largely preserved the pretrained layer weights at the initial and intermediate convolutional stages. The main parameters that we tuned were the learning rate, learning rate drop, size of mini-batch, and the number of epochs. We utilized grid search and Bayesian optimization search for parameter tuning. Among the deep neural networks, Resnet18 yielded the top ACC of 64.4% and the top AUC of 67.5% (Table 2).

Conventional SRC We then evaluated the performance of the conventional SRC method. We utilized multiple undersampling factors to address convergence to infeasible solutions mostly caused by linearly dependent vectors that yielded different classes. In Table 3, we show results from the top performing experiments producing 59.2% classification accuracy for resampling of 1/20, corresponding to feature dimensionality of 400 using leave-one-out cross-validation. We also applied conventional SRC to the texture feature set produced in section

Integrative Sparse Classification Here we report the performance of our block-based ensembles of

sparse classifiers. We employed block sizes ranging from 100×100 pixels to 10×10 pixels to observe the impact of this variable on the classification performance. We repeated these experiments using the BBMAP and BBLL decision functions in this

Table 3 Classification performance for bone characterization using conventional sparse classifiers and ensembles of block-based sparse classifiers. The block size in the first

Method	Block Side	TPR (%)	TNR (%)	ACC (%)	AUC (%)

	Mean ± Std	95.9 ± 7.2	93.4 ± 8.3	94.7 ± 7.6	96.3 ± 5.8

setting. We show our leave-one-out crossvalidation performance in Table 3. The experiment with block size 25×25 pixels that led to 256 classifiers performed the best classification of 100% by the BBMAP and BBLL techniques. These results imply 9.5% improvement of our method over the traditional SRC method. The block size with 10×10 also produced 100% accuracy and 100% AUC. In addition, we estimated the statistical significance of the differences between the AUC values of BBLL with optimized threshold τ_{LLS}^* and BBMAP by applying DeLong’s statistical test between the ROCs produced by BBMAP and BBLL. The p-values for block sizes of 100×100 , 50×50 , 25×25 and 10×10 were 0.47, 0.66, 0, and 0 respectively, suggesting significant differences for block sizes of 100×100 , 50×50 , 25×25 , and 10×10 . BBLL achieved the top AUC for 25×25 and 10×10 block size that was also found to be significantly different from the corresponding BBMAP result.

Discussion

The cross-validation experiments indicate that BBMAP and BBLL produce better separation than texture-based, BoK, deep neural networks, and SRC. Texture-based techniques may

two rows implies no block decomposition (as in conventional SRC)

achieve moderate classification rates. The feature computation and selection stages are key factors for improving separation accuracy. Smaller block sizes do not improve texture-based classification, because smaller sizes reduce the amount of information represented by the texture descriptors.

Bag of Keypoints, which shares some similarities with sparse representation methods, showed potential for exceptional results. This method computes patch-based feature vectors that are used for training and testing. SVM classification enables the estimation of nonlinear discriminant functions. On the other hand, deep learning methods did not perform very well, mainly because of the limited size of the training set. These methods have potential to outperform their conventional feature-based machine learning counterparts, if we are able to provide a big number of informative labeled samples to train the networks.

The results in Table 3 suggest that the block-based approach finds more accurate sparse solutions than the conventional SRC approach and improves the classifier performance. A reason for the improved group separation may be that the block-based ensemble technique employs multiple learners of over-complete dictionaries that are more amenable to sparse coding and representation. Between the block-based decision

functions, BBLL yielded higher classification rates for larger block sizes, because it accounts for estimation bias. Although both BBMAP and BBLL achieved perfect separation for small blocks, their performance drops when the number of training samples increases and the number of test samples decreases. We expect that effective dictionary learning will help to improve the generalization capability of these methods.

From the above studies and results, we conclude that machine learning-based methods using digital radiographs have the potential to assist the noninvasive diagnosis of osteoporosis, or the identification of high fracture risk. A meaningful element of such approaches would be to use the concept of signal sparsity to generate representations of the bone structure.

Abstract

The purpose of this chapter is to present the main literary sources concerning machine learning (so artificial intelligence) application to laboratory medicine field, with the appropriate language, understandable also for clinical chemists, medical staff, and so on. This goal is

tackled with a systematic debate of the main research works, developed in this field, in which the clinical task is well-defined and a proper statistical or machine learning algorithm is implemented. The main results for each research work will be described to underline and prove the workability and the feasibility of machine learning to laboratory data and the reliability of machine learning models to solve diagnostic or prognostic tasks and then support the medical staff in its decision process.

To provide a better overview also for non-expert audience (in terms of computer and data science), a gentle introduction will be provided, regarding what machine learning is and what machine learning experts strive to accomplish in their daily work routine. Moreover, the advantages of the transition from expert systems to machine learning systems and the general benefit of switching toward

Introduction

This chapter will present and report the latest applications of artificial intelligence (AI) in laboratory medicine. In particular, machine learning (ML) is the AI subfield that is going to be considered. The reasons for this interest in ML techniques lie on their capability to reach human performances on several tasks and in some cases even outperform them.

Laboratory medicine is traditionally used to apply technology and innovation, including automation, robotization, and computer science [1]. Quality control was introduced in clinical laboratory 60 years ago; data automatic transfer from instrument to a laboratory information system was routinely introduced in the 1980s and the telematic release immediately later. Industrialization of procedures, in other terms, is a characteristic of total laboratory automation and integration between chemistry, immunology, hematology, and serology with computer science, and it is a regular and expected pathway both inside and outside the hospital. Laboratory medicine was a vanguard in informatics technology applied to medicine; thus it seems obvious that laboratory should lead the AI projects in clinical medicine. However, this approach is moderately applied in the real world, although the interest of professionals is very high.

Some simple machine learning approaches were introduced in the early phase of informatization and robotization of the clinical laboratory. For example, the rules for internal quality control, the most famous are the Westgard ones, were introduced into the software of standalone instruments or in total lab automation systems. The Bull algorithm could be also quoted, based on the weighted mean of series of

20 consecutive patient results, particularly applied to control hematology instruments, where some parameters are very stable, having low biological variability: mean corpuscular hemoglobin concentration, for example, is low only in frank and severe anemia, and in this case the values are eliminated from the algorithm, and high in rare pathological conditions, namely, spherocytosis and cold agglutinins.

Some additional examples of clinical laboratory involvement in an early state of machine-based data evaluation are the retest when a specimen is measured to control a value out of alert range, and the reflex, i.e., additional tests performed on a specimen when a value is out of a reference range, as typically done for thyroid parameters. Image identification was introduced many years ago in urinalysis instruments for the sediment evaluation, and also in hematology systems, where the integration between data evaluation and slide preparation is now a common procedure.

In light of recent high-profile articles and editorials in high-impact journals (e.g., [2, 3]), it appears that with the decline of so-called expert systems, ML has gained a place in medicine and captured the interest of medical researchers and practitioners in predictive methods within this subfield of computer science.

The automatization of classification, segmentation, or anomaly detection tasks for both diagnostic and prognostic purposes can lead to an improvement of the medical service provided by the hospital facilities since doctors and medical staff can rely on additional guidance, which draws its conclusions from the evidence of data. Besides, the potential for applying machine learning to laboratory data deserves more attention by the readership of this journal, as well as by physician-scientists who will want to take advantage of this new computer-based support in pathology and laboratory medicine.

The ever-wider use of ML in clinical and basic medical research is reflected in the number of titles and abstracts of papers indexed on PubMed and published until 10 years ago (2006) as compared to the last 10 years (2007–2017), with a nearly tenfold increase from 1000 to slightly

more than 9000 articles in the past decade. In this chapter, the meaning of ML will be introduced in terms that physicians can easily grasp, and then the most recent applications of this computational approach to laboratory medicine will be surveyed.

The clinical laboratory is really ready for machine learning and artificial intelligence, also for integrating different specialized laboratories, having common methodologies, e.g., molecular biology, but different expertise, e.g., genetics, microbiology, and pathology.

A Gentle Introduction: What Is Machine Learning?

Put in very general terms, ML is about learning by machines. More specifically, ML is an umbrella term for diverse computational methods by which machines can incrementally build an accurate data model according to a measure of how well the model supports a given task, which in medicine is usually of discriminative nature, i.e., classification, clustering, or regressive. Classification, as the word says, regards the identification, for each record given to the model as input, of its target class, or correct category; on the other hand, regression regards the estimation of the correct value of a continuous variable. Lastly, clustering is an approach which allows to group different instances together, by associating them to groups (i.e., clusters) on the basis of their similarities. So, there are three players: *model*, *task*, and *measure of performances*. In an ML context, by model, we refer to the functional representation of a data set, i.e., the representation of any mapping that can be drawn to bind portions of the data set to a particular value on a specific measurement scale. The scale is either nominal or ordinal in a discriminative classification task, and the value is usually a label. In a discriminative regression task, on the other hand, the scale is either an interval or a ratio, and the predicted value is a number indicating some quantity, e.g., creatinine levels. Most of the ML models described in the medical literature so far regard functional mapping between a set of values, likely associated with a single clinical case, and a single category (e.g., yes/no or one

class out of a taxonomy) in order to support either a diagnosis or a prognosis.

The ML goal is to improve the model performance on a specific task by taking the measure of performance as a loss function to decrease (or increase, it depends on the task).

To illustrate, let's call this set of values x : in a prognostic decision task, the model is applied to answer questions like "does x represent (or values pertaining to) a patient who is affected by a certain disease or not?" In a supervised ML context, the data are usually data sets that describe different cases along various dimensions or attributes, called features, and that human experts have already associated with "correct" values, which we shall call " y ." Therefore, in the very concise terms that data scientists love, ML models work with functions like $y = f(x)$: the value of this function lies in its capability to yield the correct " y " also for some " x " that has not previously been classified by a human expert, thus providing aid in the classification task. Data scientists program machines, called "learners," to optimize a given model (i.e., make it more accurate in predicting y on the basis of a given unknown x taken from the target population) by autonomously and iteratively tweaking its parameters until no further improvement can or should be achieved: the process that the learners apply to a part of the available data, the "training data," without the direct intervention of human programmers, is called learning, in this case, machine learning.

A Brief Overview of Machine Learning Implementation in Laboratory Medicine

Machine learning is widely used in biochemical development and for evaluating and interpreting data in genomics, transcriptomics, and proteomics pathways (e.g., [4, 5]), whereas in clinical laboratory medicine, it has been applied to classical biomarker testing of biological materials. Several so-called expert systems have been recently described, patented, and commercialized for clinical laboratory purposes. Designed to evaluate specific data in hematology, urinalysis, or clinical

chemistry, they are traditionally based on a pre-defined decision tree encompassing logic rules and checks to exclude diagnostic hypotheses or define them or suggest further analysis to complete the diagnosis and support decision-making. By contrast, ML is a completely different approach, where “rules” are learned by the machine. More often than not, speaking of explicit rules is inappropriate, as the prediction is somehow hidden in the model’s nonlinear parameters that bend the decision boundaries around the data. Therefore, it’s clear that the application of ML in laboratory medicine should be supported as a means to enhance laboratory organization and expand the core skill set of laboratory experts, within a broader process of change and innovation.

There are several reasons supporting the previous sentence. First, laboratories are a major part of today’s healthcare systems. However, despite high throughput with low turnaround times, the capacity to screen data for results of special interest has decreased, and few tests are directly diagnostic [6]. Second, technological advances have enabled the integration of expert system capabilities and software applications, including auto-analyzers and modules of laboratory information systems (LIS) [7]. Since this kind of support is usually based on dichotomous thresholds or rigid mutual exclusion of data, it can be difficult if not impossible to obtain precise or personalized results [8], suggesting an obvious margin for improvement. Third, because patients can now immediately access their laboratory test results by downloading them from the Web portal of their diagnostic provider, there is an increasing demand for meaningful, possibly personalized reference limits and the need to interpret precision asterisks [6], the conventional signs indicating abnormal or borderline values. Finally, with the convergence of smartphones and innovative biosensors based on microfluidics and microelectronics, the vision of the lab-on-a-chip (LOC) and related models for laboratory medicine has opened chances [9].

In this context, apomediation refers to progressive disintermediation whereby traditional intermediaries, such as healthcare professionals who

give “relevant” information to their patients, are functionally replaced by apomediations, i.e., network/group/collaborative filtering processes [10]. ML systems can be seen as new and “cleverer” apomediations that act as gap fillers that analyze the increasing amount of diagnostic data a patient can access without intervention by a general practitioner or laboratory specialist and then assign the patient to a specialist only in case of likely positive or anomalous results. This can be done by factoring together the diverse phenotypic attributes of a patient (i.e., in addition to body mass index [BMI], age, gender, and ethnicity) or, better yet, of the patient’s history of past basal values associated with a healthy condition. In this case, the very notion of reference limits would change, and ML, by leveraging and improving other statistical approaches, could help limit the misinterpretation of values outside of reference limits or of apparently normal data but also diagnostic for some conditions.

Some imagine a ML-based clinical decision support that, by predicting correlated test results and improving the diagnostic value of multi-analyte sets of test results, could help to reduce unnecessary laboratory testing [11] and, hence, lower healthcare costs, which are budgeted to total \$5 billion yearly in the United States alone [12]. Finally, the growing number of available and affordable types of diagnostic tests has produced an unprecedented complexity of data interpretation and integration that calls for novel management technologies.

Machine Learning Models in Laboratory Medicine

In this section, several research works are reported, showing the potential of ML models to address the previously mentioned challenges in laboratory medicine.

Lin et al. [13] mined concepts from clinical narratives and lab values gathered from electronic medical records to automatically detect rheumatoid arthritis. After experimenting with a range of ML algorithms, they found that the linear kernel support vector machines performed best, with an

AUROC curve of 0.83, after which also inflammatory markers were considered (an increase of 6% as compared to no laboratory test).

Razavian et al. [14] collected administrative claims, pharmacy records, healthcare utilization, and lab test results of 4.1 million individuals between 2005 and 2009 to evaluate a prediction ML model for type 2 diabetes. Among the different variables associated with the development of diabetes, high aminotransferase (ALT) concentrations were associated with the highest odds ratio. Among the lab tests, the best prediction variables were glycated hemoglobin (HbA1c), glucose, high-density lipoprotein cholesterol, carbon dioxide, and glomerular filtration rate (GFR). The authors observed that the study also showed how administrative data can be a powerful tool for population health management and clinical hypothesis generation for risk factor discovery and that these data can help guide interventions in at-risk populations.

In a study involving 757 patients, Nelson et al. [15] applied logistic regression and an ML model they called “a relevance vector machine” and found that creatinine level was a clear predictor of outcome in traumatic brain injury, whereas glucose, albumin, and osmolality levels were predictors depending on the model used.

Diri and Albayrak [16] evaluated the performance of four classifiers applied to the data from five lab tests for thyroid dysfunction, distinguishing between a diagnosis of euthyroidism, hypothyroidism, and hyperthyroidism. The tests were as follows: T3-resin uptake test, total serum thyroxine, total serum triiodothyronine, basal thyroid-stimulating hormone (TSH), and maximal absolute difference of TSH value after injection of 200 μ g of the thyrotropin-releasing hormone as compared to the basal value. The authors also used cobwebs to visualize classifier performance when the data had more than two classes. A Bayesian classifier showed the best overall performance, with an average accuracy of 96%.

Given the complicated characteristics of warfarin, Liu et al. [17] used two well-known lab tests, alanine aminotransferase (ALT), and serum creatinine (SCr), in combination with data about warfarin dose, gender, age and weight, to build a

classification model that could predict adequate or inadequate warfarin therapy and minimize the odds of drug-to-drug interactions. In an analysis of 377 inpatients, they compared the performance of seven classification techniques and found that C4.5 decision tree and random forest scored best and predicted the adequacy of warfarin “more accurately than does the clinical physicians’ subjective decision.” This result, the authors claimed, showed the importance of making the best use of lab test results in clinical practice, especially in virtue of the relative simplicity and low cost of collecting accurate lab data.

Putin et al. [18] applied ML to laboratory parameters to predict chronological age via an ensemble of 21 deep neural networks developed and applied to more than 50,000 samples. They found that albumin concentration, followed by glucose, best identified chronological age. The ensemble identified five markers (albumin, glucose, alkaline phosphatase [ALP], urea, and erythrocytes) as the most valuable for predicting subject age.

Dermici et al. [19] used a commercial software program to train an ANN for application in the central laboratory of a large university hospital for the efficient, rapid, and reliable evaluation of biochemical test results. The ANN was applied to more than 250,000 samples to evaluate a set of routine parameters (sodium, potassium, calcium, magnesium, glucose, uric acid, chloride, urea, creatinine, aspartate aminotransferase, ALT, gamma-glutamyl transferase [GGT], ALP). Evaluation by ANN was compared with evaluation by seven pathologists of different expertise. The sensitivity of the model was 91% and specificity was 100%, with a K-score of 0.95. The K-score analysis revealed that five out of seven pathologists gave very high agreement scores in the evaluation of model judgment (0.81–1.00). When a reassessment of the specialists’ decision was requested, after comparison with the ANN evaluation, the pathologists changed their reports significantly in many cases, so as to increase agreement between the human and the automatically generated report. The time between receipt of the data and release of the reports was clearly lower in the case of ANN. The authors concluded

that a decrease in time and related costs, at similar quality and appropriateness levels, can be expected from the introduction of similarly accurate automatic supports.

Yuan et al. [20] built and evaluated three classifiers based on supervised ML methods to discriminate between positive and negative urine samples. Based on a classification and regression tree (CART), the model showed the best results on the test set, with a sensitivity of 86.0%, a specificity of 98.0%, an AUC of 94.3%, and an overall accuracy of 95.6%. The results implied that ML is a valuable method to construct classifiers for urine microscopic review rules that can supplement other reported microscopic review rules.

Advocates of ML methods affirm that ML may be useful for prognosis, i.e., predicting disease evolution and progression; early detection, when a disease is still in its early asymptomatic stage; and primary prevention to reduce the risk of development of the disease. The predictive approach has been based on regression models, e.g., the logistic model to predict 30-day mortality risk for patients with ST-segment elevation myocardial infarction (STEMI), the Weibull model for the SCORE (systematic coronary risk evaluation) model, and a Cox model applied to the Framingham Risk Score for cardiovascular diseases.

Goldstein et al. [21] described an ML method for cardiovascular risk prediction that was trained with the data of 1944 patients with a primary diagnosis of acute myocardial infarction. The authors used 13 lab parameters measured in at least 80% of the patients (calcium, carbon dioxide, creatinine, creatine kinase-MB, hemoglobin, glucose, mean corpuscular volume, mean corpuscular hemoglobin concentration, platelets, potassium, red cell distribution width [RDW], sodium, leukocytes) and calculated the median and the minimal and maximal values of these parameters to obtain 43 predictor variables of hospital mortality. The ML model trained on this data set showed that there is a nonlinear relationship between calcium and hemoglobin and post-infarction mortality. The authors employed five ML approaches to build models with different characteristics and performance: the variables were similarly relevant, and the models detected

the high impact of carbon dioxide (minimum value), calcium (all measures), hemoglobin (median value), potassium (all measures), and leukocytes (maximum value).

An epidemiological expert group reported on examples of ML applied to biochemical and hematological tests, including the demonstration of a relationship between GGT and liver function tests (ALP, albumin, lactate dehydrogenase, and aminotransferase), enhanced prediction of hepatitis B and C through the use of hepatitis C virus, and the correlation between RDW and hemoglobin in anemia diagnosis [22].

Somnay et al. [23] used serum levels of preoperative calcium, phosphate, parathyroid hormone, vitamin D, and creatinine as predictors of primary hyperparathyroidism in a sample of 11,830 patients. Among the ML algorithms tested, the Bayesian network models proved most accurate, correctly classifying 95% of all primary hyperparathyroidism patients (AUROC 0.99). Interestingly, excluding parathyroid hormone from the model did not substantially decrease its accuracy. The study concluded that ML can accurately diagnose primary hyperparathyroidism without human input even in cases of mild disease.

Luo et al. [24] investigated the utility of automated clinical decision support to predict test results using the results from other tests. As a proof of concept, they showed that ML models based on patient demographics (age and gender) and results of other lab tests (each collection had a median of 23 of the 40 tests) can discriminate normal from abnormal ferritin results with a high degree of accuracy (AUC 0.97, held-out test data) and even predict numerical results for ferritin (by regression) with moderate accuracy. They also reported that predicted ferritin results could better reflect underlying iron status than measured ferritin in some cases. Their results were shared by other studies, like that of Waljee et al. [25], who found that the miss Forest model outperforms other methods for imputing missing laboratory results.

Chen et al. [26] developed an ML model for predicting changes in GFR in Chinese patients with type 2 diabetes. Because current GFR equations (Cockcroft and Gault, Modification of Diet

in Renal Disease, Chronic Kidney Disease Epidemiology Collaboration) are known to be inaccurate in persons with diabetes, a model including sex, age, serum creatinine, and BMI provides an optimal modification of these equations in such patients.

Another interesting example of ML models that estimate the effectiveness and efficacy of well-established lab tests is the evaluation of the role of tumor markers in cancer diagnosis in asymptomatic subjects. Tumor marker testing is currently suggested for diagnostic assessment and especially during follow-up after chemotherapy but not during screening. Multiple tumor marker applications could be employed even in the screening phase, with the probabilistic power of a group of molecules reaching the proper edge, sufficient to identify asymptomatic disease. This approach is now supported by new metabolomics and proteomic approaches. Surinova et al. [27] found that five proteins not routinely measured in laboratories were selected by an ANN from among approximately 300 secreted and cell-surface candidate glycoproteins, which could represent a panel for the early diagnosis of colorectal cancer before clinical symptoms appear. Classical tumor markers, however, even when grouped by increasing sensitivity and specificity, are not useful for cancer screening in apparently healthy subjects, as reported by Wang et al. [28] who implemented an ML method to study its diagnostic power in screening with the tumor markers AFP, CEA, CA 19.9, CYFRA 21.1, and SCC, in addition to PSA for men and CA 15.3 and CA 125 for women. Evaluation of tumor marker screening in approximately 21,000 individuals showed an inadequate positive prediction value, a reduction in absolute risk and an increase in absolute risk. The authors concluded that combined tests should not be proposed for cancer screening.

Brinati et al. [29] propose ML models to improve the blood bag allocations and consequently save costs associated with patients' blood management system (PBM) of an important hospital facility. This study aims to demonstrate that ML models can improve the current hospital PBM strategy, based on a simple heuristic method

(threshold on hemoglobin value equal to 12.9 g/dl; if lower, the patient is treated as transfused), also in terms of cost-savings. The researchers use medical information and anographical personal data about 11,814 hospitalizations, attributable to 4593 patients, from January 2019 to May 2019. Each instance was provided with the following attributes: *age*, *gender*, *hemoglobin HGB (g/dl)*, *type of operation*, and *operation urgency*. The study presents ML models able to use such information to predict the transfusion risk and then treat the patients predicted as transfused with drugs, such as ferritin, in order to mitigate the transfusion risk. Several ML modes were trained and evaluated through nested cross-validation, which also allows hyperparameter tuning. Model evaluation has been focused on precision, recall, F1-score, and area under the ROC curve (AUC) as measures of performances, due to the class imbalance of the target variable. The best performing model is random forest that outperforms the current PBM strategy in terms of precision (or positive predictive value), F1-score, AUC, and cost per patient (computed with the associated cost for misclassification), with a net saving of about 30 euros per patient. This study represents an example of ML application aiming to improve not only the medical process but also the management of an important resource such as blood bags and its financial aspect.

Another interesting implementation of ML models for a diagnostic task is given by Brinati et al. [30], where ML techniques are employed for the detection of COVID-19 infection, using as input routine blood test values (hematochemical test). This study shows the workability and clinical soundness of using blood test analysis and ML as an alternative to rRT-PCR for identifying COVID-19-positive patients. This is especially beneficial in those countries, like developing ones, where rRT-PCR reagents and specialized laboratories are often missing. The authors of this work made available a web-based tool for clinical reference and evaluation, where everyone can upload his blood test data and look at the ML model response. The tool is available at this link: <https://covid19-blood-ml.herokuapp.com>. Data about 279 cases, randomly extracted from patients

admitted to the hospital from February 2020 to March 2020, was used for this study. Information contained in the dataset regards patient's age; gender; several routine blood test values such as alanine transaminase (ALT), aspartate transaminase (AST), white blood count (WBC), lactate dehydrogenase (LDH), gamma glutamyl transferase (GGT), C-reactive protein (CRP), etc.; and finally the result of the RT-PCR test for COVID-19. The ML models implemented and validated for this task are decision tree, extremely randomized tree, K-nearest neighbors, logistic regression, naive Bayes, random forest, and support vector machines. The model selection phase has been performed via nested cross-validation which also provides the best hyperparameters. The measures of performance adopted to evaluate models are accuracy, balanced accuracy (computed as the average of recall obtained on each class), precision (or positive predictive value), recall (or sensitivity), specificity (or true negative rate), and area under the ROC curve (AUC). Authors elected accuracy and recall as the main quality metrics since false negatives (i.e., patients positive to COVID-19 which are, however, predicted as negative and possibly let go home) are more deleterious than false positives in this screening task. The best model turned out to be random forest that records on the test set (20% of the initial instances) an accuracy equal to 82%, recall = 92%, precision = 83%, specificity = 65%, and AUC = 84%. The random forest also provides a feature importance rank, very useful for model interpretability. The feature importances were computed by estimating, for each feature, the total normalized reduction, across the decision trees in the trained random forest, to the variance of the target feature. The five most important features for the prediction of COVID-19 infection are AST, lymphocytes, LDH, CRP, and WBC. This chapter shows the feasibility of an alternative COVID-19 test (machine learning based) that works with hematochemical values as input.

Lastly, ML may be implemented to identify reference limits for lab parameters. Reference intervals should be determined for each specific test by the laboratory, considering the method used, the preanalytical phase, and the type of

population accessing the diagnostic service. However, because setting reference ranges is difficult, expensive, and time-consuming [31], reference ranges are generally collected from the literature or adopted from those suggested by the laboratory test manufacturers. The methods described in the specialist literature are usually based on traditional, descriptive statistical approaches and used to obtain reference limits directly from laboratory data. This is feasible, especially when a large amount of outpatient data is available or when the population is currently known as healthy or has a low prevalence of diseases.

Conclusion

The potential employment of machine learning models to laboratory data is relevant but not yet fully achieved. Although it is reasonable to expect that as machine learning techniques become better known they will be implemented to reduce costs, support clinical decision-making, and improve outcomes, further study is needed to understand whether and how the best machine learning practices can be advantageously transferred to laboratory medicine from other areas that pioneered this computational approach, like cardiology, oncology, and radiology, to tap into the related opportunities and strengths and avoid threats and weaknesses [32].

In the near future, ML will aid the pathologist and the clinical chemist to elaborate big amounts of data, and finally to make decisions, or, better, to suggest the best decision to clinicians. Definitely, ML will not substitute the experts, as predicted some years ago for radiologists. Actually, the current scientific scenario confirms that ML is superior when the number of facts (images) is very high and their interpretation is defined, but, when the incidence is low and the interpretation is difficult, there is no evidence toward the ML use only. Thus, in clinical laboratory, ML could aid in the diagnosis using the current parameters (high number of tests, defined thresholds, clear symptoms) and also could aid to elaborate, resume, and validate the big amount of data (e.g., genomics, miRNA, vitamin D, which can be validated by experts only for small

cohorts of patients) to define a possible link with symptoms or disease.

The spread of knowledge about ML (and AI), in the field of clinical chemistry, is a relevant topic and for its pursuit is essential to create a link between the clinical chemist and the expert on computer science and data science, to build a system which can be really effective for laboratory professionals and their meaningful use and safe adoption.

Abstract

Cardiovascular disorders are one of the major causes of death in developed countries, and they form an important entity in clinical medicine and medical economics due to extended life expectancy. The diagnosis and treatment of cardiovascular diseases require multiple

complex laboratory tests and invasive procedures. Attempts to introduce artificial intelligence (AI) technology are underway in each stage of these processes. Electrocardiogram diagnosis is the most traditional and basic cardiovascular examination, and many diagnostic programs based on algorithms and machine learning have been developed so far. Introduction of AI has also been attempted in other noninvasive diagnostic tests, such as echocardiography and cardiac computed tomography and invasive examinations and treatments, such as coronary angiography and catheter interventions. With the growing popularity of

deep learning, AI programs are making progress in their detection and diagnostic abilities. Several research groups have aimed toward more accurate detection or more efficient treatment using AI. This chapter discusses previously reported AI research in the areas of general cardiovascular care, ischemic heart disease, heart failure, and arrhythmia.

Cardiovascular diseases · Coronary artery disease · Heart failure · Arrhythmias

Introduction

Cardiovascular disorders are well-known major causes of death in developed countries. This trend will continue for a while due to extending life expectancy. Cardiovascular disorders remain significant in general medicine and health economics in such countries.

Diagnosing cardiovascular disorders require multilaterally specialized and complex processes to determine the fundamental cardiovascular pathologies underlying the various comorbidities or individual differences between patients.

After diagnosing them, the treatment of cardiovascular disorders also consists of complex steps. A number of cases require invasive procedures, such as catheter-based interventions, in which multiple examinations run continuously in parallel. Additionally, regarding the drugs prescribed in the hospital or after discharge, it is not easy to find the optimal dosage, particularly, in patients of advanced age because most of them have multiple underlying diseases and require a combination of drugs.

In current clinical situations, complicated diagnosis and treatment processes are accomplished according to medical standards, such as guidelines, and are based on the experience of each practitioner.

Artificial intelligence (AI) technology has been introduced into the field of cardiovascular medicine because it has the potential to recognize the information that human physicians cannot distinguish or even recognize, which could be an

advantage in the process of complicated diagnosis and treatment. It also suggests the possibility of an order-made diagnosis and treatment based on individual data. In this chapter, reports on AI technology are discussed with a focus on the diagnosis and treatment of cardiovascular disorders at hospitals.

Overview of AI Research on Cardiovascular Disorders

Most AI programs for cardiovascular disorders are based on machine learning. Recently, more groups have started to adopt deep learning using neural networks instead of predefined machine learning algorithm constructions.

The input data for building such AIs have included data of electrocardiogram (ECG), chest X-rays, echocardiography, cardiac computed tomography (CT), cardiovascular magnetic resonance imaging (CMR), and laboratory blood results.

The most common data source has been ECG, which records the electrical signals of the myocardium through electrodes on the body. In clinical practice, the signals are usually recorded using 12 leads and are described as two-dimensional (2D) waveforms for interpretation by physicians. In studies that used ECGs as input data for building AIs, various forms of ECG data were adopted, such as electrical raw data, 2D image data, or data recorded with reduced leads, such as single-lead or monitor ECG.

Chest X-rays, echocardiography, cardiac CT, and CMR are few other diagnostic imaging modalities. The image data, parameters, and diagnostic information from these investigations have also been utilized in building AI.

The amount of input data used for machine learning has increased from hundreds to millions of cases in some projects.

Studies targeting general cardiovascular disorders have been aimed at efficient diagnosis using each of these investigations. Their results suggest further possibilities in the subsequent diagnostic and treatment steps. There have also been projects that have targeted certain cardiac disorders, such as ischemic heart disease, heart failure, or

arrhythmia, which constitute a majority of cardiovascular disorders with an aim of early discovery and efficient treatment.

Research in General Cardiovascular Disorders

Studies on general cardiovascular disorders have mainly focused on major investigations in the current diagnostic processes.

ECG is a major traditional examination in cardiovascular disorders. Before the introduction of AI technology, computer programs had been developed to detect ECG abnormalities and disorders based on fixed algorithms [1]. These are commonly installed on ECG equipment currently used in clinical practice. Recently, several research groups have developed programs built using machine learning, including deep learning, to interpret ECG data. For automated ECG analysis, identification of the heartbeats in the ECG data is a fundamental step. A research group has previously developed a program based on K-Nearest-Neighbor (KNN) algorithm to recognize the heartbeats using electrical raw ECG signals [2].

Echocardiography is also a major diagnostic modality in the assessment of cardiac function and anatomy in cardiovascular disorders. It involves the emission of high-frequency ultrasonic waves toward the heart and visualization of its internal structures based on the reflected waves. Three-dimensional (3D) reconstruction and visualization of the heart is achieved by emitting the ultrasound waves from various angles. Therefore, echocardiography enables physicians in evaluating whether the myocardium is moving correctly, cardiac contraction per heartbeat, and structural defects, such as valve stenosis or regurgitation.

For the analysis of these video image data, it is essential to identify the angle of each image as well. The identification of this angle leads to an understanding of the observed cardiac anatomy. A program has been developed using deep learning to recognize the angle from which the echocardiographic image was obtained [3, 4]. Although the angles that can be distinguished were limited to a

few, these reports suggest the possibility of advanced features in analyzing the echocardiography data using AI.

AI has also been introduced in pharmaceutics. Warfarin is a commonly used traditional anticoagulant in cardiovascular disorders to prevent thrombus formation. It is widely used in patients following cardiac valve replacement or those with arrhythmias, such as atrial fibrillation. However, it is not easy to identify the optimum individual dose because of its several interactions with other medications and foods. A research group has attempted to predict the optimum dose of warfarin based on the clinical data of each patient using machine learning [5]. They have suggested the possibility of AI in efficient order-made medicine although their results did not seem sufficient for clinical and practical use.

There have also been studies on AI technology based on general data. One research group has developed a program to predict the risk of cardiovascular disorders using results of blood investigations [6]. Another group has reported a program based on transdermal optical imaging for the estimation of blood pressure using the image of faces recorded using smartphones [7]. These results could contribute to the prevention or early discovery of cardiovascular disorders.

Research Targeting Ischemic Heart Diseases

Ischemic heart disease is a clinical condition in which the blood flow in the coronary arteries is blocked at one or more sites. Consequently, oxygen cannot be supplied to the myocardium distal to the occluded sites, thus, leading to myocardial dysfunction. Myocardial infarction (MI) and angina pectoris are typical ischemic heart diseases with typical symptoms of chest pain and dyspnea. In simple terms, a coronary blood vessel is partially obstructed in angina pectoris and completely occluded in MI in which necrosis of the myocardium has begun. It has been reported that 15% of 30-year-old individuals will develop ischemic heart disease (MI or angina pectoris) in their lifetimes [8].

Most ischemic heart diseases are induced by atherosclerotic growth in the coronary arteries. The blood vessels, including coronary arteries, harden with age or due to other reasons, where the deposition of atherosclerotic plaques, such as cholesterol, progresses on the endovascular wall. When an atherosclerotic plaque suddenly ruptures and forms blood clots in the vessels, they can occlude the coronary arteries, thus, resulting in necrosis of the distal myocardium due to insufficient oxygen supply. Arteriosclerosis can occur due to high blood pressure, diabetes, renal dysfunction, or smoking and increase the risk of ischemic heart diseases. MI or angina pectoris occurs frequently due to physical burdens, such as strenuous exercise, psychological stress, or sudden fall in temperature.

If ischemic heart disease is suspected based on the onset and progression of clinical symptoms, the first diagnostic step is ECG. If ischemic heart disease is also suggested by ECG, echocardiography and cardiac CT are performed to determine the pathologic changes and to identify the sites of stenosis/occlusion as well as assess their severity. Furthermore, the degree of myocardial necrosis should be evaluated using blood sampling. If severe stenosis is noted, the site of stenosis should be dilated invasively using catheter interventions to restore the blood flow. The current guidelines recommend immediate catheterization in case of MI to avoid necrosis of the myocardium [9].

AI in Noninvasive Evaluations

There are some studies regarding AI technology aimed at the improved efficiency of noninvasive diagnostic and treatment processes.

Some groups have developed programs using machine learning to detect MI based on ECG [10–12]. One of those programs could judge MI and the site of stenosis in every heartbeat [10]. Other groups have reported programs built using deep learning based on electrical raw ECG data [11] or using ECG image data to recognize MI at least as accurately as human physicians [12].

There have also been efforts to introduce AI technology into cardiac CT assessments. It has

been reported that an algorithm built using machine learning can estimate the size of the ischemic area and the severity of stenosis using cardiac CT images [13]. By combining deep learning and other machine learning methods, the ischemic area can be estimated on cardiac CT images to identify those areas that require catheter interventions [14]. The severity of coronary artery stenosis is often assessed using an invasive index called fractional flow reserve (FFR), which functions as a criterion for further invasive catheter interventions. A study group has attempted to estimate FFR noninvasively based on cardiac CT data [15].

AI During Invasive Procedures

In coronary angiography (CAG), a contrast medium is injected during cardiac catheterization into the target coronary artery to assess the stenosis. A study group has developed a program using deep learning to recognize the branches of coronary arteries automatically and the shape of stenosis using CAG images [16]. To evaluate the state of the blood flow, it is important to assess CAG images that are synchronized with each heartbeat from various angles. An AI program has been reported to identify the image frames of the precise timing/phase in the cardiac contraction cycle from various angles [17].

For a detailed analysis for coronary stenosis, the instantaneous wave-free ration (iFR) is one of the modalities to assess hemodynamic appropriateness for catheter intervention. A group has reported that the severity of coronary artery stenosis and requirement for invasive catheter intervention could be well interpreted using machine learning [18].

Although several stages are yet to be achieved before such technologies can be used in clinical practice, they may be developed into an automatic analysis system of CAG images in the future.

AI in Risk Assessments

Patients who have experienced ischemic heart disease are predisposed to higher risks of subsequent cardiac arrest and mortality [19]. Therefore,

the prediction of their risks accurately is an important theme in order to mitigate these risks after the diagnosis of ischemic heart diseases.

An AI program can estimate mortality using machine learning based on cardiac CT and other clinical data [20]. Another group has also reported AI based on the random-forest regression model to predict the risk of rehospitalization due to heart failure, and cardiovascular mortality after catheter interventions [21]. The use of a multilayer perceptron has enabled the prediction of inhospital mortality and mortality over 1 year after discharge from the hospital under the diagnosis of acute MI more accurately than the risk stratification using the current clinical scoring system [22].

Research Targeting Heart Failure

Heart failure is a comprehensive clinical condition caused by dysfunction of the heart pump. Breathlessness, ankle edema, and fatigue are typical symptoms of heart failure. Left ventricular ejection fraction (LVEF) is a major index of cardiac function. LVEF in patients with heart failure can be in the normal range ($\geq 50\%$), midrange (40–49%), or highly reduced range (<40%), which are defined as heart failure with preserved ejection fraction (HFpEF), heart failure with midrange ejection fraction (HFmrEF), and heart failure with reduced ejection fraction (EFrEF), respectively [23]. The ejection fraction is assessed using imaging tests, such as echocardiography and CMR. The common causes of heart failure include MI, valvular disease, cardiomyopathy, and myocarditis.

People of advanced age are prone to develop heart failure. The morbidity in patients with heart failure is reported to increase, which corresponds to the extending average life expectancy [24, 25]. The Framingham Heart Study has reported that heart failure was observed at 0.8% in the 50s and 6.6% in the 80s [26]. The prognosis of patients with heart failure is poor. The mortality of patients hospitalized due to heart failure is three times higher than that in patients without heart failure [27].

AI in Diagnosing Heart Failure

HFrEF can be diagnosed based on significantly reduced cardiac function as assessed using echocardiography and cardiac MRI. If HFrEF is diagnosed, its causative cardiovascular diseases should be identified, which requires complicated professional evaluations. Several attempts have been made to introduce AI technology into this diagnostic process.

A program built using deep learning has been reported to interpret the echocardiography findings to not only assess the cardiac function but also suggest the causative diseases out of three possible choices [28].

In HFpEF, the apparent cardiac function appears to be normal, but symptoms of heart failure are noted. It is believed to be associated with insufficient relaxation of the left ventricular myocardium. The prevalence of HFpEF has increased in the last 20 years [29]. A study group has reported an AI program built using clustering to classify patients with HFpEF into three phenotypes [30], which could contribute in efficient risk stratification of their prognosis.

Both constrictive pericarditis and restrictive cardiomyopathy can result in HFpEF; however, it is not easy to distinguish them using echocardiography, especially, for inexperienced physicians. A research group has developed a program using cognitive machine learning to distinguish these two conditions based on the parameters of speckle tracking echocardiography [31].

AI to Predict Prognosis of Heart Failure

As mentioned above, the prognosis of patients with heart failure is poor, and it is important to predict their prognosis as precisely as possible in order to prevent life-threatening aggravations. The Seattle Heart Failure Model (SHFM) is a traditional scoring model used to predict such prognosis using multiple clinical data [32]. A study group has adopted logistic regression and random-forest methods to demonstrate the possibility of a better risk prediction with SHFM parameters using additional clinical data

[33]. Another group has reported a recurrent neural network (RNN) model to predict the risk of rehospitalization due to heart failure during 12 or 18 months of follow-up from the first onset of heart failure using the data of the diagnosis, drugs, and procedures [34].

Some research groups have applied machine learning in the general population not limited to patients with heart failure. A CNN model has been developed to detect severe cardiac dysfunction on ECG [35]. Interestingly, the individuals in whom cardiac dysfunction was screened as “positive” by the CNN but actual cardiac function was judged “not severely reduced” according to echocardiography demonstrated a four times higher risk of developing cardiac dysfunction in the future. This suggests that there could be signs on ECGs that human physicians cannot recognize at the moment.

Furthermore, a research group reported an AI program to predict the inhospital mortality in patients who underwent transcatheter aortic valve implantation (TAVI) [36]. This program judged mortality based on the given clinical information and demonstrated better predictions than the current scoring systems.

Research Targeting Arrhythmias

Arrhythmia is the general term for abnormal heartbeats, such as tachycardia, bradycardia, or extrasystole. Tachycardia is defined as rapid heart rate ($\geq 100/\text{min}$) and needs treatments in cases of symptoms, such as palpitations, shortness of breath, chest pain, dizziness, or syncope. Bradycardia is defined as slow heart rate (≤ 50 or $60/\text{min}$) and necessitates treatments in case of symptoms, such as shortness of breath or dizziness. Extrasystole is a premature contraction that occurs in the atrial or ventricular myocardium independent of the normal rhythm. The cause of these arrhythmias varies widely between patients; however, the prevalence of arrhythmias generally increases with age and increasing comorbidities.

During the normal heart rhythm (sinus rhythm), electrical signals are generated regularly at the sinus node in the right atrium, conducted to

the left atrium, and subsequently to the right and left ventricles through the atrioventricular node, which leads to myocardial contraction. If this process is disturbed, it can result in arrhythmias. For example, ischemic or valvular heart diseases can trigger arrhythmias where the electrical signals are often blocked because of the injured myocardium. Abnormal activities, such as extra signaling, may be enhanced in this injured area. Hereditary genetic disorders, electrolytic abnormalities, or side effects of drugs can also evoke arrhythmias.

Atrial fibrillation, ventricular tachycardia, and ventricular fibrillation are common arrhythmias that influence the clinical outcomes. During atrial fibrillation, the atrial myocardium trembles rapidly and finely ($>400/\text{min}$), which can result in a thrombus in the left atrium, thus, predisposing the patients to thromboembolic stroke. Ventricular tachycardia and fibrillation impair the heart’s ability to pump blood because of the rapid excitement of the myocardium in the ventricle (ventricular tachycardia) or because of the uncoordinated trembling of the ventricle (ventricular fibrillation), which increases the risk of sudden cardiac death.

Arrhythmias are diagnosed using ECG and should be treated according to the life-threatening risk and symptoms. Tachyarrhythmias can lead to lethal incidents, such as a stroke or sudden cardiac death; therefore, catheter intervention should/ could be considered to identify and eliminate the origin of arrhythmias using radiofrequency or cryoablation (catheter ablation). In the case of bradyarrhythmia that can possibly lead to lethal incidents or result in serious problems, such as syncope, pacemakers can be implanted to maintain sufficient heart rate.

AI to Diagnose Arrhythmias

ECGs are imperative in diagnosing arrhythmias. In this context, some research groups have reported on the detection of arrhythmias based on ECGs using deep learning.

Recently, a model was developed by a Chinese study group to derive rhythmic diagnoses using

12-lead-ECGs [37]. This model could choose one or more diagnoses from 21 choices of rhythm or conduction abnormalities. They gathered over 180.000 ECGs from more than 70.000 patients and utilized over 130.000 ECGs to train their CNN model using residual blocks. This model achieved a higher accuracy than that of 53 cardiologists, including experts.

Another group developed a CNN model using residual blocks to derive a diagnosis based on 12-lead-ECG from six choices of heart rhythm and conduction disorders [38]. They gathered over 2.300.000 ECGs from approximately 170.000 patients for this project.

ECGs must be recorded during the arrhythmia for a precise diagnosis; however, arrhythmias do not always appear while ECGs are being recorded. A model to solve this problem has been reported to identify potential patients with atrial fibrillation based on their sinus rhythm on ECG [39]. They used approximately 650.000 electrical raw 12-lead-ECG data from over 180.000 patients. Additionally, approximately 450.000 and 60.000 ECGs were used for training and validation, respectively. The remaining 130.000 ECGs were used for testing. They used a CNN architecture with residual blocks. This model would be useful not only for the early discovery of arrhythmias but also for the treatment strategy, for example, in patients with prior embolic stroke of undetermined source (ESUS). Patients with ESUS are divided according to the presence of atrial fibrillation because they require different therapeutic strategies that can otherwise lead to lethal incidents, such as restroke or intracranial bleeding. Identifying potential atrial fibrillation based on sinus rhythm on ECGs will help in developing appropriate medication strategies.

AI to Monitor for Arrhythmias

Some studies have focused on detecting arrhythmias and not the underlying diagnosis.

ECGs recorded through fewer electrodes are less useful for precise diagnoses but can be used to detect the heart rhythm. Fewer electrodes result in smaller ECG equipment and easier application in

mobile equipment, such as smart watches. Monitoring and early detection of arrhythmias in daily life can be highlighted with these small wearable devices. For such ECG monitoring using fewer leads, AI technology has been introduced toward efficient detection of arrhythmias. This technology will provide potential patients a chance for early treatment or secure the patients with cardiovascular disorders from their high-risk prognosis.

The functionality of a program based on algorithms to detect arrhythmias has been previously reported [40]. Using a machine learning methodology called echo state network, a group demonstrated the possibility of detecting ventricular arrhythmias efficiently [41]. A 33-layer CNN model to detect one of the 12 rhythm classes has also been reported [42]. Over 90.000 single-lead ECGs from more than 50.000 patients were utilized to train this model.

Various research groups have demonstrated that false arrhythmia alarms based on ECG monitoring in the intensive care units could be reduced using AI programs built using machine learning based on ECG data monitored with fewer electrodes combined with additional clinical data (arterial blood pressure and photoplethysmogram signals) [43, 44].

AI to Identify Arrhythmias from Sources Other than ECGs

There is an interesting report on arrhythmia detection using deep learning based on general data and not medical data [39]. In their presentation, the group reported that atrial fibrillation could be detected based on video images of the patients' face. This may provide potentially asymptomatic patients with the opportunity for early treatment. Further developments are expected.

Discussion

AI technology has demonstrated great potential toward more efficient diagnostic and treatment processes in cardiovascular disorders. Its recognition capability, which is superior to that of

humans, can be a strong advantage considering the complex evaluations in clinical practice. Most of the already accumulated clinical data are objective and easy to digitalize for building AI. According to reports, a large amount of data is not always necessary to build an AI, which suggests the possibility of model development suitable for minority groups or each individual.

However, AI technology is not yet mature enough for clinical use in the field of cardiovascular medicine. Each model reported so far could solve only simple questions, unlike human physicians who can process various clinical information, including subjective and nondigitalized data simultaneously. Some of the studies were at the prestage in the diagnostic process, for example, to judge the angle of images. Furthermore, we cannot judge whether the AI “learns” as appropriately as human medical students or residents. AI can be easily deceived by fake or unimportant information [45]. Further technical developments in AI are essential to guarantee quality and safety in clinical use.

Despite the aforementioned problems, we can still expect AI technology to overcome certain challenges. The current simple programs can be combined into providing more complicated and comprehensive judgments. The weakness in guaranteeing the learning process can be partially overcome using other ideas, such as visualization of the parameters of neural networks with a heatmap. The heatmap could help in visualizing the points on ECG that the AI focused on for its judgment by using the ECGs as image data and not electric raw data [12], which can help the AI “explain” its thought process.

In summary, political and legal agreements aside, AI can be useful in clinical situations, at least as an assistant, particularly, in the absence of professional equipment or expert physicians. The quality and safety can be guaranteed by using final decisions of human physicians. AI technology is still developing intensively and its technical limitations will be resolved in the future, which will help improve the trust in AI and integrate it into clinical settings. It is expected that AI technology will bring significant progress in the diagnostic and treatment processes in cardiovascular disorders.

Abstract

Medical robotics emerged in the 1980s to improve clinicians' technical capability and increase safety in clinical procedures. This chapter specifically addresses the topic of surgical robots. Major opportunities for artificial

intelligence (AI) here include (i) surgical planning, (ii) intra-operative registration, (iii) surgical execution, and (iv) surgery evaluation/assessment. This chapter provides an overview of AI methodologies developed so far in these four fields, reporting main limitations and open challenges. Deep learning (DL) models for pre-operative image segmentation, classification, and detection are presented, along with DL architectures for intra-operative registration. In the context of surgical execution, intra-operative image analysis is described, focusing on endoscopic images for tissue and surgical tool segmentation. Considering the rapid evolution of AI applications in the field of surgical robotics, the proposed contribution is aimed at giving to young researchers and surgeons working in the field of surgical

Medical robotics · Artificial intelligence · Surgical planning · Intra-operative registration · Intra-operative image analysis · Virtual-fixture control

Introduction

Medical robotics is an interdisciplinary field that emerged in 1980 as a new branch of robotics. A large number of challenges has to be tackled to bring robots into the clinical routine, including high accuracy for surgical procedures and the need for human-robot interfaces. These challenges are far from those of industrial robots, and this motivated the birth of the new field [1].

Nowadays, robots are used in several domains, including neurosurgery, orthopedic surgery, nose and throat surgery, and laparoscopy. Medical robots allow improving surgeons' technical capability to perform procedures by exploiting the complementary strengths of humans and robots: robots can be more precise and geometrically accurate than unaided average surgeons. Medical robots can also increase surgical safety by means

of forbidden-region, virtual-fixture control (e.g., to avoid surgical tools damaging sensitive structures). As a last advantage, medical robots allow capturing detailed procedural data, which can be analyzed to update/adjust the current surgical practices to improve the surgical outcome.

Broadly, surgical robots may be grouped into:

- *Surgeon extender robots*, which manipulate surgical instruments under the direct control of the surgeon, usually through a teleoperated or hands-on cooperative control interface, and allow tremor filtering, region-avoidance/targeting control and remote surgery. Examples include the da Vinci system (Intuitive Surgical Systems, Sunnyvale, CA) and the Steady Hand microsurgery robot (a research prototype from Johns Hopkins University).
- *Auxiliary surgical support robots*, which generally work alongside the surgeon and perform routine tasks, such as endoscope holding. Examples include the AESOP endoscope positioner.

Following the nomenclature proposed in [2], the main aspects of surgical robots are (Fig. 1) surgical planning (section “[Pre-operative Planning](#)”), registration (section “[Pre-/Intra-operative Registration](#)”), execution (section “[Execution](#)”), and evaluation (section “[Monitoring and Assessment](#)”), which all

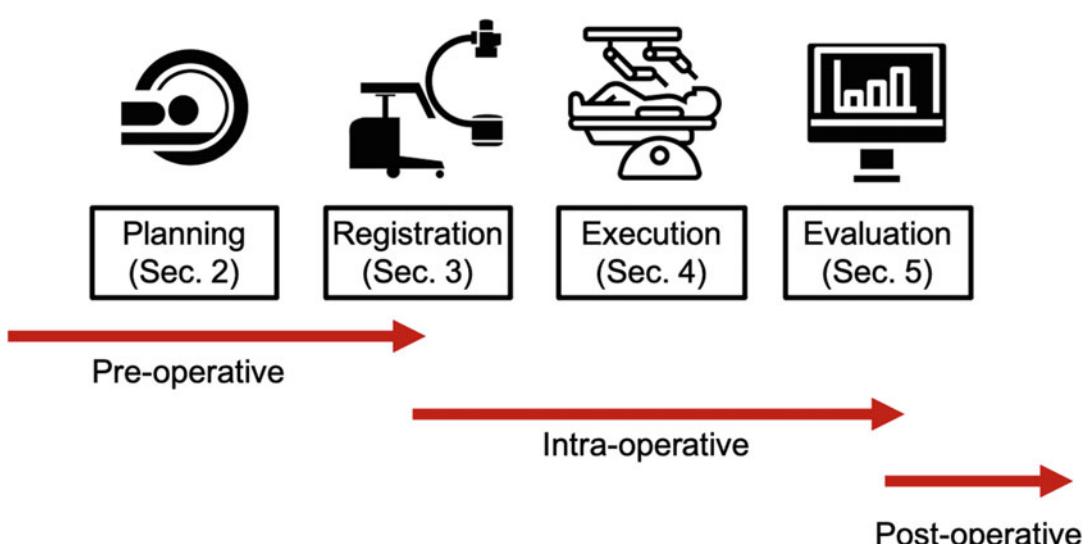

Fig. 1 Standard workflow of robotic surgery

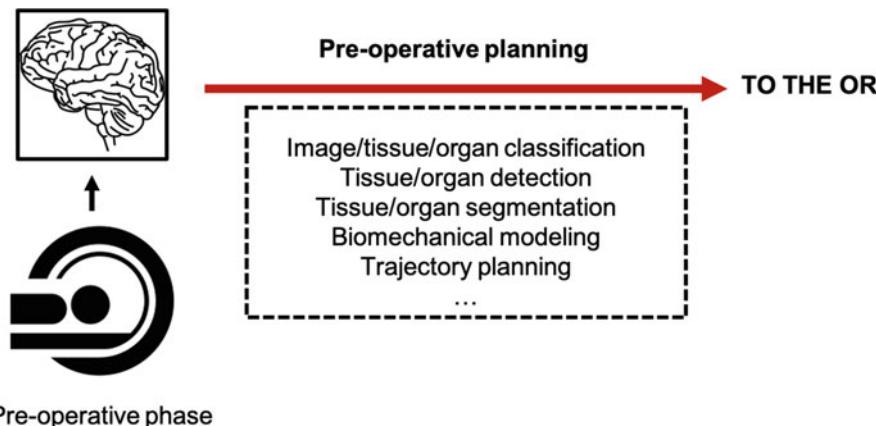

Fig. 2 Pre-operative surgical planning. OR: operating room

together can be referred to as CAD (computer-aided design)/CAM (computer-aided manufacturing). This chapter will cover all these aspects, focusing on specific points in which artificial intelligence (AI) technologies mainly contribute.

Pre-operative Planning

Surgical planning relies on pre-operative imaging, such as magnetic resonance imaging (MRI) and computerized tomography (CT), to provide anatomical/morphological information on the patient (Fig. 2). Surgical planning covers a major role for percutaneous keyhole surgeries (e.g., liver-tumor ablation) and stereotactic procedures (e.g., key-hole neurosurgery). Such surgeries require accurate positioning of the instruments to guarantee an effective and safe procedure, but usually do not provide a clear view of the surgical scenario. Surgical planning is also crucial for orthopedic and cardiac surgery, where it allows choosing the best prosthesis size and its best positioning with respect to the patient's anatomy. In laparoscopy, surgical planning allows estimating the optimal location of the skin incision, as well as the optimal placement of surgical instruments.

Different researchers are working on developing surgical planners for helping surgeons in processing pre-operative images and performing surgical planning [3]. Pre-operative planning involves a variety of aspects, ranging from biomechanical modeling to

tissue segmentation, classification, and detection. While AI for biomechanical modeling is at its infancy, AI covers today a major and undisputed role in image segmentation, classification, and detection [4]. Classification involves images (e.g., to understand if a structure of interest is present in the image) and object/lesion classification (e.g., for staging tumors). Standard deep learning (DL) architectures, mostly convolutional neural networks (CNNs) pre-trained on large natural datasets such as ImageNet, are commonly used. Examples include VGG16, AlexNet, ResNet, and Google Inception [5].

Opposite to classification, detection spatially locates objects in the image. The problem of detection is called localization if only one object has to be found in the image. Main applications include tissue, organ, and surgical tool detection. Here, region-proposal architectures, such as RCNN, Fast RCNN, and Faster RCNN [6], as well as detection architectures inspired by Yolo [7], are the most exploited.

Image segmentation is mostly applied for segmenting organs and pathological tissues (e.g., cancerous areas). A plethora of segmentation algorithms today exist. The U-Net [8] is among the first CNN models for medical image segmentation. With U-Net, the concept of encoder-decoder architectures with long skip connections has been introduced to allow accurate and fast segmentation. Modern algorithms involve more complex architectures, following the adversarial training paradigm [9]. Besides

tissue segmentation, AI algorithms can be also used to estimate morphological and metabolic parameters, such as tissue oxygenation [10], starting from metabolic images such as positron emission tomography (PET).

AI in the field of pre-operative planning finds space also in trajectory optimization for keyhole surgeries. Examples include the application of machine learning to predict the entry and target regions [11], as well as the optimal trajectory to minimize the probe depth while maximizing the distance from critical structures [12]. A systematic review of surgical planning assistance in keyhole and percutaneous surgery has been recently published [3]. For brain surgery, large attention is given to the localization of stimulation zones, to estimate the size and location of tissue that has to be removed or treated [13]. This can be done by exploiting additional signals, such as electroencephalography and functional near-infrared spectroscopy. A systematic review on the possibilities offered by AI in brain intervention planning (i.e., from diagnosis to intervention) has been published [12].

Pre-/Intra-operative Registration

In the operating room, the pre-operative patient model and plan must be registered to the actual patient. With registration, the pre-operative

patient anatomy is aligned with the intra-operative view. The workflow of image registration is shown in Fig. 3. The registration process can be described by a mathematical operator called transformation, which can be rigid or deformable. Rigid transformation is described by 6 degrees of freedom (3 for rotation and 3 for translation), and the Iterative Closest Point is the most used rigid transformation algorithm. Deformable registration can be described up to infinite degrees of freedom [14].

There is an extensive literature on techniques for coregistering coordinate systems associated with robots, sensors, images, and the patient. Typically, the transformation is estimated by identifying corresponding landmarks or structures on the pre-operative model and the patient by using (i) additional imaging, (ii) tracked devices, and (iii) the robot itself [2]. If the patient's anatomy has changed from the pre-operative plan, then the planning needs to be updated.

The role of AI in registration has impacted especially the field of image-based registration, where DL has changed the landscape of image registration research. Today, more and more advanced imaging devices are introduced in the operating room [15]. Such devices produce images that may be quite different from those acquired pre-operatively. Typically, intra-operative imaging modalities are X-ray,

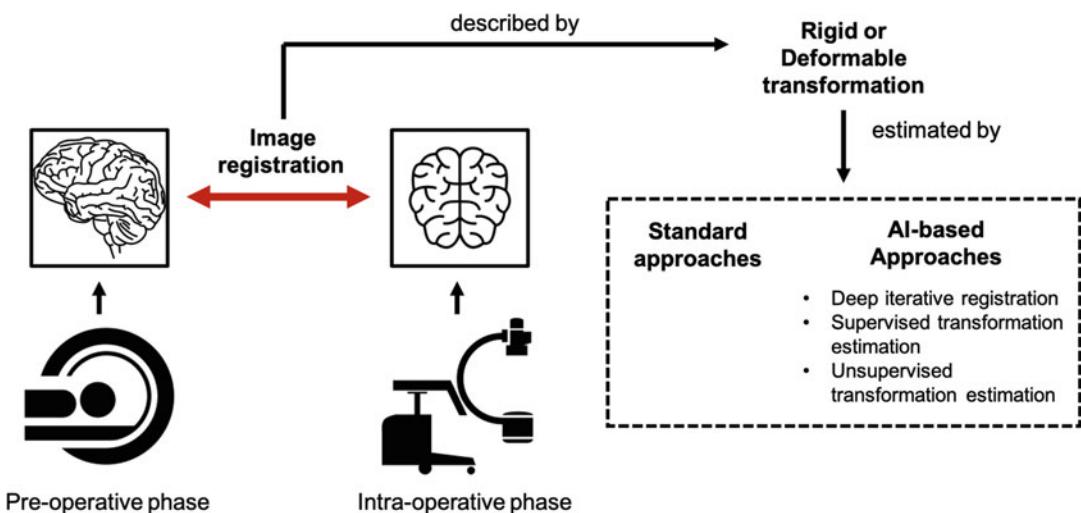

Fig. 3 Pre-operative to intra-operative image registration

ultrasound, and video laparoscopy. This poses additional issues for the registration process, as multi-modal registration has to be performed.

First approaches dealing with AI and registration were used to improve the performance of standard intensity-based registration algorithms. The need to shorten the computational time of registration algorithms motivated researchers to move forward, by designing one-step transformation estimation techniques, mostly with unsupervised methods to tackle the lack of generating ground truth data.

Registration using AI can be categorized in:

- *Deep iterative registration*, among the first approaches in the field, where researchers use DL to learn a similarity metric between images. This similarity metric is used in a classical intensity-based registration framework.
- *Supervised transformation estimation*, where a supervised DL model is trained to estimate in one step the transformation parameters:
 - Fully Supervised Transformation Estimation, where the DL model is fully supervised. In this case, the quality of the registrations is clearly dependent on the availability and quality of the ground truth. Usually, synthetic data are used to overcome such limitations.
 - Dual/Weakly Supervised Transformation Estimation, where the dual supervision refers to using both ground truth data and some image similarity metrics to train the DL model, while weak supervision refers to using the segmentation of corresponding regions in the pre- and intra-operative images for designing the DL model loss function. This approach partially attenuates the limitation of methods for fully supervised transformation estimation, representing one of the most promising methods in the field of image registration.
- *Unsupervised transformation estimation*, where the transformation is estimated without the need of an annotated ground truth. The power of unsupervised estimation has been unlocked by the implementation of the spatial transformer network, which explicitly allows

the spatial manipulation of images (and activation maps) within the DL network [16]:

- Similarity Metric-Based Unsupervised Transformation Estimation, where similarity metrics are used to train the DL network. Approaches in the field make use of both standard similarity metrics (e.g., normalized cross-correlation) and more advanced ones (e.g., based on the generator output of a generative adversarial network). Unfortunately, today the problem of quantifying image similarity for multimodal registration applications is still open. This poses issues considering that pre-operative to intra-operative image registration is often a multimodal registration problem.
- Feature-Based Unsupervised Transformation Estimation, where the feature representations of the images are used to train the DL network. This approach is significantly more difficult than the previous ones, as the estimation of the registration has to be performed starting from the estimation of feature representations.

Execution

As introduced in section “[Pre-/Intra-operative Registration](#),” modern robotic surgical rooms are equipped with multimodal imaging systems, to provide all possible support to the surgical team. Intra-operative ultrasounds, X-ray, optical coherence tomography, interventional MR or X-ray imaging, and endoscopy are among the most exploited imaging modalities and are rapidly evolving to provide more and more accurate information. New imaging modalities, such as diffuse reflectance spectroscopy and multispectral imaging, will enter the actual surgical practice in the next decades. Each modality has its own characteristics in terms of field of view (FoV), image resolution, noise, and enhanced tissues. Besides imaging systems, the operating room is equipped with a variety of other medical devices, which provide quantitative and continuous information on the patient status. The robot itself provides information on the surgical procedure.

The centrality of AI for intra-operative data analysis is undeniable. During the last decade, a new discipline has emerged, called surgical data science (SDS), which exploits AI for processing intra-operative data analysis, as to provide surgeons with decision support and context-aware assistance [17] in robotic surgery. This section describes some of the major opportunities for SDS in intra-operative image analysis (section “[Intra-operative Image Analysis](#)”), with a focus on endoscopy.

Intra-operative Image Analysis

Intra-operative image analysis for endoscopic images may be classified in the following categories:

- Informative frame selection
- Detection, classification, and segmentation of anatomical structures and surgical tools

Such categories will be shortly described hereafter, while a more in-depth review on the topic can be found in [18].

Informative frame selection. From the surgeon’s side, reviewing an endoscopic video is a focus-intensive operation. While focusing on particular structures during the video examination, clinicians may miss important clues indicating suspicious conditions (e.g., early tissue alterations). This process could be further compromised by the presence of uninformative video portions. Developing a strategy to select informative frames has the potential to reduce the amount of data to review, lowering the surgeons’ workload. Several approaches have been proposed to select informative video frames, from (time-consuming) manual frame selection to random or uniform frame selection, which is fast but does not guarantee that all informative frames are extracted. More recently, DL approaches have shown promising results.

Detection, classification, and segmentation of anatomical structures and surgical tools. The analysis of an intra-operative informative frame usually starts with the *classification, detection,*

and segmentation of structures in the FoV. This means to understand if a specific structure (such as a pathological tissue or a surgical tool) is present in an image. Structure detection and classification have strong diagnostic value but can be also used to determine the surgical phase (hence, in each phase of the surgery, different structures are present in the FoV). The most used approaches in the field are similar to those described in section “[Pre-operative Planning](#).” The main difference here is that endoscopic videos naturally encode the temporal information. Hence, models to analyze this information are becoming more and more studied by the researchers. Examples include recurrent CNNs and spatiotemporal CNNs [19]. Here major challenges are relevant to the higher complexity of models analyzing temporal clips (with several frames), opposite to those processing still frames. This may pose issues relevant to overfit. To attenuate this issue, short temporal clips (up to 10 frames) are used. In the field of intra-operative segmentation, interesting results are achieved by adversarial models [20, 21].

Providing automatic interpretation of the surgical scene would be fundamental to increase the level of autonomy of robots in surgery [22]. The approach presented in [23] combines a deductive approach for surgical step classification with an inductive approach derived from an ontological description of the surgical process (i.e., partial nephrectomy). Recently, some groups have started integrating logic formalism and rules management into the surgical process in order to allow for continuous learning of new rules by performing the surgical tasks [24].

Monitoring and Assessment

The role of AI in monitoring and assessing surgical procedures is growing rapidly. Surgical skill assessment is among the major opportunities in the field. Surgical skill assessment is particularly useful during surgeon training [25]. Nowadays most assessments of trainee skills are still

performed via outcome-based analysis or structured checklists. Modern surgical robots are able to collect a large amount of sensory data: such data represent a unique opportunity for evaluating the skills and proficiencies of the trainees.

Surgeon's skill levels can be defined according to the Dreyfus model [26], shown in Table 1. The role of AI algorithms for surgical skill assessment is to abstract the Dreyfus model by analyzing data available in the operating room.

To design algorithms for automatic surgical skill assessment, researchers usually take inspiration from available standards used in clinics, such as the Objective Structured Assessment of Technical Skills (OSATS). The evaluation here relies on respect for tissue (used forces, caused damage), time and motion (efficiency), instrument handling (movement fluidity), knowledge of instruments (types and names), flow of operation (stops frequency), use of assistants (proper

strategy), and knowledge of specific procedure (familiarity with the aspect of the procedure). Such aspects can be derived from (Fig. 4):

- Kinematic data (e.g., instrument travel time, path length, velocity)
- Endoscopic videos
- Additional sensors (e.g., force sensors)

When using specific robots, more data may be available. Examples include system events, such as frequency of master controller clutch use, third-arm swap, and energy use, for the da Vinci system.

Once these data are available, algorithms to process them have to be designed. Approaches in the literature can be mainly divided in [27]:

- Descriptive statistic analysis, which aims to compute relevant indicators from surgical data to quantitatively describe skill level via

Table 1 Dreyfus model of skill acquisition. Columns and rows refer to mental function and skill level, respectively

	Novice	Competent	Proficient	Expert	Master
Recollection	<i>Non-situational</i>	<i>Situational</i>	<i>Situational</i>	<i>Situational</i>	<i>Situational</i>
Recognition	<i>Decomposed</i>	<i>Decomposed</i>	<i>Holistic</i>	<i>Holistic</i>	<i>Holistic</i>
Decision	<i>Analytical</i>	<i>Analytical</i>	<i>Analytical</i>	<i>Intuitive</i>	<i>Intuitive</i>
Awareness	<i>Monitoring</i>	<i>Monitoring</i>	<i>Monitoring</i>	<i>Monitoring</i>	<i>Absorbed</i>

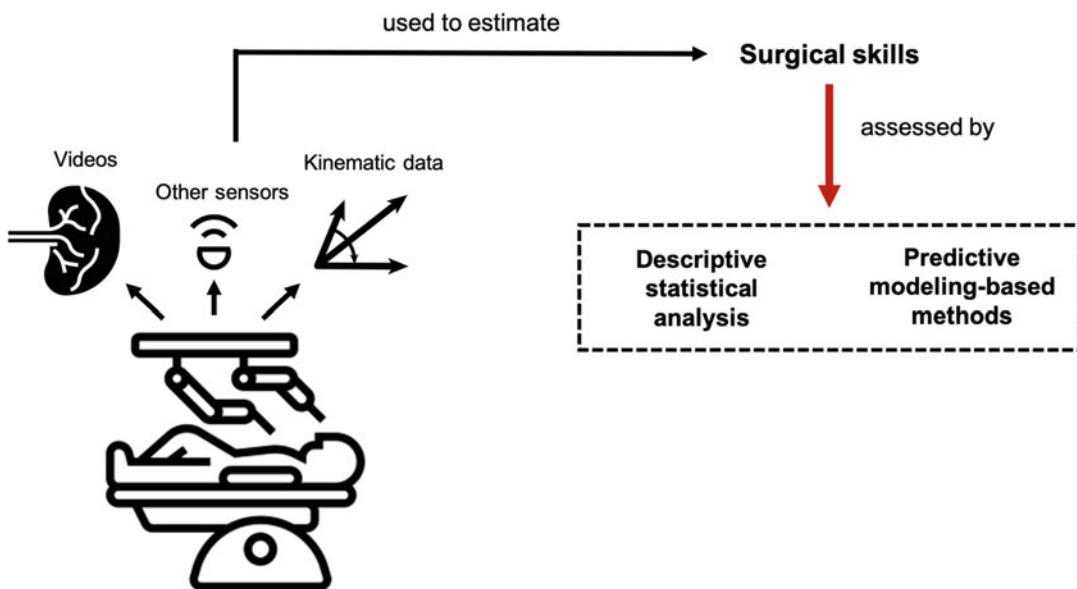

Fig. 4 Surgical skill assessment workflow

- statistical analysis. Sample indicators are path length, motion jerk, and tool orientation. However, selecting the most suited indicators may not be trivial considering the intra- and inter-variability in surgical procedure execution.
- Predictive modeling-based methods, which work on raw data to automatically extract and classify surgeon skill level. Here, AI covers a major role.

Among predictive modeling-based methods, a class of algorithms starts from features extracted following the OSATS guidelines and applies traditional machine-learning classifiers (e.g., support vector machines, random forest, k-nearest neighbors) to classify the skill level. To take the temporal information into account, hidden Markov models are commonly exploited. Focusing on video data, similarly to what introduced in section “[Intra-operative Image Analysis](#),” DL models processing 2D + t data (e.g., spatiotemporal CNNs or recurrent networks) are the most used approaches. DL models are commonly used to classify short video sequences (to avoid training large models, which are prone to overfitting) and are then followed by a consensus layer to predict the overall surgical procedure skill level.

Conclusion

In this chapter, the main steps of robotic surgery have been presented. The field of surgical robotics is evolving rapidly, thanks to the cooperation of surgeons, research institutions, and industry deploying surgical robots, with the final goal to have a direct impact on patients’ health.

In the close future, surgical robots need to become more precise, dexterous, and sensitive while also becoming much more compact and inexpensive. At the same time, surgical robots should be highly modular architectures that allow a high degree of reuse, with open interfaces between major subsystems. These are two main challenges that need to be tackled from the hardware perspective.

The use of AI for surgical robotics probably sees its main application in imaging, modeling,

and analysis: AI can help building patient-specific anatomical models from pre-operative images and real-time sensor data, for incorporating biomechanical information into these models and for using this information to help control the robot.

Abstract

The future of surgery is tightly knit with the evolution of artificial intelligence (AI) and its thorough involvement in surgical robotics. Robotics long ago became an integral part of the manufacturing industry. The area of healthcare though adds several more layers of complication. In this chapter we elaborate a broad range of issues to be dealt with when a robotic system enters the surgical theater and interacts with human surgeons – from overcoming the limitations of minimally invasive surgery to the enhancement of performance in open surgery. We present the latest from the fields of cognitive surgical robots, focusing on proprioception, intraoperative decision-making, and, ultimately, autonomy. More specifically, we discuss how AI has advanced the research field of surgical tool tracking, haptic feedback and tissue interaction sensing, advanced intraoperative visualization, robot-assisted task execution, and finally land in the crucial development of context-aware decision support.

Introduction

Robots are a crucial part of multiple industries, allowing greater productivity and efficiency by taking over repetitive, labor-intensive, menial, high-power, and dangerous tasks. This field of complex control systems has had a huge torrent in adoption to surgery, due to the key benefits it poses such as less pain, scarring, risk of infection, blood loss, and high precision, especially when operating in confined spaces or in minute settings like ophthalmic surgery. However, in reality, most robotic systems that are employed today are primarily machines with manipulators that are pre-programmed for conducting a set of predefined manual tasks automatically. This also requires prior knowledge of the environment so that the

robot will be deployed in such a way that all possible changes and interactions can be modeled and defined in advance. This became possible with the advent of sensors embedded in the robots that provide information about the environment and feedback of performance in accomplishing the given task.

However, robotic autonomy in a highly dynamic environment like surgery where external manipulations that occur in the form of interactions with the patient is challenging. This is because soft tissue deformation, varying material properties, and the manipulation of anatomical structures with respect to the robotic tool cannot be pre-programmed or defined as a set of instructions over time. Hence, the prior motivation of robotic development that was mainly to increase productivity and reduce costs by tackling menial, repetitive tasks needs to be challenged. This is exactly what the field of intelligent systems or in particular Artificial Intelligence (AI) aims to achieve. Research in AI has enabled endowing robots with the ability to adapt to a changing environment by analyzing their sensor data to have greater perception and adaptability to an uncertain environment. Additionally, AI enables them to recognize hidden patterns in data at high dimensions, such that they can autonomously determine the optimal action even in cases difficult for humans.

Evidently, AI is essential for the evolution of robotics to cognitive robotics. Here, AI is the information processing engine like the brain, and robotics gives it a physical form to interact with the environment. Despite the high synergy between robotics and AI, yet the two fields progressed distinctly apart in the previous few years. Recent advances in computer vision, machine and deep learning, data analytics, and robotics have enabled the development of cognitive robotic systems capable of operating at varying degrees of autonomy to assist the surgeon intraoperatively and improve the efficacy and outcome of surgery.

In this chapter, the application of AI in the field of surgical robotics will be extensively discussed. In particular, we will explain how we can use AI to endow robots with cognitive abilities such as proprioception and decision-making and how these methodologies pave the way for robotic autonomy to enhance the capabilities of the surgeon and improve surgical outcome. The following sections discuss the enabling technologies of AI to achieve the above goal focusing on navigation and 3D scene understanding, advanced visualization using augmented reality, followed by diagnosis support for intraoperative decision-making. Finally, we present an outlook into the future.

Cognitive Surgical Robots

For robots to be capable of interacting with the surgical scene in a safe manner, it is vital we embed them with intelligence and perception power similar to that of humans. As an example, humans have exemplar ability of proprioception and thereby make decisions on self-motion in a dynamic environment. This is achieved through the processing of many neural impulses the brain receives via the sensory inputs, thereby making the human aware of the local surrounding and make decisions on how to navigate themselves in complex three-dimensional space with ease. Providing robots with the necessary cognitive capabilities to perceive their environment and feedback that information will enable decision-making and ultimately robot autonomy.

The degree of autonomy achievable by a surgical robot ranges from robot assistance (Level 1) to conditional autonomy (Level 3) and full autonomy (Level 5) at the highest level [1]. Each of these autonomy levels is characterized by different technical challenges and therefore relies on different technologies for successful execution. Surgical platforms operating at low degree of autonomy (Level 1) provide the surgeon with either cognitive or physical assistance without taking control of the action being performed. Examples include systems that assist in optimal robot deployment and systems that provide augmented reality. To achieve this goal, the robot needs to have a good understanding

of the surgical scene. More specifically, the 3D structure of the surgical scene, the tracking and recognition of surgical tools as well as their interaction with the tissue are fundamental for intraoperative robotic assistance. For seamless augmented reality visualization, the detection of anatomical landmarks and the registration of multimodal data are required.

Task autonomy (Level 2) enables a surgical robot to execute repetitive and well-defined tasks that may be ergonomically difficult for the surgeon, but without being able to update the task planning during execution. Robot-assisted execution of surgical tasks such as tissue retraction, suturing, and ablation require the analysis of the surgical workflow to permit the robot to provide dedicated support at the right phase of the operation.

As the degree of autonomy increases, surgical robots operate with conditional autonomy (Level 3), being capable of planning how to execute a surgical task and updating the plan during execution. To achieve this, the robot is constantly monitoring the surgical environment to extract contextual information and execute the task in real time. Key AI technologies to enable this involve modeling of the tissue deformation and high-level feature tracking.

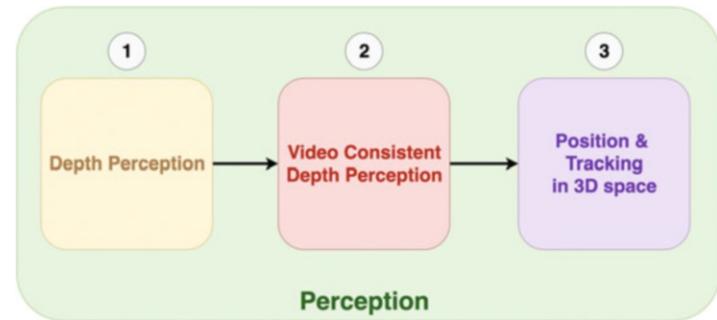

The robotic platforms operating at high autonomy (Level 4), have the ability to make clinical decisions and execute them under human supervision. As a future application, they could be used for the intelligent removal of cancerous tissue, including identification of the tissue state, adaptation of the plan with real-time data, and ablation of the cancer while sparing as much healthy tissue as possible. To this end, AI techniques for tissue characterization have a crucial role toward tumor detection and resection. Finally, fully autonomous surgical robotic platforms (Level 5) have not been developed yet.

Proprioception

Depth Perception

This area of research relies heavily on computer vision and in particular extracting 3D models of the scene. Three-dimensional information is

Fig. 1 Process pipeline of embedding proprioception in robotics from computer vision

quintessential for registering preoperative data to the surgical field of view, which can then be further visualized through mixed reality. These steps are broken down and illustrated in Fig. 1.

The core aim in the first instance is to generate a dense 3D model of the scene captured through a camera. To get a 3D model of the surgical scene we essentially need to calculate the distance of various points in the image relative to the position of the camera. This not only provides the information captured in the image but also its 3D location in the scene. This information is referred to as a “depth map,” a single channel matrix that encapsulates the distance value for each respective pixel in the image. The general method of depth information extraction from images is to acquire a pair of images using two cameras displaced from each other by a known distance called the “baseline.” This pair of images is known as stereo-images, which are similar to that of a biological visual system, where the eyes together are capable of establishing 3D information of what you see. The main idea is as follows: by estimating the per-pixel displacement between the two frames horizontally, commonly known as the “disparity map,” depth can be inferred as an inverse function. As an alternative, two or more images taken from a moving camera can also be used to compute depth information. This method of dealing with a moving camera and multiple images is known as Structure from Motion (SfM), discussed further in the next subsection 3.2. Hence, the methods of extracting depth from an image can be divided into the following categories: single image depth (mono-depth), stereo image depth (binocular-depth), and multiple views (SfM). Recently, deep learning models

have become very attractive in the depth perception workflow, providing end-to-end solutions for depth estimation.

Single image depth: Traditional vision uses multiple frames for inferring depth and thus, one would state extracting depth from a single image is an ill-posed problem. However, if humans were to cover one of their eyes, they are still capable of perceiving depth even from a single vision system, as they are capable of using priori information of their surroundings. The seven monocular depth cues are: relative size, interposition, linear perspective, aerial perspective, light and shade, and monocular movement parallax. Hence, this argument motivates a lot of the work in single image depth estimation. Approaches for depth estimation fall into two categories, namely, supervised learning based, which require ground truth depth data and self-supervised learning based, which do not rely on any ground truth for training.

Supervised learning based approaches, frame depth estimation either as a classification or a regression problem, since ground truth labels are available. The loss signal is typically some type of distance metric such as L1, L2, etc., between the predicted depth map and the ground truth depth map. One of the earliest works predicted dense depth maps via a 2-stage process, where in the first stage a deep neural network produces a coarse depth map followed by the second stage where another deep neural network refines it [2].

In the first stage the coarse depth map is based on the network learning global features from images, like object locations, coarse outlines, etc. In the second stage the finer scales are estimated by the network learning more local features such as textures of specific objects, edges of local

points, etc. The authors treated the problem as a regression task and defined losses that were invariant to image scale. Other methods were later published that built upon Eigen et al. [2], such as Cao and Shen [3], which treated the problem as a classification task of the valid pixels in the ground truth depth maps. The authors of [4] deviated from the aforementioned approach and treated monocular depth estimation as an ordinal regression problem. Modeling traditional regression onto an ordinal scale means any predicted variable can be from any arbitrary scale. Hence, only the ordering between intermediate values is vital to capture the relationship of the variable. This enables the model to discretize a continuous depth map into intervals, which is beneficial since standard regression-based losses result in models suffering from slow convergence or convergence to local extrema. However, supervised approaches depend upon high quality ground truth depth during training, which is subject to availability.

Whereas **self-supervised** methods do not require this ground truth data. Typically, methods in this category predict a disparity map. Estimating the disparity map for each of the images in the stereo pair enables synthesizing the corresponding image via warping the original. For example, given the left input image, the right disparity map can be used to warp this input, to generate a hypothesis of the right view. Hence self-supervised learning methods focus on the reconstruction of images based on optimizing for photometric re-projection error by comparing the original input images and the synthesized predicted images. Ensuring these synthesized images appear similar to the original input indirectly optimizes the model to hone its disparity map output. This disparity can then be utilized to infer depth since depth is inversely proportional to disparity.

One of the earliest methods to formulate a self-supervised monocular depth estimation approach was [5]. They utilized a photometric consistency-based loss to train their deep learning model, in particular an L2 loss. In [5] the reconstruction loss is not fully differentiable, hence a Taylor approximation is performed to linearize the loss with respect to the model, which adds further complexity to the method. Moreover, Godard, Mac Aodha,

and Brostow [6] utilized a weighted sum of Multi-Structural Similarity Index (MS-SSIM) [7] and L1 distance as their photometric error. They also introduced two additional components as part of their loss term: the disparity smoothness loss computed between the left and right predicted disparity maps and the left-right disparity consistency loss. Both of which act as regularizers and ensure the output disparity is consistent with the corresponding one. These loss components from Godard, Mac Aodha, and Brostow [6] have become somewhat standard in self-unsupervised depth estimation.

Stereo image depth: This is where both the stereo pairs (left and right) are fed as an input to the model for depth estimation. Traditional stereo methods aim to generate a disparity map that minimizes an energy function, which essentially comprises of two terms: matching cost and smoothness regularization [8, 9]. Traditional methods tend to follow a four-step process for disparity estimation:

1. Feature extraction, from the two input images
2. Feature matching, between the two images
3. Computation of disparity
4. Refinement and post-processing of disparity

The first two steps construct a cost volume, which is simply a matrix that has aggregated the relevant features from the left and right image pipelines. Earlier deep learning-based methods in stereo matching simply replaced (1) & (2), which comprised of hand-designed feature extraction and matching with convolutional neural networks for doing high-dimensional feature matching [10]. Recent work advances on this methodology and focuses on improving stereo network architecture components. Chang and Chen [11] introduced a new network architecture, entitled “PSMnet,” which comprised of spatial pyramid pooling in their stereo matching network that consisted of 3D convolutions. This type of pooling module enables the network to encode hierarchical context information, which is difficult to attain from pixel intensities alone. Guo et al. [12] further developed on PSMnet, by innovating the way cost volume is aggregated in the network. Typically, this volume is aggregated by

concatenating left and right feature maps or via cross-correlation; Guo et al. [12] however, experimented with group-wise correlation. Unlike full correlation it is more efficient and still retains all the representations for conducting feature matching. The aforementioned methods are supervised learning based, and just like in monocular depth estimation self-supervised learning approaches are also utilized in stereo matching. These methods typically extend [6] to compute losses with respect to both input images or advance on the photometric loss component. Pilzer et al. [13] took a self-supervised approach by defining the photometric loss as an adversarial learning problem, where an additional network called the discriminator is utilized as a loss function [14].

Some of these aforementioned techniques in depth perception have also been utilized on surgical scenes to attain great performance for clinical applications. A recent challenge in minimal invasive surgery (MIS) entitled Stereo Correspondence and Reconstruction of Endoscopic Data, i.e., SCARED [15], had multiple submissions that utilized the work of Chan and Chen [11], Garg [5], and Goodfellow et al. [14] adapted to stereo inputs. These models achieved comparable performance on MIS data, to their natural scene counterparts. Another work by [16] utilized a self-supervised approach for depth perception on laparoscopic images. In particular they utilized an autoencoder model that took a pair of calibrated stereo images as inputs to predict their corresponding disparity maps. Similar to that of [5], however with the exception of stereo inputs as opposed to the monocular as done in the original. Furthermore, [17] trained a conditional generative adversarial network (pix2pix) [18], to generate a depth map from input monocular endoscopic images for colonoscopy. They originally train on synthetic images, due to lack of data availability and show robustness on transferring to real data during testing. They train their model in a joint adversarial and supervised manner. Furthermore, deep learning requires large quantities of training samples to train models, especially for self-supervised-based approaches for depth estimation. To that extent [19] created a software entitled “*VisionBlender*” that can be utilized for

generating synthetic data for minimally invasive surgical scenes including depth ground truths for training deep learning in surgery.

Navigation

Structure from Motion: Structure from Motion (SfM) is the process of extracting (3D) depth information and camera motion from a sequence of standard images (2D), typically a monocular video. Models designed for SfM need to estimate depth and camera pose between adjacent frames conjointly to understand the spatio-geometric relationship in the video. Traditional SfM methods rely on Bundle-Adjustment [20], where depth and camera motion for every view is conjointly optimized via Levenberg-Marquardt (LM) [21] algorithm, which is a form of iterative nonlinear least squares optimization. However this approach is successful only in limited scenarios since they are restricted to the regions overlapping in multiple views and also they fail to reconstruct textureless and reflective surfaces due to missing correspondences. Hence, deep learning tries to alleviate some of these shortcomings of conventional SfM. Zhou et al. [22] introduced “SfMLearner,” one of the first methods to train a depth prediction model from monocular video. They jointly trained two models, one that predicts depth and another that predicts camera pose between adjacent frames. Their model predicts depth and camera pose for the transition of current frame to the next, and current frame to the previous frame. For robustness to nonrigid scene motion, an additional mask was predicted that ignored the occluded pixels caused by motion in the scene. Similar to the self-supervised losses above, photometric per-pixel error is calculated between the predicted synthesized frame via warping and the unoccluded pixels of the ground truth to optimize the models. SfMLearner at the time was the state-of-the-art depth estimation from training solely on monocular videos. However, the sharpness of its predicted depth map was still an issue since missing finer structural details like edges of the object were not effectively penalized in the self-supervised loss.

The work in [23] further improved on this methodology by estimating multiple motion masks such as estimating object and camera motion separately and utilizing it to improve the depth prediction. Yin and Shi [24] further decomposed motion into rigid and nonrigid motion, through depth and optical flow. This enabled the network to be more robust to dynamic moving objects since the model can differentiate between the two types of motion in the scene. Rigid motion here is estimated by the camera motion estimation model and the non-rigid motion is estimated through processing optical flow maps and performing consistency checks between intermediate frames. More recently, Godard et al. [25] built upon the work of Zhou et al. [22], and showed that instead of averaging the reprojection loss between the past and future frames, taking the minimum of these reprojection losses attains superior performance. Furthermore, during training they also ignore stationary pixels with respect to ego-motion. Lastly they adopt the original [6] multi-scale structural similarity index measure (MS-SSIM) as part of their photometric loss.

Some examples of SfM in surgical scenes include [26] where the authors combined information from monocular videos captured in both structured light and white light with traditional SfM for surface reconstruction. In particular they utilize SURF features [27] detection conjointly with Lucas-Kanade optical flow estimation [28] to reconstruct shape. They assumed the surface of the organ system was rigid in a small time frame, therefore, making it possible to estimate the relative camera position via singular value decomposition (SVD) (provided enough correspondences were measured between the two consequent frames). Another example [29] designed a deformable structure from motion, where they fuse inertial motion captured by MEMS sensors together with vision, for more robust camera pose estimation. They fuse these two information modalities via a novel upgraded version of Unscented Kalman Filter. They follow the standard SfM pipeline for 3D reconstruction with the exception of accounting for tissue deformation via Gaussian mixture models for clustering pixels with coherent motion between video frames.

There is still limitation in the uptake of deep learning for structure from motion in surgical scenes, especially since deformable reconstruction is still an open research question. Furthermore estimating camera pose is challenging when the scene has dynamic moving objects and deformable scenes. Hence, improvement in methods robust to these challenges can result in more modern deep learning methods utilized for solving this research question. In particular, an interesting study by Tukra et al. [30] trained a see-through vision convolutional neural network, for removing occlusions in monocular endoscopic video. Potentially this can be further utilized to reduce the impact of highly dynamic objects within the scene to enable more robust camera registration and localization pipeline and indirectly the SfM 3D reconstruction. An example of this type of “see-through vision” is shown in Fig. 2.

Simultaneous Localization and Mapping (SLAM): This takes the information from step 1 and 2 in Fig. 1 to enable the robot to localize itself in the environment. Hence, this section covers step 3 of Fig. 1. SLAM shares some of the characteristics of SfM such as jointly estimating camera pose and depth map of the scene via features detected across multiple frames and both utilize Bundle Adjustment [20]. SLAM however, takes this process one step further to build a map of the environment to enable robots to navigate and track certain key points of interest in it. Hence, the goal of SLAM can be distilled to estimating positions of the robot onto a map, thereby utilizing multiple sensory data, depth information, camera pose, etc., to achieve it. SLAM bridges the gap between SfM for scene understanding to proprioception for robotics.

Traditional structure of SLAM is defined by the following steps:

- Feature detection: of points of interest within the scene
- Feature matching: matching the detected features between adjacent images and tracking them
- Optimization: updating these features to be robust to adversarial effects like motion, blur, etc.

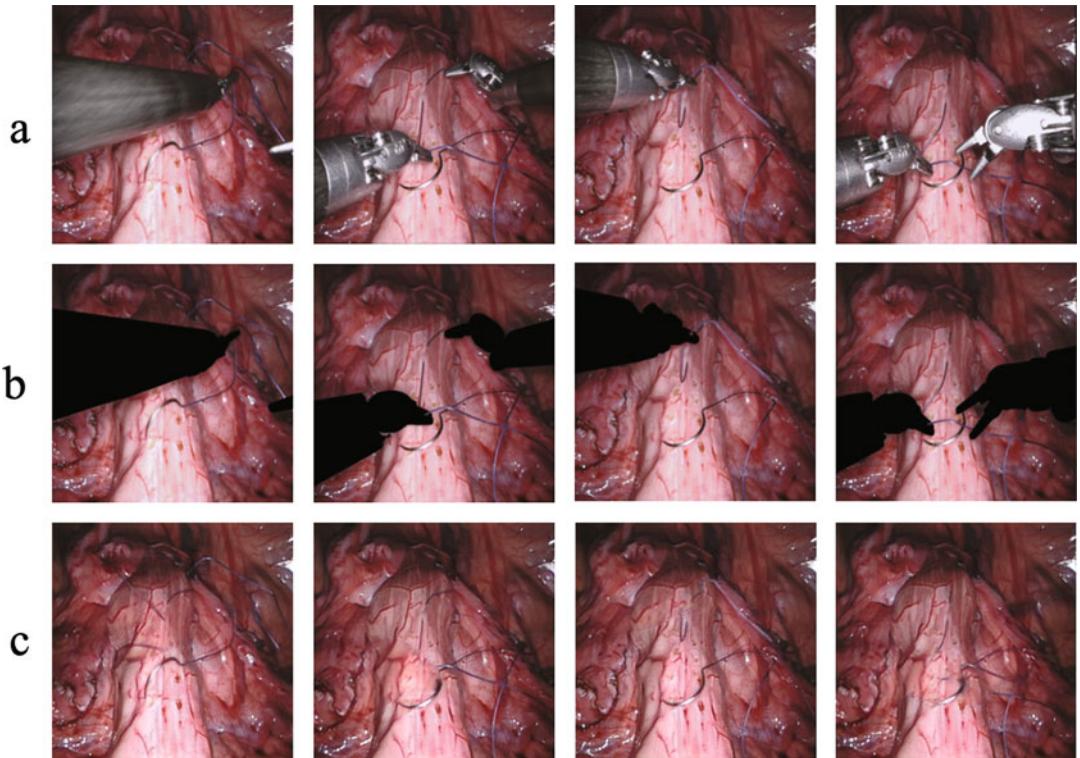

Fig. 2 Showing the output of [30] given a monocular video from a surgical scene. Where (a) are the individual video frames from the original source video with the robotic tool as the occlusions, (b) the robotic tool occlusion

mask, and (c) the reconstructed video frames by Tukra et al. [30] where the tool occlusions have been removed. (Figure reproduced from [30])

- Loop closure detection: an algorithm that processes previously visited areas and/or information to define a map

Combining all of the points above creates a full working SLAM system, and typically research focuses on improving one or multiple of these individual tasks using methods from modern machine learning. Additionally, SLAM has been combined with sensory inputs to attain better results, and such sensors fall into two categories: proprioceptive and exteroceptive. Proprioceptive sensors enable the robot to map its own trajectory like gyroscopes, inertial measurement units (IMUs), etc. Exteroceptive sensors enable the robots to understand the external world around them, such that environmental information is registered. Examples of such sensors include cameras (mono, stereo), LIDARs, etc. In this particular section we will discuss SLAM purely focusing on computer vision, camera-based

inputs as this is where machine learning plays a huge role in SLAM (context understanding).

One of the earliest works done to prove SLAM is indeed possible via a single camera as a data source was MonoSLAM [31]. Here the authors took a filtering approach, which involves estimating a probability density function over the robot's current position with respect to the features detected on images, via Extended Kalman Filter (EKF). Peter Mountney et al. [32] extended this EKF SLAM method to stereoscopic videos and estimated soft tissue deformation as periodic motion of the respiratory system. Grasa et al. [33] experimented with Andrew J. Davison et al. [31]'s method to see the efficacy of EKF SLAM on hernia repair surgeries. The most popular form of SLAM that is also available on open source programs like OpenCV today is ORB-SLAM [34], that utilizes ORB features to perform keypoint matching between intermediate frames. Song et al. [35] introduced MIS-SLAM,

which further built on ORB-SLAM by using the full potential of compute power, i.e., both CPU and GPU for computation, and thereby achieving high performance even from ORB features. Dense SLAM was conducted on the GPU and ORB-SLAM was conducted on the CPU and later the two estimates were fused for greater performance.

Surgical Tool Tracking

Tool tracking in the context of robotic surgery entails the estimation of the translation and rotation of an instrument as it moves with six degrees of freedom (6DoF) in the surgical environment. In the literature, frameworks that fuse kinematic and visual information have been proposed [36, 37]. However, kinematic information is not always available and in addition these methods rely on the transformation from the laparoscope to one of the actuators to be precisely estimated and continuously updated [38]. Therefore, vision-based tool tracking frameworks have been developed that are highly attractive since they rely on laparoscopic video data, which is directly available and do not require changing the operating theater or the design of surgical tools. This category of methods includes feature-based frameworks, and end-to-end tool pose estimation using deep learning [39, 40]. The main issue with current deep learning frameworks is the lack of generalizability. More specifically, if the camera parameters change, the model needs to be retrained or fine-tuned. Recent approaches aim at overcoming this limitation [41].

Feature-based tool tracking frameworks can be divided into marker-less and marker-based methods. Marker-less frameworks focus on tracking surgical tools using features that are naturally present on the surgical tool [37, 42, 43]. These features depend on the specific surgical tool; hence a new set of features must be extracted every time a new tool is used. Conversely, marker-based frameworks are less restrictive since they can be used by simply attaching a marker to a surgical tool, making

them an attractive solution for tracking. In robot-assisted Minimally Invasive Surgery (MIS), depending on the shape of the tool, planar and cylindrical markers have been used. Planar markers have been used to track imaging probes with planar surfaces [44, 45]. Since in robotic surgery most of the surgical tools are cylindrical objects, frameworks for tracking cylindrical markers have been developed [46–51]. Although tracking of planar markers can achieve high accuracy, the tracking error of cylindrical marker frameworks is still in the millimeter range, which is too large for applications that require sub-millimeter accuracy such as neurosurgery.

Haptic Feedback and Tissue Interaction Sensing

Surgeons heavily rely on haptic feedback when they are operating as it can enable them to identify buried tissue structures or stiffer regions during palpation, as well as safely control tool–tissue interactions, preventing iatrogenic injuries. To achieve haptic feedback in robotic surgery, extensive research has been carried out on integrating force sensors on the tip of surgical instruments. However, the additional complexity due to biocompatibility, sterilization, and space constraints and the cost associated with external sensing, limit the clinical applicability of these methods [52]. Technological advancements in sensing and actuation have led to the development of approaches based on mechatronics [53] as well as pneumatic [54] and hydraulic [55] systems. Recently, neural networks have been used to estimate the inverse dynamics of the da Vinci surgical robot, which enables estimation of the external torques/forces acting on the joints of the robot [56]. In another attempt to gain force sensing with the da Vinci robot, a deep learning framework has been proposed for end-to-end force estimation [57]. The model is trained using data collected by both moving an instrument in free space and by palpating a tissue phantom that has an embedded force sensor for ground truth (Fig. 3).

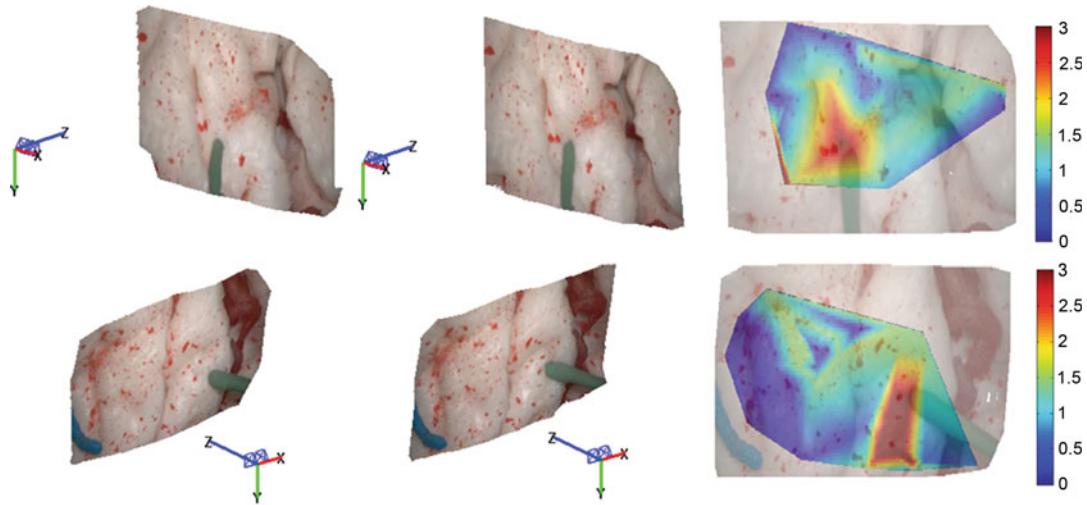

Fig. 3 Vision-based tissue deformation recovery. Estimated 3D structure before tool–tissue interaction (first column); estimated 3D structure during tool–tissue

interaction which causes tissue deformation (second column); deformation heatmaps overlapped on the images (third column) [37]

As an alternative, vision can provide an indication of exerted forces. Vision-based approaches for force estimation, which are based on the use of the existing endoscopic cameras, are particularly appealing as they do not require the introduction of additional equipment to what is often an already crowded operating room, and allow seamless integration into the existing surgical workflow. For this purpose, stereo depth estimation has been combined with surface mesh analysis based on spring-damper models [58] to recover force information. The vision-based framework proposed in [59] used quasi-dense 3D stereo reconstruction and soft tissue tracking to recover tissue deformation. The surface displacement has been combined with biomechanical modeling to estimate applied forces during tool–tissue interaction. A recurrent neural network architecture has been proposed in [60] to map soft-tissue deformation and tool data to interaction forces. This work has been enhanced in [61] with the incorporation of a Long-Short Term Memory (LSTM) network. Recently, a force estimation model based on CNN and LSTM networks has been proposed using both, the spatiotemporal information present in video sequences and the temporal structure of tool data such as tool-tip trajectory and grasping status [62]. In the above literature, the vision-

based estimation of forces has mainly been studied on simple tasks, such as pushing, whereas surgical tasks that result in complex interactions, such as grasping, have not been explored yet.

Advanced Visualization with Augmented Reality

Augmented Reality (AR) enables the surgeon to visualize subsurface anatomical structures such as tumors, by overlaying virtual objects on the endoscopic scene. For realistic results, AR visualization needs to be capable of seamlessly integrating multimodal images of dynamic anatomical structures while attaining a high level of spatiotemporal accuracy. This alignment is achieved using registration methods that either rely on external devices, such as optical or electromagnetic tracking systems [63] or focus purely on the processing of intraoperative images [64]. Although the latter category of registration methods has greater potential for clinical deployments as it does not require additional hardware, it is not yet widely used in surgery. This is due to the highly complex deformations of the anatomical structures during the operation due to tissue motion as well as topological changes during resections. For

successful registration of multimodal images, similarity measures have been proposed, which are invariant to local changes in brightness and contrast [65, 66]. Recently, unsupervised deep learning-based methods have been proposed for image registration based on the optimization of a loss function, which represents image similarity [67]. However, these methods cannot deal with multiple modalities or significant data variability. To overcome this limitation, deep learning frameworks have been proposed which, instead of modeling intensity correlations between images, optimize alternative correspondence measures such as the overlap of corresponding image areas, or spatial transformation models [68]. To guarantee successful image alignment, direct approaches to initialization have been proposed [69, 70]. Another category of image registration methods is based on the detection and identification of anatomical landmarks. In this case, deep learning models have been designed to produce a pose invariant latent representation of the appearance of landmarks, which can be used to establish image correspondences [71–73]. However, the performance of these methods has not been evaluated yet under challenging conditions with significant image pose differences.

In the last decade, there has been a great effort to bring mixed reality (MR) into the operating room to assist surgeons intraoperatively. MR “mixes” virtual and real objects, thus allowing, for example, a surgeon to see a virtual tumor inside a real patient’s body. In addition, it allows a surgeon to consult data when and where needed, making it a valuable tool for intraoperative decision-making. Using the Microsoft HoloLens, previous research has mainly focused on projecting a virtual 3D model into a patient’s body [74–76] or just above it to avoid obstructing a surgeon’s line of sight [77]. Besides 3D virtual objects, a few studies [78] have used MR to display surgical data through virtual 2D screens, which can also display crucial data to the surgeon from multiple imaging modalities. However, in the above studies, the interactions between a surgeon and the virtual world have been restricted to moving, scaling, or rotating the virtual objects. Recently, a MR visualization platform has been developed for the HoloLens, which

advances existing platforms by integrating multimodal data for intraoperative surgical guidance and incorporating novel interactive functionalities [79]. The visualization components include a 3D organ model, volumetric data, and tissue morphology captured with intraoperative imaging modalities. The introduced functionalities allow the surgeon to customize and interact with virtual objects, namely, scrolling through volumetric data and transparency adjustment of the objects. A pilot study verified the usability of this platform in the operating theater. Despite the above progress, we are still on an early stage to achieve the goal of bringing MR into a standard operating room to assist surgeons intraoperatively. In addition, little attention has been paid to get feedback from surgeons participating in MR experiments [80].

Robot-Assisted Task Execution

Current research on autonomous robotic task execution has mainly focused on robot-assisted ultrasound elastography [81], motion compensation in cardiovascular surgery [82], autonomous tissue dissection [83], brain ablation [84], and cochlear implant installation [85]. Robot-assisted tissue scanning with imaging probes under image guidance has attracted significant interest. Current approaches to robot-assisted tissue scanning with imaging probes have focused on applications using Ultrasound and probe-based Confocal Laser Endomicroscopy (pCLE) as imaging modalities [86, 87]. This is because the above modalities should firmly touch the tissue surface while closely following the tissue motion to capture good quality imaging data (Fig. 4).

Current research on autonomous scanning with pCLE has focused on optimizing the contact between the imaging probe and the tissue. For this purpose, force feedback from force sensors and stereo vision for pose estimation have been used in [86]. The visual servoing framework proposed in [89] employed Optical Coherence Tomography (OCT) to estimate the distance between the probe and the tissue to control the probe during scanning. Reinforcement learning and image blur characteristics have been used to

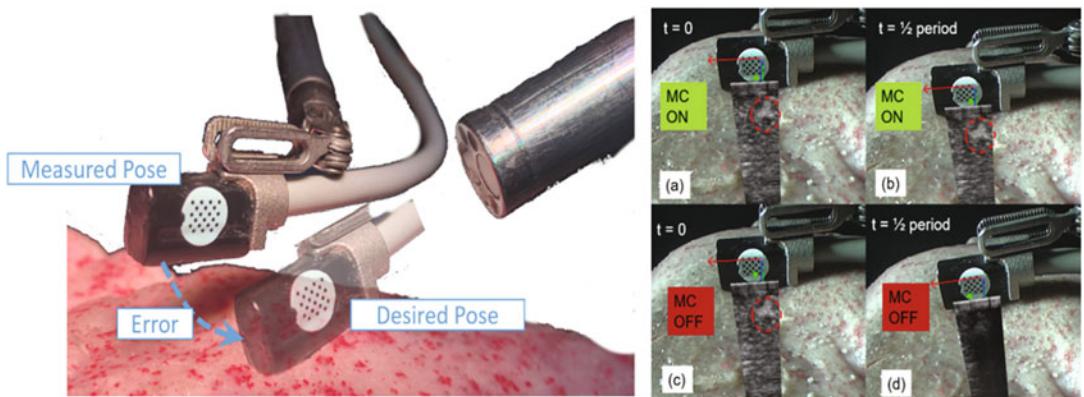

Fig. 4 Autonomous Tissue Scanning under Free-Form Motion. (Left) Graphical representation of visual servoing. (Right) Robot-assisted tissue scanning with and without

classify the position of the probe as too close, too far, or at the right distance from the tissue [90]. Endomicroscopic information has also been used in [91] to control the distance between the probe and the tissue applying the Crete-Roffet Blur Metric (CRBM) along with fuzzy logic. To expand the small field of view captured by pCLE probes and enhance visualization, image mosaics have been generated [92, 93].

Previous studies on autonomous Ultrasounds scanning have focused on image-guided needle insertion [94], Focused Assessment with Sonography for Trauma (FAST) [95], tumor detection [87], and vessel tracking [96]. In the above, visual servoing frameworks information either from the Ultrasounds data [97] or the endoscopic camera [98] has been used as visual feedback for probe positioning or sweeping scanning. Recently, force feedback has also been included for Ultrasounds-guided flexible needle insertion with haptic feedback [99]. For applications where the robot trajectory needs to be planned in advance, the 3D structure has been recovered using stereo cameras [87], RGB-D cameras [100], or combination of RGB-D and preoperative MRI images [101].

The above approaches to robot-assisted local tissue scanning rely on the assumption that the tissue is static or moving with periodic motion. The visual servoing framework for autonomous tissue scanning proposed in [88] advances state-of-the-art autonomous tissue scanning methods

by eliminating the requirement for learning the tissue motion before scanning and dealing with free-form tissue motion in real-time. It optimizes probe-tissue contact by tracking the motion of the tissue surface and updating the desired scanning trajectory to follow the tissue motion and control the movement of the robotic arm.

Context-Aware Decision Support

Recent advances in biophotonics have allowed intraoperative tissue characterization with the advantages of being noninvasive or minimally invasive. For instance, techniques such as probe-based Confocal Laser Endomicroscopy (pCLE) allow for real-time morphological imaging at sub-cellular resolution and have demonstrated efficacy in distinguishing neoplastic lesions from normal tissue [102]. Furthermore, intelligent surgical devices such as the “iKnife” and Laser Desorption Ionization Mass Spectrometry (LDI-MS) enable real time tumor phenotyping in the operating room for tissue characterization that corresponds with histopathology [103]. Raman spectroscopy (RS) [104] can analyze the tissue *in vivo*, *in situ* at a microscopic scale, and provide information about its histochemical state. Recently, the use of hyperspectral imaging has shown promise in neurosurgical oncology for intraoperative margin delineation at macroscopic scale [105].

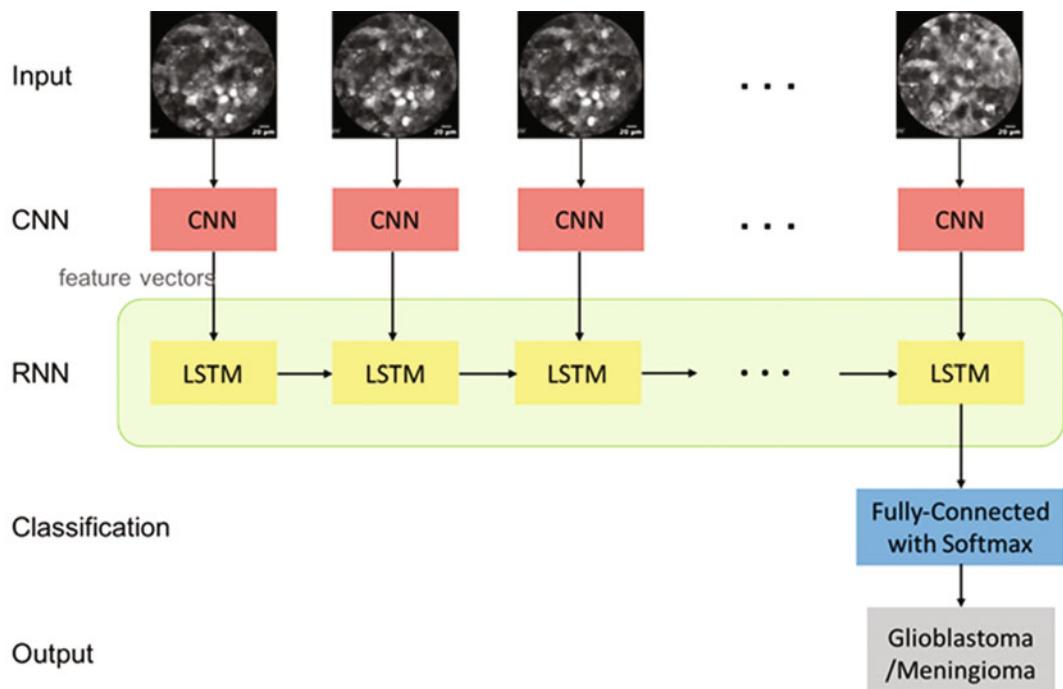

Fig. 5 Context aware decision support in neurosurgical oncology based on video classification of Glioblastoma and Meningioma endomicroscopic data [113]

However, the interpretation of the information captured with the above techniques remains challenging, particularly for surgeons who do not themselves routinely review histopathology or biochemical data. There is also significant intra- and interclass variability in the captured tissue characteristics. Furthermore, even among experts, the diagnosis can be examiner-dependent, leading to considerable interobserver variability. Hence, automatic tissue characterization, based on a database of previously annotated data by expert physicians with diagnosis confirmed by histology, would support the surgeon in establishing diagnosis and guide autonomous robotic tissue scanning to focus locally on pathological areas (Fig. 5).

Computer-aided diagnosis (CAD) systems designed for the analysis of pCLE data are composed of three main steps, namely, visual feature extraction, feature encoding, and supervised classification. A content-based image and video retrieval framework based on the Bag-of-visual Words (BoW) approach has been proposed in [106] for the differentiation of neoplastic and

benign colorectal polyps. Clinical evaluation of this framework presented in [107] shows that automated classification of pCLE videos of colonic polyps achieves high performance, comparable to off-line diagnosis of pCLE videos established by expert endoscopists. The above video retrieval framework has been extended in [108] to include high-level knowledge for the pathological interpretation of pCLE images. For that purpose, binary semantic concepts commonly used by expert endoscopists to diagnose pCLE videos of colonic polyps have been extracted and used as additional information that complements the visual outputs of the retrieval framework.

Wan et al. [109] used an efficient feature encoding scheme based on codeword proximity and a support vector machine (SVM) classifier to classify from pCLE images two types of commonly diagnosed brain tumors, namely, Glioblastomas and Meningiomas. This work has been extended in [110] by exploring more encoding schemes for data description and using a majority

voting-based classification scheme for video classification. To further improve the retrieval accuracy, approaches to content-based image retrieval of pCLE data have focused on learning discriminative visual features. In [111], a MultiView Multi-Modal Embedding (MVMME) framework has been proposed to learn in a supervised way discriminative features of pCLE videos by exploiting both mosaics and histology images. This work has been extended in [112] where an unsupervised multimodal graph mining (UMGM) approach has been proposed to learn the discriminative features for pCLE mosaics of breast tissue.

Recently, an efficient representation of the context of pCLE data has been proposed in [113] by exploring CNN models with different tuning configurations to classify brain tissue into Glioblastoma and Meningioma. Furthermore, a video classification framework based on the combination of convolutional layers with long-range temporal recursion has been developed to estimate the probability of each tumor class. Deep learning models have also been designed for super-resolution in endomicroscopy [114, 115].

Hyperspectral Imaging (HSI) captures spectral and spatial data beyond the limited electromagnetic bands perceived by the human eye. It has been proven that the interaction between electronic radiation and tissue carries useful information for tumor detection in surgery. Although medical HSI data bears rich information, it is characterized by high-dimensionality and difficulty to interpret for clinicians as it generates a temporal flow of 3D information that cannot be simply displayed in an intuitive fashion. In addition, the inter-patient spectral variability and the limited number of samples, makes the processing of HSI data challenging.

The processing of HSI entails mainly the pixel-wise classification of the data based on its spectral information. For this purpose, Machine Learning techniques based on Linear Discriminant Analysis (LDA), decision trees, random forest (RF), and kernel-based methods have been developed. For gastric cancer detection, quadratic SVMs have been used to classify fat, muscle, and tumor areas on HSI data with high accuracy [116]. In [117], the recursive divergence method has been used to

select the most significant wavelengths in the spectral range, which have been used to detect colon cancer on *in vivo* data. To identify cancerous and noncancerous areas on breast tissue [118], the Fourier coefficient selection method has been used to extract features from HSI data, followed by dimensionality reduction using the Minimum Redundancy Maximum Relevance method. To classify the two tissue states, the SVM classifier was used with the radial basis function (RBF) kernel.

The ensemble linear discriminant analysis (LDA) has been successfully used in [119] to delineate the boundaries between the normal and cancerous tissue on head and neck tissue samples. LDA has been combined with PCA for dimensionality reduction to identify malignant changes in the oral cavity [120] and in particular to discriminate between healthy, hyperplastic, dysplastic, and squamous cell carcinoma (SCC) tissue. For the processing of laryngeal HSI data [121], rigid image-to-image registration based on normalized cross correlation (NCC) was used as a pre-processing step to deal with misalignment due to cardiac motion as well as noise removal based on the minimum noise fraction (MNF) transformation. To identify healthy and cancerous tissue areas, the random forest (RF) classifier was employed.

To facilitate the semantic segmentation of brain HSI data, the Fixed Reference T-distributed Stochastic Neighbors (FR-t-SNE) method has been proposed in [122] to reduce the dimensionality of the data volume and generate high contrast images for accurate brain tumor detection. In [123], supervised classification based on a combination of a SVM, PCA, and KNN algorithms was fused with the K-means classifier for unsupervised segmentation, through a majority voting procedure, to delineate the margin of brain tumors.

Recently, deep learning has been used to extract high-level spatial features from HS data and classify different tissue areas. CNN-based architectures have been developed to discriminate between cancer and normal tissue in Head and Neck surgery [124, 125], outperforming traditional ML techniques. Promising results have also been reported for the performance of deep learning approaches on the classification of

glioblastoma tumors [126, 127]. To take into account the inter-patient variability, a leave-one-patient-out cross-validation approach was followed. Despite the good performance, extensive validation of deep learning techniques is still required on large medical datasets. In addition, clinical validations of the developed systems should be carried out to assess their performance.

Outlook

Robotics has huge potential in being widely adopted in surgery, due to improved sensing, machine learning pipelines for perception, and deep learning for enhanced feature understanding. Endowing cognition in such robotic tools such that they are robust to the ever-changing scenarios presented in a surgical scene. Especially since the use of AI allows learning a shared representation from multiple sources of data captured through sensors such that robots can have an improved representation of their surrounding environment. Enabling them to comprehend the complexity of the environment and model it for decision-making, greater precision, and eventual automation of surgical tasks. Therefore, paving the foundation to change the surgical practice as a whole and moving it into the new age of intelligence, comprising advancements in (and not limited to) technologies for imaging, navigation, and robotic intervention.

However due to the general complexity of the dynamic surgical environment, such AI methods still require improvement in generalizability, to accommodate transferring its learnt knowledge to other unobserved tasks while reducing its hunger for new data. One consideration for the future is understanding the ethical and moral deployment of such autonomous/cognitive robots in surgery. It is vital that research into human behavior, ethical and legal implications in the use of autonomous robotics, is further advanced in parallel to technological advances in AI. As robots definitely bring divergent advantages to the field, one cannot neglect how they may be perceived in the eyes of a patient. Safety being the top priority, the rules and regulations behind privacy, accountability in

presence of errors, ethical decision-making in whether robotic surgery should even be conducted or an alternative should be performed, has to be updated alongside robotics. We still have a distance to go in endowing robotics with the sensory and cognitive ability of surgeons. However, the current ongoing research in fusion of AI and robotics is certainly moving toward that direction.

Abstract

Artificial intelligence (AI) is the study of algorithms that give machines the ability to reason and perform cognitive functions. Applications of AI in medicine broadly and surgery, more specifically, have grown over the last few years

as technology has advanced and clinical data has become more digitally accessible. It is becoming more important for surgeons to develop a fundamental understanding of the common techniques, applications, limitations, and ethical considerations of AI in surgery. This chapter provides an overview of AI for surgeons and describes ways in which surgeons can play a role in future development of AI applications.

Introduction

Artificial intelligence (AI) has been long applied to many medical fields for the purposes of diagnostics, decision-making, or clinical research. The application of such technology in surgery will bring unparalleled benefits such as enhanced patient selection/management, a truly automated operating room environment with intraoperative assistance to the surgeon, and a real-time surgical workflow detection which will result in increased efficiency and safety.

Much of the recent advances in the application of AI in surgery were recently fostered by computer vision (CV). Such application has brought the ability to provide in-depth analysis of intraoperative surgical footage with the short-term goal of providing live intraoperative feedback and the long-term goal of partial automation of certain surgical procedures. CV is, in its simplest explanation, machine understanding of images and videos [1]. It constitutes the way machines understand and interact with our reality. The first goal of such interaction will be plain understanding followed by cognitive augmentation during a surgical procedure. Augmentation will most likely take the form of intraoperative live feedback to the operator. Current efforts are focused on developing better CV algorithms which “understand” a surgical operation; however, such endeavor is a challenging task to achieve.

To provide a comparison with the automotive industry, the Society of Automotive Engineers has provided six possible levels of automation in cars ranging from 0 (no automation) to 5 (full automation and lack for requirement of oversight by the driver) [2]. Despite some early promises of reaching level 5 by the end of the decade, billions of dollars of investments, and almost half a century of work by the industry and academia, we are presently only able to produce vehicles with partial automation and that still require partial driver’s oversight (level 3 automation). Although comparisons are somewhat difficult to make, cognitive augmentation could be assimilated to level 1 automation, much like a car can provide notifications and even real-time intervention if you are

steering off your lane on the highway or if an obstacle is in front of you and you need to brake. In a similar fashion, you could be soon operating with a “Surgical GPS” which can tell you in real time whether you are about to cut the wrong anatomical structure or if you are likely to experience postoperative bleeding at the end of an operation.

Much of the hurdles that we have to face to provide live feedback to the surgeon hinge on data processing. The average self-driving car requires tens of thousands of sensors and processes an average of 100 terabyte of data every 8 h. A “Surgical GPS” will likely require a similar data handling capability. This brings unparalleled challenges both in terms of acquisition and processing of data.

For such reason, in the short run, current technology still focuses on early applications such as automated performance analysis in the postoperative setting. Currently, automated analysis of surgical videos was successfully used for video segmentation [3], identification of core anatomical features such as the critical view of safety during laparoscopic cholecystectomy [4], and determination of adequacy of a lymph node dissection [5]. The next logical step toward cognitive augmentation will likely require FDA clearance since such software will likely bring real-time modifications in the intraoperative decision-making.

AI-Powered Techniques

AI is a larger parent field that encompasses sub-fields like machine learning and computer vision, which further encompasses techniques like neural networks and deep learning. These subfields and others are actually quite interrelated, and techniques from one may be subsumed or used in concert with another, depending on the application.

Neural networks, inspired by biological nervous systems, process data in layers of simple computational units that are intended to be analogous to neurons. Thus, unlike in classical machine learning, neural networks can extract features

from data and use them as inputs, adjusting the weights of those features accordingly to be used within an activation function to yield some output, [6] that is, the system automatically, using predetermined mathematical functions, tweaks weights to strengthen/weaken connections within the network to yield the best possible results.

Deep neural networks are, effectively, a neural network with more than three layers, allowing for learning of more complex patterns than those that are discernible from simple one- or two-layer networks. As with “non-deep” neural networks, deep learning will select features that are most likely to yield best results. This technique works particularly well with unstructured data such as audio, images, and video. Generally, each layer of a deep neural network performs a set of operations to generate a representation of the data that is then fed to the next layer.

Computer Vision

Technical Aspects of Computer Vision in Surgery

Computer vision is a field of artificial intelligence that uses deep machine learning models in order for computers to understand and evaluate their surroundings. Computer vision and image processing technology are being developed in order to read, interpret, segment, analyze, and assess surgical videos. One goal of computer vision and robotic technology is to create a surgical robot that can analyze a surgical situation to make corrections intraoperatively, but the ultimate goal is to design a robot that can operate autonomously.

Computer Vision and Supervised Learning

Within machine learning (ML), the two most common learning types are supervised and unsupervised learning. Supervised learning is a task-driven process wherein an algorithm is trained to predict a prespecified output, such as identifying a stop sign or recognizing a cat in a photograph. The “supervised” term comes from the need to provide annotated (i.e., labeled) data

so that it can learn the associations between inputs and the desired output. Several software are available to provide the user with annotation capabilities. Annotating is a time-consuming endeavor where both temporal sequences are determined (e.g., determining the time stamp in the different phases of an operation) and anatomical structures are labeled. Thus, datasets are divided into a training set (with labels provided) for learning and a test set (no labels provided) that allows for the assessment of the performance of the algorithm on new data [1, 7]. Such application of ML is particularly useful in surgery given the current technological options. Recognition of anatomical structures starting from a known dataset is in fact one of the early goals of surgical automation and the foundation of intraoperative feedback. Such modality, however, if fraught by the particularly long-time consumption required as annotating surgical images frame by frame requires several hours of work from an experienced operator. Temporal annotations are similarly time-consuming. The purpose of those and the exact sequence determination during a surgery is, however, equally important. Applications of such annotation range from monitoring the workflow during a surgery and allowing for a more streamlined time management strategy to determining when a training surgeon is struggling or identifying more difficult portions of a surgical operation once you are reviewing the footage.

Computer Vision and Unsupervised Learning

Unlike supervised learning, unsupervised learning does not utilize a prespecified annotation; rather, it draws inferences from unlabeled data to identify patterns and/or structure within a dataset. This type of learning can be useful in identifying relationships between groups (e.g., clustering) for further hypothesis generation. This can be applied to typical, discrete surgical data such as patient outcome databases or to more unique datasets such as surgical motion and activity. For example, unsupervised learning has been used to identify high-risk cardiac surgery patients and to automatically identify suturing motion in surgical video

[8, 9]. A third category of learning is reinforcement learning, a form of unsupervised learning. It is analogous to operant conditioning, where learning occurs through successive attempts via trial and error and rewards/punishments guide the behavior of the model to optimize rewards. The most common architectures in deep learning that are currently being used for surgical applications are convolutional neural networks (CNNs), recurrent neural networks (RNNs), and residual neural networks (ResNets).

Natural Language Processing

Natural language processing (NLP) focuses on machine understanding of human language beyond identification of vocabulary (e.g., synonyms, antonyms, definitions, etc.). Without NLP, computers are limited to reading machine languages or code (e.g., C+, Java, Visual Basic) to execute instructions based on explicitly programmed codes that are compiled to yield an output. NLP allows machines to approximate the understanding of human language as it would be used in day-to-day life. It strives to achieve understanding of syntax and semantics to approximate meaning from phrases, sentences, or paragraphs [10].

NLP is perhaps most readily recognized in home assistant devices such as Amazon Alexa (Amazon, Seattle, WA) or Google Home (Alphabet, Mountain View, CA). Analogous functions are found in digital platforms used for operative dictation (e.g., Nuance's Dragon software [Nuance, Burlington, MA]). Beyond the provider-facing functions such as dictation, NLP is utilized heavily in the analysis and utilization of data within the electronic medical record. Because NLP can be used to analyze some forms of human language, unstructured free text such as radiology reports, progress reports, and operative notes can be analyzed and structured in an automated manner. As examples, it can be utilized to assess for sentiment in patient notes for the prediction of patient health status, to analyze records for risk prediction in cancer patients, or to detect surgical site infection from providers' notes [10–12].

Current Applications of AI in Surgery

Preoperative Risk Prediction

As up to 20% of surgical procedures can result in a complication [13], preoperative risk stratification is of the utmost importance for therapeutic planning. Ideally, risk prediction would both guide patient-centered decisions to evaluate operative candidacy and predict possible postoperative complications.

Many risk calculators and decision algorithms exist on the market. Since adequate cardiac function is of utmost importance, the most prominent calculators assess and predict risk of major adverse cardiac events (MACE). Examples include the Revised Cardiac Risk Index (RCRI) and Gupta Perioperative Risk for Myocardial Infarction or Cardiac Arrest (MICA) [14, 15]. Unfortunately, these models often underperform. The POISE trials showed that a MACE rate of 6.9% in patients rather than the RCRI-predicted rate of 1–2.4%. Outside of risk calculators, subjective patient-reported measures of cardiac functional capacity, such as metabolic equivalents (METs), also tend to under-triage patients [16]. One study found that subjects report their cardiac capacity with only a sensitivity of 19% [17].

More recent efforts attempt to solve the prior predictors' shortcomings through the use of objective "big data" to address model underperformance. For example, the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) released a risk calculator. Their calculator used information from 393 hospitals with almost 1.5 million patients to create a generalized linear mixed model to predict risk of mortality and various complications. This model had good performance, with a c-statistic of 0.944 and 0.816 for mortality and morbidity, respectively [18].

Until recently, the majority of risk calculators have used traditional linear and additive models for risk prediction. Recent advances utilize machine learning (ML) methods for better approximation of the non-linearity of patient risk factors. Researchers at Duke University trialed

3 different ML methods on their single-institution database of 100,000 patients: least absolute shrinkage and selection operator (LASSO) penalized logistic regression, random forest models, and extreme gradient boosted trees [19]. Comparing the three methods, they found that LASSO performed best for over 8/14 outcomes, while extreme gradient boosted trees excelled in 5/14 outcomes with area under the curve (AUC) ranging from 0.747 to 0.924. With their algorithms, they created an online calculator with 9 input data fields that outperformed the ACS-NSQIP calculator in postoperative mortality and morbidity prediction across the board for a random sample of 75 patients.

Similar work has come out of the University of Florida with their MySurgeryRisk score. They used their EMR data to create risk prediction scores using ML techniques such as random forests. Interestingly, their risk prediction was particularly patient-tailored since they linked training data to census data tied to ZIP codes and to surgeon-specific outcomes. Beyond just the creation of a risk calculator, they also created interfaces for seamless EMR integration, so that not only risk prediction happened in real time but their models underwent continuous learning and tuning from physician feedback [20].

Preoperative risk calculation has evolved over the past decades. Medical practitioners can combine the ever-increasing big data from EMR with ML algorithms for objective, and increasingly accurate, predictions of patient outcomes. With continuous EMR integration and even deployment to smartphones, this wealth of information is immediately available and creates the promise that one day, we may be able to exactly answer our patients when they ask “What are the risks of this surgery?”

Intraoperative Video Analysis

Most of the readily recognizable advances in CV have come from the fields of radiology and pathology, perhaps due to the readily available nature of digital images in both fields. CV has also demonstrated promise with screening applications in

ophthalmology, such as automated detection of diabetic retinopathy, and dermatology, where automated recognition of benign versus malignant skin lesions has been described [21, 22].

However, CV applications in surgery are increasing as access to intraoperative footage increases. With greater, cheaper storage capacities and more user-friendly laparoscopic, endoscopic, and robotic camera systems, many surgeons are choosing to record their operations for teaching, education, and research purposes.

AI technology, through CV, allows computers to comprehend visual cues and therefore interact with the world in real time. With sufficient training and incorporation of thousands of operations, an AI model could guide surgeons, in real time, just as if they had the world expert in surgery looking over their shoulder. We already know that experience matters, with an inverse relationship between a surgeon’s case volume and their patient’s mortality [23]. Analysis of a surgeon’s ability on visual cues alone is even predictive of a surgeon’s rate of complications [24]. If a CV system could guide surgeons and take their performance from the bottom to the top quartile, patients would receive immediate improvement in their care. We know that almost 70% of cases have “near-miss” events of which two-thirds will need additional intervention to fix, perhaps something a CV model could warn the operator ahead of time and prevent from happening in the first place [25].

With the promise of a safer OR, a few groups across the world have tried to tackle the difficult problem of teaching a computer to see and think like a high-level surgeon. CV is still quite new, with accurate image recognition only possible since 2012; therefore, applications of CV in surgery are still in their early stages [25, 26]. The initial work has involved analysis of laparoscopic cases given the ease of video acquisition and reproducibility of surgical images. In particular, groups have worked on identification of surgical phases of an operation with good accuracy across cholecystectomy (86.7%), sleeve gastrectomy (85.6%), and sigmoidectomy (91.9%) [3, 27, 28]. Additional applications of such technology have been investigated for its potential impact on

improving operating room workflow and logistics such as through the prediction of remaining operative time from intraoperative video alone [29].

Knowing that accurate phase recognition is possible, the next steps will include development of intraoperative decision support. For example, likely applications include guidance for port placement, confirmation that a critical portion of the case has successfully been obtained (e.g., the critical view of safety in cholecystectomy [38] or adequate dissection during an inguinal hernia), and, in the more distant future, even a real-time intraoperative “GPS” to guide surgeons in their dissection. As the AI models train with an increasing number of cases, they will soon develop an unparalleled surgical knowledge – a “collective surgical consciousness” – that will help any surgeon, anywhere, to deliver optimal intraoperative care to their patients [30]. Similar to a chess game, a player has to play so many games and take so many different approaches to become proficient, but he can only learn one game at a time. If all the chess players in the world could share their collective knowledge with each other through AI, the learning would be exponentially higher and faster. This is the concept of a collective consciousness. By using AI, surgeons could be sharing their individual experiences to generate a similar collective consciousness for surgery.

There are, however, key advances that must be made. An important, early advance in the process of translating computer vision to the operating room is the establishment of clear labels for operative videos. Hashimoto et al. demonstrated that surgeons, even within the same institution, can differ in their conceptualization of the boundaries of the steps of an operation, [3] that is, when does one step of an operation end and the next begin? As previously described, for supervised learning, defining a “gold standard” or ground truth is important to be able to train a model to recognize aspects of surgical video [4]. Establishing ground truth can be difficult when a surgical operation has several different variants and there might no single correct way to perform it. Efforts are currently underway through the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES)

to convene an international consensus on guidelines for annotating operative video for the purposes of machine learning and computer vision research.

Surgical Workflow Analysis

Several applications were recently devised to both increase surgical safety and enhance performance in the operating room [31]. Most of them rely on the identification of the personnel in the operating room through environmental cameras. Identification is done automatically through visual cues that are captured by the cameras through CV. As such, the software can automatically detect the surgical workflow in the operating room. Common events which can be captured include the patient entering the operating room, the scrub tech setting up the instrument tray, or the circulating nurses holding up a brightly colored board during surgical timeout. Automatic workflow detection has the potential to enhance both productivity and safety of the surgical environment [32]. As more complex software is currently being devised to recognize motion of the surgeons in greater detail, this will invariably increase the yield of in-depth analysis of the operating room environment in real time.

Regulatory and Legal Considerations

AI applications in surgery are a growing reality. Surgeons should familiarize themselves with this technology and its medicolegal implications, including intellectual property and data ownership, consent and scope of videos, privacy, and the potential for litigation. Highlighting the specific nature of these algorithms, the Food and Drug Administration (FDA) approved the first diagnostic utilization of an AI algorithm in 2018 – a program that assists in screening for diabetic retinopathy through automated analysis of images of the fundus [2]. The list of FDA-approved algorithms continues to grow with approved applications in radiology, cardiology, and pathology as well. With ongoing

development and application of AI technologies in medicine, it is important for clinicians in every field to understand what these technologies are and how they can be leveraged to deliver safer, more efficient, more cost-effective care. Furthermore, it is important to keep in mind that these technologies are not a panacea and to understand the limitations inherent to any tool.

Conclusion

In summary, artificial intelligence as applied to surgery is early in its development. While significant advances are being made in AI, these advances are focused on narrow applications of the technology to specific problems within surgery. The field is very much in a phase of discovery and development, and a critical appraisal of new publications, software, and devices is necessary to appropriately evaluate its impact on patient care and surgeon workflow. As with any new technology, a healthy measure of skepticism is necessary to guard against hype; however, data on potential applications of AI to surgery have thus far been promising.

Abstract

Urology is intertwined with surgical technology. Endoscopic and robotic surgery found early acceptance within the practice of urology. Artificial intelligence research has begun to permeate through the urologic literature. In urologic oncology, AI systems have been developed to diagnose malignancy, guide therapeutics, and predict surgical outcomes. These systems have been shown to grade prostate cancer biopsies more accurately than general pathologists and can accurately predict postoperative length of stay based upon robotic laparoscope kinetics. AI enables accurate

prediction of kidney stone passage and stone clearance rates after surgery. Robotic systems using AI have successfully guided renal puncture in early clinical trials. The evaluation and treatment of the infertile male is seeing a paradigm shift as AI systems predict fertility potential and sperm retrieval success. In the future, AI algorithms may inform sperm retrieval for in vitro fertilization optimization. While many of the aforementioned AI systems remain isolated within single-institution research endeavors, published online AI predictors make these analyses accessible to general urologists. In time, AI can be expected to take a larger foothold into modern urologic practice.

Introduction

Urology has always been at the forefront of research and innovation within the medical community. The field was one of the early adopters of endoscopic technology by implementing cystoscopy into the urological workflow. Endoscopy quickly became an integral diagnostic and therapeutic tool for a wide variety of urological ailments. Urologists also established one of the first biomarkers for cancer surveillance in prostate-specific antigen. While there are many other notable examples of these advancements in urology, it was the early adoption of robotic surgery into practice that reflected the field's propensity for innovation [1]. Artificial intelligence (AI) is the next technological frontier with promise for significant advancements in patient care, and its application has begun permeating the urologic literature.

Artificial Intelligence in Urology

Urologic Oncology

History

Urologic oncology has a rich history of implementing predictive models to guide clinical practice. Notably, the 1993 Partin Tables used a nomogram with inputs of preoperative prostate-specific antigen (PSA) level, clinical stage, and Gleason score on biopsy to predict pathological stage at the time of radical prostatectomy [2]. These analyses remain the standard in predicting pathological stage and subsequent risk stratification of men newly diagnosed with prostate cancer. Similarly, urologic oncologists are well accustomed to adoption of new technologies. While urologists were not the first to use the Da Vinci Robotic Surgical System (Intuitive, Sunnyvale, California), the widespread use of the technology for robotic-assisted laparoscopic radical prostatectomy was critical for the adoption of the

robotic systems into modern-day surgery over the last two decades [3]. Not surprisingly, the use of artificial intelligence (AI) has made some early inroads into the modern practice of urologic oncology.

Prostate Cancer

Prostate cancer is the area of urology with the most robust application of AI to date. AI has been used to determine Gleason grades on prostate biopsy and MRI, predict postoperative surgical outcomes, and guide optimal treatment regimens. Auffenberg et al. used a state-wide database from Michigan to create a random forest machine learning model to predict treatment decisions based on patients with similar characteristics. Model inputs included pre-treatment data from 7543 men diagnosed with prostate cancer for 45 urology practices across the state. Outputs were primary treatment prediction including radical prostatectomy, radiation therapy (either external beam, brachytherapy, or both), primary androgen deprivation therapy, active surveillance, and watchful waiting. Using a 2:1 train-test split, the random forest performed with an AUC of 0.82 and good calibration [4]. These data may be useful to inform critical shared decisions made during localized prostate cancer care. Other AI models have been implemented to improve prostate cancer diagnostics.

Nagpal et al. developed a deep learning algorithm to predict Gleason grade group from prostate biopsy specimens [5]. These analyses included 752 prostate needle core biopsy specimens from 4 institutions. Ground-truth grade group was determined by concordance from two expert pathologists. The deep learning algorithm was trained and validated on 752 biopsy specimens including 322 external validation specimens from a single institution not used in algorithm training and tuning. Model performance was assessed by comparing majority opinions from 19 general pathologists. The deep learning algorithm grade group determination agreed more often with expert pathologists (71.7%; 95% CI, 67.9–75.3%) than general pathologists did (58.0%; 95% CI, 54.5%–61.4%) ($P < 0.001$). The authors concluded the algorithm showed

higher proficiency than general pathologists at Gleason grading prostate needle core biopsy specimens on an external validation data set.

Subsequent analysis by Steiner et al. further assessed the aforementioned deep learning algorithm as a decision support tool to improve the accuracy of prostate biopsy Gleason grade grouping [6]. Twenty general pathologists reviewed 240 prostate biopsy specimens with ground truth established by concordance from 2 expert genitourinary pathologists. Pathologists were randomized into two groups reviewing cases in batches of ten alternating between AI assistance and without. After a 4-week washout period, the pathologists reviewed the same cases with the opposite assistance or without. The author's found artificial intelligence-assisted review caused a 5.6% increase (95% CI, 3.2%–7.9%; $P <0.001$) in agreement with specialists (from 69.7% for unassisted reviews to 75.3% for assisted reviews). AI assistance decreased review time by the pathologist 13.5%. These data show the promise of increasing diagnostic accuracy and efficiency with artificial intelligence. However, the algorithm could not achieve the levels of expert genitourinary pathologist and could not elevate the performance of a general pathologist to that of an expert.

In the past decade, magnetic resonance imaging (MRI) has become an integral tool in urology for identifying potential prostatic lesions of clinical significance that may have been missed on standard template systematic transrectal ultrasound-guided prostate biopsies. With the advent of technology to allow for MRI-ultrasound fusion biopsy of the prostate, patients are provided more targeted diagnostics and results. Current classification of prostatic lesions is according to the Prostate Imaging-Reporting and Data System (PIRADS) criteria. While there is a consensus on lesion features for classification, there remains a subjective bias in grading. Schelb et al. utilized a deep learning algorithm (U-Net) to combine T2-weighted and diffusion MR imaging phases and found potential in supporting clinical classification of prostatic lesions. Sensitivity to detect clinically significant prostate cancer was found to be 88% versus 92%

(PIRADS vs. U-Net, $p >0.99$) and specificity 50% versus 47% ($p >0.99$). Collating data between U-Net and clinical radiologist assessment resulted in improved positive predictive value for clinically significant prostate cancer from 48% to 67% ($p = 0.01$), and negative predictive value remained unchanged ($p >0.99$) [7]. Additionally, MRI may contain texture features of the prostatic lesion that reveal further information regarding the malignant pathology yet are indistinguishable to the human eye. Fehr et al. combined apparent diffusion coefficient (ADC) and T2-weighted MR imaging phases with sample augmentation and utilized recursive feature selection support vector machine (RFE-SVM) to robustly predict (a) cancerous vs. noncancerous lesions, (b) low- vs. intermediate-/high-risk prostate cancer, and (c) sub-classification of intermediate-risk prostate cancer [8]. Their work suggests the feasibility to classify prostate cancer with imaging despite highly imbalanced data. As AI applications continue to evolve in urologic radiology for prostate cancer, these will improve diagnostic information available to patients and physicians for shared decision-making.

Urologists and computer scientists from the Center for Robotic Simulation and Education at the USC Keck School of Medicine have implemented AI to predict postoperative outcomes based on Da Vinci Surgical System kinematic data during robot-assisted laparoscopic radical prostatectomy. A random forest model was trained to predict postoperative length of stay (≤ 2 days or > 2 days) from 25 various intraoperative instrument, camera, and energy usage metrics in 78 cases from 9 surgeons (67 with length of stay ≤ 2 days and 11 > 2 days). The model performed with an accuracy of 87.5% accessed with k-fold ($k = 10$) cross-validation. Features related to camera manipulation were most predictive [9]. In a subsequent analysis, the research group developed a deep learning algorithm to predict urinary continence after robot-assisted laparoscopic radical prostatectomy from Da Vinci kinematics data. Using 100 cases from 8 surgeons, a deep learning model performed with an moderate predictive

accuracy measured by a mean-absolute error on 85.9 days and a cindex of 0.6. While accurate prediction of incontinence has a significant room for improvement, the three most informative inputs were the kinematics of suturing the anastomosis between the bladder and urethra [10]. Most importantly, these papers shed light on the potential AI applications in surgical performance evaluation.

Kidney Cancer

Recent clinical advances in AI-applied urological oncology extend beyond prostate cancer. Renal cancer has been well represented in recent years at the Medical Image Computing and Computer-Assisted Intervention (MICCAI) conference grand challenges. These grand challenges serve to elevate medical image algorithms through open data and outcome sharing. The KiTS19 challenge saw 106 teams from 5 continents compete to develop an AI algorithm capable of auto-segmenting kidneys and kidney tumors from CT images. The challenge consisted of 300 CT data sets with segmentation masks. Teams trained on 210 paired data sets and tested their algorithms on 90 CT images producing the predicted segmentation masks. The winning team achieved an average Sorenson-Dice coefficient of 0.974 for kidney and 0.851 for tumor. These data approached the inter-annotator Dice for kidney segmentation (0.983) but not for tumor (0.923) [11]. A similar EndoVis sub-challenge 2017 Kidney Boundary Detection used laparoscopic nephrectomy video files with labeled pixels containing kidney edges to create algorithms to automatically segment kidney boundaries [12]. A future KiTS21 MICCAI grand challenge will expand on the 2019 challenge to include segmentation of other anatomical features relevant to nephrectomy and partial nephrectomy, including the ureter and renal vasculature.

For a successful partial nephrectomy, a surgeon must successfully identify anatomical features and the tumor itself while ensuring no microscopic malignant cells are left behind in the resection tumor bed. Recent work from Haifler et al. has used Raman spectroscopy and AI to address this problem. A preliminary bench-top

model assessed six ex vivo samples of normal kidney parenchyma and six renal cell carcinoma sections and using a Bayesian machine learning classifier, sparse multinomial logistic regression, achieved an area under the ROC curve of 0.94 [13]. This data is limited by few data sets and internal validation; however, these analyses could be extrapolated to identify malignant tissue intraoperatively. The future prospect of using AI to render a 3D tumor reconstruction with intraoperative endoscopic vision and in situ pathology diagnostics may improve safety, efficacy, and accuracy of tumor resection during partial nephrectomy.

Urothelial Cancer

Cystoscopy is the gold standard in the diagnosis of bladder cancer. Ikeda et al. developed a convolutional neural network image classifier trained on 1.2 million general images, 8728 gastroscopic images, and finally 2102 cystoscopic images to detect bladder tumors. On a test set of 82/442 images containing bladder tumors, the algorithm performed with a 95.4% sensitivity and 97.6% specificity, which was comparable to the accuracy of an experienced urologist [14]. While AI has the potential to assist with the detection and possible automation of cystoscopy, other pursuits have applied AI to reduce the need for this invasive procedure. Sokolov et al. developed a random forest model based upon atomic force microscopy data of 5 cells from urine samples taken from 43 participants without bladder cancer and 25 bladder cancer patients. Using a 70/30 train-test split, they achieved 94% discriminatory accuracy [15]. Similar efforts by Sapre et al. used a support vector machine classifier trained on a microRNA panel from urine samples taken from patients without a history of bladder cancer, patients with a history of treated bladder cancer without evidence of recurrence, and patients with active bladder cancer to predict the presence of cancer cells. The classifier performed on an independent cohort with an AUC of 0.74 and sensitivity of 88%. The authors state their analysis could have reduced cystoscopy rates in the validation cohort by 30% [16]. While these methods remain experimental, AI systems have the potential to

increase the accuracy and reduce the cost and morbidity of office cystoscopy for the detection of bladder cancer.

Endourology

Endourology, the specialty of minimally invasive urological surgery, has been developed and fine-tuned over the last 40 years. One prominent division of endourology is the management of kidney stones. AI algorithms have been developed, principally in outcome prediction, for the management of nephrolithiasis.

One in 11 persons in the United States will experience kidney stones in their lifetime, and the initial presenting symptom is renal colic. In the acute setting, there is great clinical utility in predicting which patients will spontaneously pass their stones. This aids in patient guidance in whether surgical intervention is required. Solakhan et al. assessed 192 patients with ureteral stones presenting to an outpatient urology clinic. The authors created an artificial neural network model based on baseline stone size, body weight, pain score, ESR, and CRP. On a test set ($n = 30$), the model performed with 87.3% predictive accuracy of which patient's spontaneously passed their stones [17]. In a similar study, Dal Moro et al. assessed 402 patients presenting with renal colic using age, sex, body mass index, fever, previous urological treatments, previous expulsion of stones, duration of the symptoms (in hours), and dimension and position of the stone to build a support vector machine model to predict spontaneous stone passage within 6 months of the first presentation. Cross-validation showed the model successfully predicted spontaneous passage or surgical intervention with 84.5% sensitivity and 86.9% specificity [18]. In nephrolithiasis, predicting the need for surgical intervention is highly useful, as is prediction of surgical success in stone burden clearance pre-intervention.

Extracorporeal shock wave lithotripsy (ESWL) uses shock waves from an external source to fragment kidney stones. The primary measure of a successful ESWL is subsequent stone-free status. Well-validated traditional

statistical methods have shown body mass index, initial stone size, and skin to stone distance as key factors in predicting successful ESWL. Mannil et al. used a random forest classifier trained on preoperative data from 224 ESWL cases, including CT imaging-based stone 3D texture analysis, performed with an AUC of 0.81 when predicting successful ESWL [19]. However, a random forest analysis by Cui et al. of 459 ESWL cases with 19 clinically relevant inputs including stone 3D texture analysis performed with an AUC of 0.67 when predicting successful ESWL [20]. Further prediction in ability for ESWL to successfully clear stone burden will aid physicians and patients in choosing endoscopic vs. noninvasive treatment.

Percutaneous nephrolithotomy (PCNL) is the surgical intervention reserved for the largest kidney stones. The procedure involves accessing the kidney stone via a puncture through the back. Aminsharifi et al. developed an artificial neural network based on preoperative CT imaging and clinical data from 254 patients who underwent PCNL. The algorithm predicted stone clearance and perioperative blood transfusion with accuracies of 83% and 86%, respectively [21]. Recent work by Taguchi et al. uses AI to guide intraoperative percutaneous renal puncture in a pilot clinical trial. Using a table-mounted robotic system, the software determines the optimal trajectory for puncture using fluoroscopic images to guide the needle between the patient's skin and renal collecting system. After a ten-case learning curve, the author reported a puncture time of 2.8 min and no significant adverse events [22]. These data reflect the impact AI can have on improving patient surgical selection and its potential in intraoperative surgical planning and manipulation.

In addition to kidney stones, endourologists manage voiding dysfunction related to benign prostatic hypertrophy. Whangbo et al. developed a recurrent neural network to predict and measure time of voiding events from a smart wristband. The algorithm was trained on movement and tilt angle data collected from a three-axis accelerometer to recognize common three-step behavior for urination (forward movement, urination,

backward movement). The author has studied the accuracy of the algorithm compared to patient voiding diaries. They were able to predict voiding events in 30 participants over 60 days with 94.2% accuracy [23]. In summary, AI has the potential to impact nephrolithiasis in surgical planning and voiding dysfunction management.

Andrology

Andrology is a sub-specialty of urology that focuses on the medical and surgical management of all facets related to male reproductive health. This includes aspects of male reproductive urology such as infertility, reproductive endocrinology, and fertility preservation. It additionally includes sexual medicine components such as erectile dysfunction, Peyronie's disease, and priapism management. Andrology is strongly considered an area of medicine that artificial intelligence (AI) will greatly contribute toward the field's advancement. As the prevalence of infertility in the United States rises to approximately 7.3 million couples, and a male factor is identified in 50% of these patients, further tools are needed in the urologist's armamentarium. There are too many unknowns in this field of which time is of critical importance, and thus there has been foundation laid by many physicians and researchers for incorporating AI [24].

Prediction of Male Reproductive Potential

One of the most promising areas for AI in andrology is the prediction of male reproductive potential. While a reproductive urologist may be able to diagnose a patient after thorough male infertility workup, there have been efforts to identify patients earlier on in their reproductive years that may necessitate consultation. Additionally, it may inform practitioners to focus on a male factor without the need for expensive diagnostics. An early emphasis has been on epigenetic research to uncover possible environmental or lifestyle factors that affect a patient's semen parameters, through the use of AI. Girela et al. preprocessed human variable data derived from a questionnaire obtained

from 100 healthy volunteers, such as socio-demographic data, cigarette and alcohol use, body mass index, and general health status with a decision tree. Using these data, the team developed a multilayer perceptron (MLP) artificial neural network (ANN) that predicted sperm concentration with 90% accuracy (sensitivity, 95.45%, and specificity, 50%) and motility with 82% accuracy (sensitivity, 89.29%, and specificity, 43.75%) through these factors [25]. Incorporation of these AI networks into annual practitioner visits may lead to more timely fertility interventions.

Identification of seminal biomarkers that may implicate fertility potential has also been researched. In particular, seminal zinc and leptin levels have been correlated as possible surrogates for male infertility, as an appropriate threshold may be required for basic sperm function. Ma et al. identified seminal leptin as a potential biomarker to be utilized alongside an artificial neural network (ANN) model in determining sperm retrieval success in patients with non-obstructive azoospermia (NOA). Two hundred eighty patients with NOA were trained with various inputs such as testicular volume, semen volume, hormone levels, seminal leptin levels, and semen parameters. The ANN model had a AUC = 0.83, which was better than single independent variables [26]. Vickram et al. validated a backpropagation neural network, derived from a training set of 177 semen samples, that was able to predict seminal biochemical parameters including protein (mean absolute error = 0.025), fructose (mean absolute error = -0.080), glucosidase (mean absolute error = 0.166), and zinc levels (mean absolute error = -0.057) utilizing just semen parameters [27]. While semen parameters and hormonal levels comprise the diagnostic foundation of the male infertility workup, these studies utilizing AI show promise to enable quantification of reproductive potential from seminal biomarkers.

In patients who have been identified to be azoospermic, the next step of the male infertility workup is undergoing chromosomal testing to determine possible genetic etiologies. These tests prove to be expensive and require specialized labs that cause a time lag in the infertility cycle. Akinsal et al. trained an ANN with 310 azoospermic patient

data, physical exam, hormonal levels, and ejaculate volume to identify patients with 95% accuracy who would most likely need further investigation [28].

The mark of achieving full male fertility potential begins with penetration of sperm into the ova. This is considered conception success, and Niederberger et al. attempted to predict this fertility potential just by semen analysis (SA) data. They demonstrated that neural networks showed promising results in predicting sperm penetration success rates in bovine cervical mucus on various ova based just on the SA. The neural network was able to correctly classify 67.8% of zona-free hamster egg penetration assays (1416 assays in training set) and 80% of bovine cervical mucus sperm penetration results (139 assays in training set) [29]. With the advent of artificial reproductive technologies (ART) such as intracytoplasmic sperm injection (ICSI), sperm selection among a heterogenous specimen sample has risen to be of paramount importance as penetration of the ova is bypassed. Intrinsic qualities that are currently unable to be fully evaluated by the human eye may be of integral importance for sustained conception success and resultant live birth. Current modalities include a broad set of laboratory bench manipulation such as microfluidic chamber challenge, protein binding, and morphological examination. Preliminary research as presented by Takeshi et al. at the 2018 American Society for Reproductive Medicine Conference demonstrated an ability to differentiate 8010 spermatozoa and 25,522 non-spermatozoa cells through AI. Mirsky et al. isolated sperm cell heads of 1400 human sperm cells through interferometric phase microscopy and utilized this data to train a support vector machine to automatically classify sperm as good and bad morphology for possible use in in vitro fertilization. The SVM had a ROC of 88.59% and AUC of 88.67%, with precisions at 90% or higher [30]. Further research utilizing AI in sperm selection is needed, especially as progress and promise have been shown from the embryo selection side [31].

Semen Analyses

Artificial intelligence has had an impact on the realm of diagnostics in reproductive urology. The mainstay diagnostic of an infertility workup

is the semen analysis, a test that is traditionally performed in an andrology laboratory with manual counting by a technician or computer-assisted sperm analysis (CASA) system. This has been a labor-intensive and time-consuming diagnostic with potential subjective operator bias. Agarwal et al. have demonstrated automation of SA by utilizing a novel optical microscope that is built upon a proprietary artificial intelligence algorithm. By comparing the results of a manual and AI count on 135 semen samples, they observed high degree of correlation ($r > 0.9$) in sperm concentration, motility, and pH results [32]. Advances in consumer technology have led to an increase in home semen analysis kits over the past few years. In particular, digital home kits that utilize a smartphone camera and device adaptor can provide consumers with semen parameter results within minutes. While initial versions were limited in only providing a few parameters, the supplementation of AI computer vision technology has expanded accuracy in measuring both sperm motility and morphology. Tsai et al. evaluated this AI system by comparing automatically generated semen parameters to objective grading of sperm quality by experts and found automatically generated concentration of total sperm ($r = 0.65$, $p < 0.001$), concentration of motile sperm ($r = 0.84$, $p < 0.001$), and motility percentage ($r = 0.90$, $P < 0.001$) correlated well with expert grades [33].

Predicting Sperm Retrieval Success Rates

In infertile male patients found to be with non-obstructive azoospermia, sperm retrieval is the procedure that must be undergone to possibly find sperm for ART. The success of a microdissection testicular sperm extraction (micro-TESE) has been reported to be approximately 63%. Ramasamy et al. formulated an ANN that predicted sperm retrieval success rates by training the system with preoperative clinical data and operative results from 1026 men who underwent micro-TESE. The ANN was able to accurately predict 59.4% of the operative outcomes (AUC 0.64). This algorithm with moderate discrimination ability may still be clinically useful, especially when counseling patients who are

unwilling or unable to have a micro-TESE. These analyses demonstrate promise for AI in aiding patients and physicians in managing expectations of surgical success [34].

Predicting Surgical Shunt Intervention for Priapism Management

Priapisms are defined as prolonged erections, usually greater than four, and may have various etiologies. Classification is divided into either ischemic, non-ischemic, or recurrent. Emergent management of ischemic priapism is important as it, if left untreated, may possibly lead to possible male impotence. Identification of those that may require escalation to surgical shunting would save valuable time trialing less invasive treatments that may not resolve the priapism. Masterson et al. performed a retrospective study of 364 priapism encounters at a county hospital, collecting data on patient age, race/ethnicity, type of priapism, etiology, duration of erection prior to presentation, length of hospital encounter, prior episode of priapism, interventions attempted, complications, escalation to operative intervention, urological follow-up, and patient risk factors. Three hundred thirty-four cases were determined to be ischemic etiologies. The team utilized a random forest machine learning algorithm to train the data set and were able to create an online risk calculator to accurately identify those who require surgical shunting or not 87.2% of the time with AUC 0.76. Positive predictive value remained low at 44.5%. It was identified that longer duration of priapism was a notable factor for surgical shunting. Further studies are required to increase the validity of the study, but its initial results show promise for AI in predicting surgical intervention for ischemic priapism [35].

Conclusion

Artificial intelligence is poised to make a significant impact on the field of urology, allowing for further improvements in patient care. The possibilities of AI applications are only scratching the surface, as exponentially more literature is published year after year. The broad scope of AI urologic application includes

oncology, endourology, and andrology. With the urology track record in innovation, AI will see many of its potential reflected in urologic practice over the next decade.

Abstract

This chapter will explore artificial intelligence (AI) in trauma and orthopedics (orthopedics). Orthopedics is a branch of surgery that focuses on the prevention of musculoskeletal pathology and the correction and restoration of form

and function of these structures. Orthopedics is fertile ground for adoption of technological innovations, including artificial intelligence, where small gains in the treatment of one condition can lead to improved outcomes for some of the largest patient populations in medicine. Orthopedics is well suited to innovation and the application of AI as it has clear pathways for common diseases and is a highly technical field with constant technical innovation. This chapter will review several of the key applications of AI in orthopedics including diagnostics, intraoperative robotics, and predictive analytics.

Introduction

This chapter will explore artificial intelligence (AI) in trauma and orthopedics (orthopedics).

Orthopedics is a branch of surgery concerned with the musculoskeletal system, including the extremities, spine, and their associated structures. The specialty focuses on the prevention of musculoskeletal pathology and the correction and restoration of form and function of these structures. Trauma, in the context of orthopedics, refers to a wide spectrum of acute injuries of the musculoskeletal system caused by an external force, for instance, fractures caused by a car accident or tendon ruptures caused by landing a jump awkwardly. Orthopedics also consists of elective care which is the prevention, diagnosis, and management of chronic musculoskeletal conditions such as arthritis.

As well as impacting health outcomes, including a patient's quality of life, musculoskeletal conditions are a significant burden on healthcare systems. In the UK 25% of all surgical interventions are musculoskeletal and account for 4.7 billion of NHS spending each year [1]. By impacting individual productivity, they also have an indirect impact on a country's economy. In the USA one in two adults is thought to be affected by musculoskeletal problems costing an estimated \$213 billion in treatment and economic productivity, approximately 1.4% of US GDP [2]. Consequently, the need for delivery of reproducible and effective orthopedic care means it is fertile ground for adoption of technological innovations, including artificial intelligence; small gains in the treatment of one condition can lead to improved outcomes for some of the largest patient populations in medicine and significant economic savings.

Beyond issues of scale and cost, multiple features of orthopedics mean that it is particularly

well suited to innovation and the adoption of artificial intelligence:

1. Orthopedics is a highly technical field, characterized by consistent technological development. Orthopedic practice consists of the daily use of technology ranging from prosthetic implants to robotics. Its practitioners are required to develop sound technical understanding to properly assess, plan, and deploy the use of these technologies in the treatment of their patients. The orthopedic surgeon workforce is therefore poised for relatively rapid adoption of new technologies once they are proven effective.
2. Orthopedics is used to close working relationships with technology-creating industries. These close ties with industry mean that there are established mechanisms for real-time feedback and clinician-industrial partnership development.
3. Orthopedic conditions have well described diagnostic and treatment pathways, which lend themselves to optimization on a large scale.
4. Many common orthopedic operations are reproducible and are associated with highly effective outcomes, for instance, hip replacements [3]. The mature and established status of such procedures confers a relative uniformity for the research and development of new technologies and advances in optimization.
5. The orthopedic community is pioneer of "big data." Orthopedics was the first medical specialty to institute national and international databases that hold large repositories of procedure-specific data [4]. A key roadblock to the development of artificial intelligence can be access to sufficient data to optimize accuracy and performance. The maturity of extant orthopedic databases can offer fertile datasets for the advancement of AI applications.

Due to these factors, the research and development of a range of AI-based techniques and applications in orthopedics has been advancing rapidly. A recent review has mapped the breadth of these applications across orthopedic practice and the AI techniques employed (Fig. 1) [5].

Learning in Orthopedics – A Literature Review, Cabitza et al. Copyright. Reproduced with permission by Creative Commons Attribution 4.0 international [5])

This chapter will explore the use of artificial intelligence in some key domains in orthopedics, diagnostics, robotics, and predictive analytics including orthopedic databases and postoperative complications.

Diagnostics

Orthopedics diagnosis is heavily reliant on radiological imaging, with the most common tests used to diagnose and quantify orthopedic images being radiographs (X-ray), ultrasound, computed

tomography (CT), and magnetic resonance imaging (MRI). A diagnostic image is most commonly the key instigator for orthopedic referral and treatment. The great majority of injuries are first seen by a primary care practitioner or the emergency department, who orders the initial imaging. In these cases it is not uncommon for insufficient radiological views to have been ordered to allow for diagnosis and quantification or ruling out a specific injury. An orthopedic specialist may then make another order for additional views or a more sensitive scan at a later time point in the patient journey. This can lead to a delay in starting

treatment or missed fractures, resulting in poorer outcomes for patients, increased need for complex delayed intervention, and increased cost [6, 7]. Missed or occult fractures also account for a significant proportion of medicolegal claims [8].

Examples of commonly missed fractures with associated morbidity include scaphoid fractures, leading to increased incidence of avascular necrosis [6]; up to 20% of these are missed radiologically, and capture of these fractures can be improved with appropriate views, serial imaging, or a protocol to urgent CT or MRI scan [6, 9]. Lisfranc fracture dislocations in the foot are missed in 20% of cases [7]. If the wrong X-ray views are taken, these can be missed in up to 50% of cases [10]. In both of these examples, early recognition of the mechanisms of injury that lead to the injury, the correct image protocol, and a low threshold to use imaging with higher diagnostic capability can reduce missed fractures and therefore morbidity and cost significantly.

The applications of AI in orthopedic diagnostics can help reduce the likelihood of missed injuries and ensure timely treatment. Applications range from improving upstream functions such as faster image acquisition and improved protocoling to downstream applications such as automated image analysis and interpretation.

Musculoskeletal Image Scheduling and Protocoling

Improved image scheduling and protocoling in orthopedics can lead to faster diagnosis. Natural language processing (NLP), a form of machine learning (ML) that enables computers to derive meaning from unstructured human input, has shown early promise in this area.

The technology may enable processing and triage of electronic health records and imaging requests to schedule and protocol accordingly, ensuring appropriate imaging and views. Deep learning convolutional neural networks (CNNs) have already been developed to choose between tumor or routine musculoskeletal MRI protocols based on clinical information and indication with an accuracy level of 94% [11]. One group

developed a natural language classifier that was able to extract the need for contrast for musculoskeletal MRIs with an accuracy of 83% [12]. Applications of this technology have also been able to extract radiologist recommendations for follow-up imaging from reports [13]. Examples like this could act to streamline the imaging pathway and reduce time between scans for many orthopedic patients.

Musculoskeletal Image Acquisition

AI has been applied to expedite the acquisition of knee MRI. In acute soft tissue knee injury, it is important for patients to receive treatment in a timely manner so as not to suffer poorer outcomes [14–16]. Patients often present to ED, where radiographs are taken and a referral made to orthopedic clinic. Complete assessment of suspected ligamentous or meniscal injury of the knee necessitates an MRI, which is often ordered by the orthopedic specialist once the patient is seen in clinic, as these are costly and require considerable time to scan. Availability of faster acquisition MRI could reduce costs and scan time and therefore could be ordered earlier in the patient journey, increasing the likelihood of timely treatment and better outcomes. Techniques for accelerated acquisition have been available since the 2000s, but reconstructed images tend to contain artifacts – leading to a trade-off between quality and speed. Using ML to help with reconstruction of accelerated sequences, such as knee MRI, can reduce artifacts and therefore improve the accuracy of these scans. Studies have shown promising results in preserving the quality of MRI and have outperformed standard reconstruction methods [17].

Musculoskeletal Image Interpretation

AI in radiological interpretation is a popular field and has been applied to musculoskeletal imaging using convolutional neural networks (CNNs), a form of machine learning. CNNs are well suited to carry out analytical tasks such as detection (fracture detection, soft tissue knee pathology

detection or spinal pathology), classification (osteoarthritis classification, spinal deformities), or segmentation (cartilage or meniscus) [18].

Fracture Detection

Multiple studies have been published demonstrating the application of deep learning (DL) algorithms to radiographs for automated fracture detection. Systems designed to look at a variety of peripheral radiographs have shown accuracies of around 83% [19]. A DL algorithm trained specifically to identify distal radius fractures achieved even more impressive results with a sensitivity of 90% and specificity of 88% [20].

A recent review of the musculoskeletal fracture detection systems available found several AI tools that have been able to identify orthopedic injuries on X-ray with greater accuracy than physicians who are not orthopedic surgeons or radiologists [18]. A few studies have shown accuracy approaching or equal to that of orthopedic surgeons and radiologists, but the greatest results are achieved when used as clinical decision support to assist in these specialists' interpretations rather than used alone [18, 20]. The work of orthopedic surgeons or radiologists involves more than fracture detection; they also consider the patients' clinical state, compare historical images, and communicate with doctors of other specialisms; for this reason, fracture detection tool developers and healthcare providers have been unwilling to shift this workload and therefore liability from the clinician to AI tools. Instead, these computer-assisted detection (CAD) tools can be used to augment the interpretation of the non-specialist (non-orthopedic or radiology specialist) or busy clinician.

Knee Pathology Detection and Segmentation

Several pathology detection tools have been developed for the identification of soft tissue knee injuries on MRI. These have focused primarily on anterior cruciate ligament (ACL) tears or meniscal tears. ACL tears are a common orthopedic injury that require timely treatment, often surgical, to prevent undesirable sequelae such as meniscal tears or arthritic wear. Meniscal tears,

similarly, are common orthopedic injuries which often require surgery. Both of these pathologies generally require MRI to confirm a diagnosis and proceed to surgery. Given their prevalence, these injuries have been the focus of a number of AI detection research projects [21–23].

A CNN developed to identify and classify ACL tears as no tear, partial, or complete had a similar specificity but lower sensitivity than specialist musculoskeletal radiologists. When the CNN was used as a CAD tool by general radiologists, it increased specificity by 4.8% when compared with radiologist-only performance [21, 24]. CNNs developed to look only at no tear versus complete tear showed no statistical difference when compared to radiologists [23, 24]. CNNs developed for the detection and classification of meniscal tears have yielded good but slightly inferior results and have not yet been able to emulate the sensitivity and specificity of expert radiologists [21, 24]. The interpretation of meniscal tears also requires classification of type of tear as each type can be treated differently, which CNNs have not yet been able to achieve. While there are promising results, the deficiency in classification ability and detection of other concomitant soft tissue knee injury, which is often present, means that these tools are still some way off mainstream adoption.

Osteoarthritis Detection and Cartilage Segmentation

Osteoarthritis (OA) is commonly identified and confirmed after clinical assessment with an X-ray. Historically, radiographs have been the imaging of choice, but with the advent of cartilage preservation treatments and unicompartmental arthroplasty, more detailed imaging, such as MRI, is increasingly being used to quantify the degree and specific locations of most wear. AI has been developed for OA detection in both these imaging modalities.

CNNs to detect and classify cartilaginous defects and osteoarthritis based on the Kellgren and Lawrence system (a method of classifying osteoarthritis using five grades) in knee radiographs have achieved multiclass classification accuracy of up to 66.7% [25]. One model that used a combined approach of a CNN and

demographic data was able to achieve knee model sensitivities for no, mild, moderate, and severe OA of 83.7%, 70.2%, 68.9%, and 86.0%, with corresponding specificities of 86.1%, 83.8%, 97.1%, and 99.1% [24–26]. A model designed to detect the presence of hip OA from radiographs exhibited similar capabilities to that of experienced radiologists [25]. An MRI-based CNN assessing knee OA was found to show improved sensitivity but lower specificity when compared with radiologists [27]. There is some way to go to attain consistent results comparable to the expert radiologist or orthopedic surgeons, but the ongoing development of OA CAD technology could one day help in alleviating the burden of this highly prevalent disease.

Orthopedic Implant Detection

Some of the most challenging and costly procedures in orthopedics are revision arthroplasties. To appropriately deal with a problem arthroplasty, the orthopedic surgeon must first identify which implant has been used in the primary procedure. As operations are often performed at other distinct centers, with implant data often inaccessible on disparate electronic systems, it can be difficult to correctly identify implants. One survey found 88% of surgeons reported this to be a critical barrier in revision arthroplasty surgical planning and execution [28]. AI tools have been employed to classify implants thereby potentially reducing risk of delay and surgeon hours used in identifying the implant and likelihood of inappropriate surgical equipment in the operating theater. A convolutional neural network deep learning algorithm developed across four sites in the USA is able to use plain radiographs to detect and classify hip arthroplasty implants. The accuracy of the model on its test set was an accuracy of 99.6% [29]. One model trained to identify radiographs of three commonly used hip implants achieved an accuracy of 100% [30]. Such identification tools are now commercially available and can identify arthroplasties from multiple joints including knee, shoulder, and hip – though accuracy of these systems is unclear due to a lack of published research.

Orthopedic Oncology Detection

Bone tumors are relatively rare and therefore present a challenge for both radiologists and orthopedic surgeons. Work on CAD for bone tumors began as early as the 1960s with the work of Lodwick, a musculoskeletal radiologist. Lodwick developed a computer program based upon Bayes formula that returned probability of a bone tumor diagnosis using demographic data and radiographic features. It predicted correctly 77.9% of the time among eight bone tumor types [31]. More recent work has improved further on these results with the use of ML CNNs to develop CAD tools. Tools have been developed to characterize bone lesions as malignant versus benign based on radiographs [32]; classify bone destruction, staging, and grading of bone lesions using a decision tree tool on radiographic images [33]; and classify vertebral body bone lesions on cross-sectional CT imaging benign or malignant using a random forest classification [34].

Intraoperative and Robotics

Intraoperative applications of artificial intelligence in orthopedics mainly come in the form of computer-assisted navigation, computer-assisted surgery (CAN/CAS), or robotic technology. Although available in some guise since the late 1980s, this field has been relatively slow to take off and has only recently reached mainstream practice [35]. CAN systems use referencing methods to reconstruct virtually the desired operative area usually with the aid of preoperative CT, surgeon assist planning, or fluoroscopy images; they then provide the surgeon with real-time intraoperative feedback [36]. Robotic systems generally consist of computer-guided mechanical instruments that in theory allow for more accurate and reproducible placement of tools and implants.

These systems can also be divided into passive (CAN), semi-active (robot-assisted), and active (autonomous robotic) [35], with only the latter two truly falling under the scope of artificial intelligence.

Robotic autonomy can be thought of as a spectrum, with the most rudimentary robots lacking

autonomy and pre-programmed to run a set of repetitive limited functional tasks. Fully autonomous robots are able to perform complex tasks without human intervention. Between these two extremes are semiautonomous robots which may incorporate artificial intelligence algorithms into specific elements of their function or may use AI to continuously improve their performance with adaptive learning. The degree of autonomy is defined by the interplay of three factors: mission complexity, human independence, and environmental difficulty as described by ALFUS framework [37].

Fields within orthopedics that have been at the forefront of taking up the development and use of robotics have predominantly involved alignment and positioning, such as the implantation of arthroplasty components, placement of spinal pedicle screws, and bone or soft tissue resection margins in oncology surgery [38, 39]. The focus of this section will be on arthroplasty robotic systems, as an example use case.

Passive, or CAN, systems usually have multiple sensors which can track the movements of surgical instruments and assess bone morphology and alignment. They provide detailed information to the surgeon, acting as a real-time referencing system [40] (Fig. 2).

Semiautonomous Intraoperative Robotics

The ability for a robot to perceive its environment – “perception” – requires AI algorithms. A robot that has perceived its environment in order to locate and carry out a task with an adaptive response uses AI for perception and output directions, though the mechanization to carry out the task does not require AI. If the resulting output is used to guide the surgeon to perform the task, rather than perform it itself, the robot is semiautonomous. Semi-active or robot-assisted systems can act to instruct and constrain actions that the surgeon is performing, for example, during ligament balancing or ensuring that bone will only be resected within a pre-defined cutting zone in a unicompartmental knee replacement [42].

In orthopedics, knee arthroplasty is a popular area for the development of robotics; these robots are used to guide a bone cut along an optimal pre-prescribed path decided from preoperative CT by the surgeon with assistance from the planning software. The robot will then perceive its environment and constrain the movements of the surgeon using passive assistance (pushing the surgeons and saw away from a path) or active assistance (guiding the surgeon toward a path). They can also make real-time assessments of soft tissue balance and feed this back to the surgeon [35, 43, 44].

As well as increased accuracy, these systems have also been shown to have the potential to reduce the need for fluoroscopy during procedures. In some surgical specialties, though not yet in orthopedics, they can facilitate remote-operating – with the surgeon working in a different location to the patient [45]. Although these machines have been shown to improve the alignment and positioning of components in arthroplasty procedures [46], there is conflicting evidence to show whether this converts to improved clinical outcome or functional scores at short- or long-term follow-up [43, 47, 48], meaning some have felt their use (and significant cost) has been difficult to justify in widespread practice [49]. Few knee surgeons would refute however that the key to short- and long-term success in knee arthroplasty is achieving optimal alignment with good ligament balancing, and while subjective feel comes with experience, there can be no negative to objective real-time data. This can be achieved during the procedure with a combination of robotic-assisted cutting and computer-assisted ligament balancing. A recent study using the Australian Orthopaedic Association National Joint Replacement Registry demonstrated that at 3 years, a certain brand of robot-assisted unicompartmental knee arthroplasty had significantly lower overall revision rates compared to other types of non-robotically assisted procedures at 3 years. The revision for aseptic loosening was lower, supporting the theory that robotic assistance improves alignment; however, revision for infection was significantly higher in the robotic-assisted group, which could be due to longer surgical time [43, 50].

Arthroplasty: Current Concepts, by Batailler, C [41]. Image reproduced with permission under the Creative Commons Attribution 4.0 International license)

Autonomous Intraoperative Robots

Active, or autonomous, systems are what the public often perceive when they hear the phrase “robotic surgery.” The reality is that a robotic system performing even a part of a procedure without a guiding surgeon’s hand is still some way off from being accepted in clinical practice [36], both from a technical and ethical perspective. Although patient concern might be considered a potential barrier to uptake for robotic surgery in general, recent research has shown that almost half of patients would not mind at

least part of their surgery being performed by autonomous robotic technology [51].

The only long-term follow-up trial for robotic knee surgery is for an autonomous system. The study required a 10-year minimum follow-up of both conventional and robot-assisted total knee replacement (TKA). This found that there were no differences between the autonomous robot-assisted TKA and non-robotic TKA when comparing functional outcome scores, aseptic loosening, survivorship, and complications. However, the authors could not recommend its use citing the lack of benefit over conventional means and increased outlays [52].

Continued Adoption of Robotics

Globally, the number of knees implanted using robotic technology are currently very small compared to total conventional operations, but data will continue to emerge, particularly as global national joint registries have now started to collect this data.

Although huge technical advances have been made, it is difficult to see these technologies becoming widespread until clear long-term functional and clinical benefit can be proven, to outweigh the significant costs involved – initial outlay for a single robotic system can be in the millions of pounds, with annual maintenance running into hundreds of thousands [13]. It would seem that for these costs to significantly reduce, large volume of uptake would be needed to create some economies of scale. Reaching this uptake will be difficult due to the slow-growing cohort of patients who have been operated on using this technology that can be used as a study population, with more time needed to fully assess any differences in long-term outcome. Currently there is a paucity of data on the long-term outcomes of the techniques that are currently available, but there is however a reasonably steady stream of positive literature in short-term studies [43, 53, 54].

A further factor not to be overlooked is that there is clearly a learning curve involved for the surgeon using this technology [50], and it is important that appropriate infrastructure is developed to allow adequate training of current and future surgeons to be able to embrace these systems safely [55]. Equally, there is always the possibility that any robot-assisted procedures may be complicated by device malfunction, so it is crucial that the basic skills to perform the procedure manually by the operating surgeon are not lost.

Predictive Analytics

The ability of ML to handle large amounts of data and multiple concurrent variables means it is well suited to elucidating patterns that may not have been revealed by human examination and

statistical methods alone. Machine learning can approach predictive analytics in two main ways, supervised learning and unsupervised learning. In supervised learning an algorithm is derived from a human set of instructions and rules applied to the data. In unsupervised learning the machine is provided with data to process without human “rules” and can therefore identify patterns that may not have already been suspected previously. The most commonly used machine learning models used are support vector machines (SVM) and decision random forests (DRF), these having been associated with the most accurate performances. ML is increasingly being applied to predictive analytics in medicine, from personalized treatment decisions to operational management. In orthopedics ML has been employed for the prediction of surgical outcomes and postoperative complications, with the subspecialty of spinal surgery leading the way in its development and adoption.

Orthopedic Databases

National orthopedic registries, such as the National Joint Registry established in 2002, exist for the measurement of long-term effectiveness and monitoring of safety and patient outcomes [4]. The application of natural language processing, a ML technique, to extract and analyze data from these pioneering databases can provide invaluable insights for the profession. Similar techniques can be applied to smaller hospital databases and EHRs. Though not yet in widespread use, automated algorithms have been developed and trained for this purpose in hip and spine surgery.

Total hip arthroplasty is one of the most reproducible and successful procedures in medicine [3]. Orthopedic bespoke training and validation sets have been used to train NLP algorithms to extract data from orthopedic databases on total hip arthroplasty complications as defined by the American Hip Society. When comparing the output of the orthopedic NLP tool with the manual review of the dataset, the AI performed promisingly with accuracy of 95% versus that of the manual review 94.5%. When the algorithm looked at implant

characteristics, it performed significantly higher than the manual reviewer which unsurprisingly suggests data with definite variables can achieve the highest levels of accuracy. The accuracy for extracting postoperative complications was also higher than the human reviewer, though the algorithm was less accurate at extracting postoperative interventions [56]. This algorithm has been employed locally to develop bespoke consenting for patients based on local data; ML has the potential here to more accurately predict local complications rates for their patients, help surgeons appraise their local practice, and recognize issues early.

The orthopedic subspecialty of spinal surgery has leveraged ML to provide surgeons and patients with accurate and meaningful predictive analytics for use in adult deformity surgery. Spinal deformity, at its most severe, can cause crippling deformity, pain, and disability. Its corrective surgical management is complex and risky but can, if planned carefully, lead to significantly improved health and quality of life for patients. Until recently surgeons relied on personal clinical experience, consensus, and literature based on linear or logistic regression modelling to weigh their decision-making for these complex patients and procedures. More recently, spinal deformity surgeons have incorporated machine learning into their practice. The International Spine Study Group and the European Spine Study Group used prospective multicenter databases to develop an ML-based prognostic tool for major complication, hospital readmission, and unplanned reoperation in adult spinal deformity surgery. The model, created with a random survival forest algorithm, had a predictive accuracy area under curve (AUC) ranging from 0.67 to 0.92 [57]. This has now been developed into a publicly available calculator allowing deformity surgeons to better inform patients on individualized risks from accurate prognostic models and augment their surgical decision-making [58].

Predicting Disease Onset and Degree

If the efficacy of screening for scoliosis improved, this could result in the disease being identified

earlier than clinical assessment alone may allow. In turn, earlier treatment could then result in better outcomes and reduced costs. Measurement of the Cobb angle, which quantifies the magnitude of the spinal deformity, is key for treatment planning in patients with scoliosis. CNNs have been created to identify Cobb angles of greater than 30° with 100% sensitivity and 75% specificity using torso topography and radiographs [59]. ML has also been used to detect and quantify scoliosis, Cobb angle, and spinal alignment using surface topography and moiré images [60].

SVM have been used to quantify curve severity using radiographs, the results of which were statistically comparable to more time-consuming manual measurements [61]. There are multiple iterations of these tools with varying but encouraging levels of accuracy [62].

Postoperative Complications and Rehabilitation

Orthopedic surgical patients often begin their postoperative recovery on orthopedic wards where their recovery may be complicated by bleeding, infection, venous thromboembolism, sepsis, pneumonia, stroke, cardiac arrest, kidney failure, or other life- or limb-threatening post-surgical adverse events.

The analysis of big data presents opportunity to aid clinicians in preoperative decision-making by identifying prognostic factors and risks of postoperative complications and adverse events. An international consensus found that patient comorbid states are more significant drivers of postoperative complications than actual procedural characteristics [63]. Though more research is needed, it would suggest preoperative predictive models (as discussed above) and optimization could significantly help drive down these kinds of adverse events.

Routine vitals monitoring on most postoperative wards is 4 hourly; early decompensations can be missed in the windows between or by infrequent review due to staffing shortages. In the case of many of these complications, taking sepsis as an example, it is clear timely intervention saves

lives [64]. Artificial intelligence applications aimed at prevention or earlier recognition of these postoperative complications can help reduce morbidity, mortality, and length of stay of patients [65, 66]. Wearables data normally marred by data artifact can be mitigated by machine learning algorithms allowing for constant monitoring and earlier warnings prompting assessment. These same technologies can be adopted for community remote monitoring and physical activity functional assessment statuses [67].

Surgical complications such as surgical site infections (SSIs) are of great concern in orthopedic practice. Deep neural networks have been utilized to classify patients at greatest risk of developing this postoperative complication with impressive accuracy.

In spinal surgery, SSI rate is reported ranging 1.2–8.5% increasing morbidity and decreasing patient satisfactory and at significant cost [68]. Deep neural network classification models have been trained to stratify risk factors to provide predictive clinician decision support. One model was able to predict SSI with a positive predictive value of 92.56% and a negative predictive value of 98.45% [69]. These models are currently experimental and not used in widespread practice. More work is necessary to refine such models which suffer limitations including bias and manual alteration of varying model parameters during model construction.

Predictive analytics is an extensive field with endless potential application and is likely to continue to evolve with greater accuracy as further research is conducted and models optimized and further data becomes available.

Conclusion

This chapter has explored a handful of the available AI applications in trauma and orthopedics. Orthopedics is a specialty with a vast patient population and is ripe for the adoption and evolution of AI. AI has multiple applications in orthopedics ranging from detecting occult fractures on imaging to guiding the surgeon's hand to achieve optimal bone cuts intraoperatively. Although application of

technologies such as robotics to orthopaedic practice are still in many cases novel and experimental, they have begun to gain traction as short-term results have become available. With the scale of the specialty, frequency, and reproducibility of procedures, this adoption is likely to rise exponentially as further techniques and data become available.

Abstract

Indeed we live in exciting times, at the cusp of a world which is a melting pot of novel technologies and surgical advances. Artificial intelligence holds mind-boggling potential for the informed surgeon who is open to thinking out of the box and expanding learning horizons. Boundaries must merge; interdisciplinary teamwork must emerge to propel a healthcare revolution. This chapter heralds a new age in surgery, where the power of machine learning meets the surgeon's clinical acumen. The humble healing scalpel becomes a hi-tech widget! The ultimate aim is healthcare that is affordable, accessible, and par excellence so as to improve patient quality of life and disease combat.

Introduction and Background

Tracing the identity of oral and maxillofacial surgery leads to a deeper understanding of its origin, scope, and emerging roles. This branch of surgery has come a long way from the times of historically pioneering surgeons such as Simon P. Hullihen and James E. Garretson who named this branch and is considered the founder of oral surgery. The specialty deals with conditions and defects, both congenital and acquired, of the head, face, oral cavity, and neck. The maxillofacial surgeon of today needs to be equipped with training in delicate and masterful surgical techniques on prominent organs involved in vital body functions. From trauma and pathology to orthognathic, esthetic, cleft lip/palate, the maxillofacial trainee

of today must be abreast with complex lifesaving oncosurgical resections, reconstructive procedures including the use of distant free flaps, and technology-enhanced surgical care (Images 1 and 2).

Healthcare is witnessing an emerging domain of artificial intelligence (AI). A concept that seemed out of a science fiction movie is now an accessible reality. It is therefore the need of the hour to wake up to this compelling field and equip medical practitioners with the principles and practical knowledge on the subject. The convergence of medical professionals and their skill set and the potential of AI will herald the new era of "human-tech-driven intelligence."

Artificial intelligence surfaced amidst awe as well as alarm. As with any novel disruptive concept, it has been through the "hype cycle." Despite controversies, AI has been increasingly finding applications in the world around us, and naturally healthcare too has embraced AI.

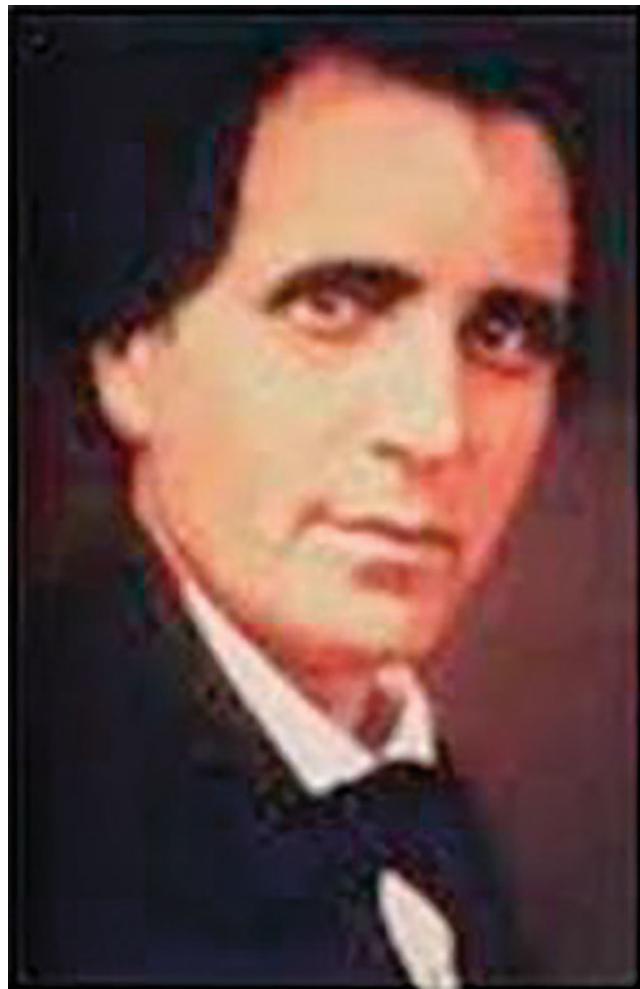

The role of AI in medicine has expanded centripetally. AI gradually inched its way from outpatient data analytics that transcended into better streamlined patient scheduling, doctor workflow optimization, resource management, etc. AI then proved its merits in radiological and pathological diagnostics and enhanced predictive capacity of clinicians. AI in the OT (operation theatre) is the ultimate goal of a futuristic surgeon.

In order to be in a position to use and develop AI tools in maxillofacial surgery, it is imperative that every surgeon holds a basic understanding of the fundamentals of this science.

This chapter aims to

- Serve as a ready reckoner on AI for maxillofacial surgeons.
- Bust myths and clarify the topic to surgeons who are not trained engineers or tech gurus.
- Shine light on principles and applications of AI by means of literature review.
- Lay the foundation and provide the insight upon which the readers can then build on and

Image 1 Dr. Simon P. Hullihen. <http://accessomfs.com/about> or Ref. [39]

develop unique tools in subspecialties of maxillofacial surgery.

- (E) Help practicing surgeons develop a thought process in the field of AI.

solving. Computer science defines AI as “intelligent agents” capable of perceiving their environment and more importantly taking learned actions to maximize their abilities of successfully executing a planned/programmed goal [1].

However, the very word “artificial” indicates an intelligence that is *unlike natural* intelligence inherent in humans. The chief distinguishing factors between the two are consciousness and emotion. Key aspects of human intellectual acumen are intuition and empathy, components AI will most likely struggle to mimic.

The current consensus from literature on AI in the healthcare points toward improved outcomes by joint human-machine tasking rather than superiority of either entity over the other [2]. Looking back we may recall how computers gained

The Maxillofacial Surgeon and AI

Is AI a Friend or Foe?

To get to the bottom of this dilemma, let us ascertain what AI definitively is. Simply put, AI can be described as machines that exhibit human-like intelligence. It involves the use of “algorithms” that give machines the capacity to reason and perform functions such as word, speech, and object recognition, decision-making, and problem-

Image 2 Dr. James E. Garretson. <http://accessomfs.com/about> or <https://www.jstor.org/stable/44445732?seq=1>

popularity. Then came the era of early Internet followed by mobile phones that today have evolved into smart phones without which we can hardly imagine our day go by. The anticipated benefits and unanticipated risks associated with any new applied science will also exist in the case of AI. In the medical field, there would be additional concerns of ethical and medicolegal implications to be sorted out.

Ultimately the bottom line is that AI can be a friend if humans intelligently harness its potential. Awareness of possible pitfalls is essential to preventing AI from becoming our foe.

Simplifying AI for the Surgeon: Suggestions for Seamless Integration of AI and Surgery

Data is the starting point, and surgeons serve as the most essential “data providers” of this

cornerstone requisite. The surgeon is the point of contact with the patient. The surgeon’s training, knowledge of disease pathophysiology, pharmacology, complications, management, and expertise of surgical techniques are what should be developed into a data bank. This data will then serve as fodder to develop algorithms that are the building blocks of the AI chain. This would require for all practical purposes, a collaboration between surgeons and AI engineers.

The various subsets of AI include machine learning (ML), deep learning (DL), artificial neural networks (ANN), natural language processing (NLP), and computer vision to name a few.

Machine Learning and Deep Learning

The machine analyzes data sets and detects sequences and patterns to come up with predictions. While machine learning strings together

data into algorithms from which it learns and makes predictions, deep learning strings together several layers of algorithms into artificial neural networks which are capable of making informed decisions on their own.

Three broad processes by which machine learning occurs are the following:

- (A) Supervised Learning – Data that has been labeled by a human is filed into a machine learning algorithm. The aim is to teach the computer a function such as recognizing the fracture line in a maxillofacial skeletal radiograph or detecting a complication post-surgery based on multiple case sheet data.
- (B) Unsupervised Learning – The machine learning algorithm receives unlabeled data. The machine itself will then find a hidden pattern within the data, for example, identifying various tissues based on color or density – the bone, blood, mucosa, skin, etc.
- (C) Reinforcement Learning – An advanced form of ML similar to operant conditioning (which is a form of associative learning in which a desired behavior is established by modification via reinforcement of good and punishment of bad behavior). Here the machine itself learns from its mistakes and success. It is particularly useful in developing automated surgical systems.

Suggested Applications of ML and DL in Maxillofacial Surgery

- AI drug delivery bots in chronic stubborn maxillofacial infections such as osteomyelitis, osteoradionecrosis, and cancerum oris. The system would recognize patterns within the wound environment variables such as type of causative organism (gram positive/negative, species, aerobic/anaerobic) microbial counts, rate of neoangiogenesis, fibroblast count and collagen synthesis turnover, and leukocyte counts (factors which are indiscernible to the human eye). The machine can learn to establish patterns such as -at what level of microbial contamination what symptom is elicited and can predict surgical site infection. Furthermore, when many algorithms work together (ensemble ML), the machine can use these generated patterns to access medical literature

and arrive at the best medication and administer timely dose modifications based on real-time changes in the wound microenvironment, thus eliminating the time delay in traditional laboratory tests and solving the pressing universal issue of the increasing ill effects of antibiotic resistance.

- Self-adjusting distraction osteogenesis (DO) devices that would identify bone morphology and histology patterns and self-formulate the ideal Ilizarov principles to ensure surgical success. The AI system would enlist the optimal latency period, distraction rate and rhythm, and consolidation phase along with providing the surgeon the best osteotomy site and plan with minimal periosteal stripping for perfect callus and new bone in cases of hypoplastic jaws and hemifacial microsomia (Images 3 and 4).

These are just two probable applications presented. Several uses of machine learning in maxillofacial surgery are awaiting to be developed, and hopefully the above examples will have served as inspiration for the same.

Artificial Neural Networks

Probably the most interesting branch of AI, made of up several “processing elements (PEs). There is an input level/layer, middle multiple hidden levels/layers, and an output level/layer. Data is received at the input level. Calculations, summations, learning, and analysis of complex nonlinear relationships between dependent and independent data variables all occur in the many hidden layers. The hidden layers finally send the determined prediction for interpretation to the output layer [3, 4].

Therefore, the applications of ANN can be vast, and surgeons come into the picture as subject matter experts to provide a knowledge base to be fed into these algorithms that form the ANNs.

The potential reach of ANNs in maxillofacial surgery range from diagnosis and prognosis [5, 6], classifications and predictions [7–10], pattern recognition [11], controlled drug design and delivery systems [12], and much more.

Suggested Applications of ANNs in Maxillofacial Surgery

- In the early diagnosis of oral cancer lesions and early onset osteoarthritic changes in the temporomandibular joints. These are two areas where early diagnosis can save life and reduce tremendous burden of complicated surgeries if the disease is caught at an advanced stage. The quest for noninvasive and alternative diagnostic aids like salivary biomarkers has been on for oral cancer screening, but clinical trials can take years to translate to full-scale use. On the other hand, ANNs can be successfully trained to detect and predict clinical outcomes of node-positive oral cancer patients. This is possible by feeding the network with input information of past patients such as patients' habit history, age, tumor size, number of cervical lymph nodes, DNA index and S-phase determination by flow cytometry, clinical follow-up, relapse rate and time, etc. (Image 5).
- ANNs can be constructed based on standard radiographic images and histological specimens' data and then trained to distinguish benign from malignant lesions. Thus, the positive predictive value of biopsies can tremendously be enhanced.
- Development of ANNs to detect hemodynamic, thermal, physical changes in postoperative ICU patients and attached to alarm

Image 5 AI trained with CT images of TMJs showing osteoarthritic changes [41]

systems will be a revolution in critical postsurgical care.

- ANNs can herald an era of smart operating room monitoring of the Boyles apparatus and patient vitals intraoperatively.

Natural Language Processing

Training a computer to comprehend human language and furthermore infer meaning from vast and unstructured data such as case files, operative notes, and clinical findings. Gradually in time, the system is able to recognize complex sentences and thus enables surgeons to input their notes more naturally rather than being confined to specific drop-down menus or computer code words.

This automation can impact millions in positive ways through downloadable apps that can translate in several world languages.

Suggested Applications of NLP in Maxillofacial Surgery

- Interhospital communication using NLP systems to compare perioperative parameters, complications, and management protocols and arrive as standardized and optimized benchmarks.
- Virtual OT and ICU assistant and scribe can be a game changer. Surgeons can dictate notes that would be efficiently documented with

higher accuracy and retrievability. These notes would further enhance the system's ability to teach itself for future use. The NLP would then be able to comb through all the progress notes and operative reports to deduce predictions that would aid other patients.

Computer Vision

This subset refers to object recognition by systems that have learned to understand images and video data. Surgery unlike other specialties of medicine and diagnostics is heavily involved with dynamic and dexterous movement-based procedures. In surgery, AI has to analyze a dynamic environment data as opposed to static images. To be of effective use during an operation, AI must be able to deliver real-time solutions. This is where computer vision along with deep learning and other subsets of AI will be of particular significance. Though predictive video AI analytics is yet in very initial stages, it holds great potential. It is estimated that even a high-resolution computed tomographic (CT) image contains 25 times less data value than a mere 1-min high-definition surgical video clip.

Thus, one can imagine the tremendous use of computer vision if leveraged to process surgical videos and images to identify and predict adverse events in real time for intraoperative assistance [13].

What is being discussed here is not to be confused with the existing laparoscopic, minimally invasive, and image-guided robotic systems already in use like the TORS (transoral robotic surgery) for oncological resections and arthroscopic surgeries of the temporomandibular joint.

Suggested Applications of Computer Vision in Maxillofacial Surgery

- Computer vision based on deep learning to improve the ability of the system to reliably automate nuances of suturing actions (AI autonomous suturing) in an uncontrolled and live anatomical scenario. In time, the system understands from previous suturing videos and is able to decide upon an apt suture (simple continuous, vertical/horizontal mattress) for a particular surgical site and perform it accurately ensuring adequate tension, closure, and precision (Image 6).

Image 6 AI learned suturing by studying surgical videos. <https://thenextweb.com/neural/2020/06/23/how-an-ai-learned-to-stitch-up-patients-by-studying-surgical-videos/>

- Computer vision assessment and decision of third molar surgical extractions based on analysis of ramal/tuberosity/alveolar bone cover, bone texture, and inferior alveolar and lingual nerve proximity. Ability to integrate this information with deep learning to provide the surgeon with best access path and flap options and predict patient risks based on medical history analytics (Image 7).
- Facial esthetic procedures are poised to benefit the most with computer vision AI analytical tools. Orthognathic facial measurements and surgeries will become ultraprecise as the human eye is no compare with computer vision when it comes to minute millimeter assessments.
- Prediction of duration of surgery by analysis of previous surgeries will allow estimation of anesthetics and postsurgical care.
- Computer vision along with augmented reality is already in nascent stages and will soon be the norm in education and training of surgical students. Universities can provide the most

realistic simulation of the human body by means of full-body robotics and augmented reality projected images of the surgical field (Image 8).

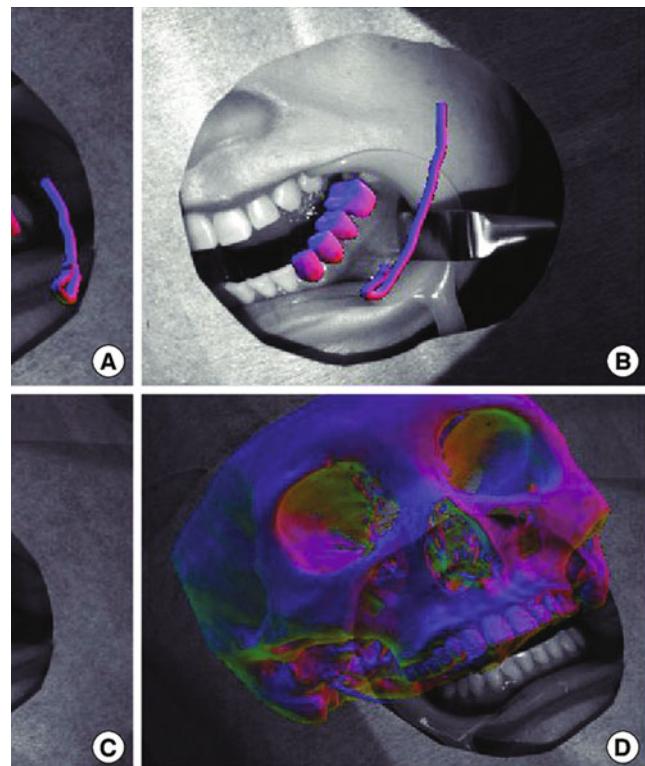

- Planning and performing mock surgery on the CT-derived AI-projected three-dimensional patient's maxillofacial region.

Surgeon Dilemmas on AI

1. Will AI take over my job?

360° Perspective – There have been strong opponents who have opined that AI would displace people from jobs and man is in a race with machine. These claims resonated with the public during periods of economic recession and meltdown. However, this argument fails to support the fact that AI like any other automation system is built to increase speed and accuracy and cannot mimic human multifaceted faculties and senses. An important point to note here is that AI is highly

Image 7 Augmented fusion of patient models for surgical field visualization (up, inferior alveolar nerve; down, maxillofacial skeleton). https://www.researchgate.net/publication/317211457_Virtual_Reality_and_Augmented_Reality_in_Plastic_Surgery_A_Review/figures or Adapted from Wang et al. Image 8 Augmented reality projected surgical site (maxilla in orthognathic surgery). https://www.researchgate.net/publication/317211457_Virtual_Reality_and_Augmented_Reality_in_Plastic_Surgery_A_Review/figures?lo=1

or Adapted from Mischkowski et al. J Craniomaxillofac Surg 2006;34:478–83 [21], with permission of Elsevier via Copyright Clearance Center

specific. It can be trained to perform one/few specific tasks, for example, determining whether a premalignant lesion is showing dysplasia or malignant transformation. Even if the AI performs this task better than the surgeon, the fact remains that a surgeon does much more than that. The surgeon communicated with the patient and co-workers, interprets the findings, and determines the type of biopsy, surgical access, armamentarium, type of surgery, medication combinations, postoperative care, and follow-up. One would require several different AI tools to be able to perform all these tens of tasks that a human workforce is capable of doing. AI could enhance accuracy of certain activities within an occupation but is highly unlikely to replace the entire occupation. Would a person experiencing persistent clicking sounds in his jaw use his smart phone to diagnose or head to his physician for an examination? The physician could then augment his clinical examination with an AI tool to improve the delivered care. Thus, AI will augment skill and expand output rather than replace workers. Therefore, the verdict from literature review, history, and plain logic is that any technology that enhances productivity leads to growth of a sector and not job cuts. Furthermore, feeling threatened by technology is not the way forward; instead helping people

understand and receive training in the new methods will give them a sense of empowerment instead of fear.

2. Will AI reduce my critical thinking, diagnostic skill, and clinical expertise?

360° Perspective – On the contrary, AI will help you make smarter decisions, heighten your diagnostic ability, and lead to evolved clinical skill set. Think of it as something that complements your surgical expertise and supports you rather than a competitor. For example, humans may have forgotten how to read paper maps with the advent of GPS-guided navigation systems, but their skill set has evolved to include Internet usage and computer navigation. Thus, AI is only reaffirming the fact that change is the only constant. It is a matter of perspective. AI will reduce laborious repetitive tasks and provide the surgeon with time to spare on tasks requiring innovation, thought, and insight. In high patient load hospitals and limited resource facilities where the patient-to-surgeon ratio is high, AI will prove highly beneficial, as it would finish mundane tasks, thus enabling the surgeon to have more time to concentrate on roles like direct patient consultations, clinical examinations, and higher cognitive activities. Remote areas and small town hospitals where access to specialist care is unavailable can leverage AI decision

systems. AI tools if smart can be used by smarter humans to learn from and improve competence.

3. *But AI could be prone to errors, isn't that a disaster?*

360° Perspective – Who/what is error-free? While on the topic of errors, one can't help but recall the famous adage "To err is Human." An automated system eliminates human errors. Machines do not tire and can perform repetitive tasks infinitely without being prone to negligence. While speculative possibility of errors in AI decision-making does exist, the point remains that on an average the errors computational machinery can make would be less than a human.

4. *We are in for trouble as AI is a technology that makes computers like human brains.*

360° Perspective – That is a notion propagated by fantasy sci-fi movies. In reality, AI only takes inspiration in naming its functional units after structural components of the human nervous system. There is no physiological resemblance, and it would be a mythical distant dream to conjure images of human-like computers. Existing scientific literature is not in favor of imagining machines that mimic the complex functioning, interconnectivity, and biofeedback loops between human neurons. Furthermore, AI is not a technology rather a methodology. AI uses mathematical methods and algorithms to analyze data and adjust parameters via learning rules.

Role of Surgeons in Enabling AI-Assisted Maxillofacial Surgeries

It is high time surgeons assume a role of leadership and step up from being mere spectators of this science to being key drivers of an AI integrated surgical era. The key element is the strategic working advantage that a surgeon holds, being the point of contact with patients. This is a two-way mantle: (A) serving as data input sources to train AI systems and (B) serving as surgical AI conveyors to the patients.

Initial steps include

- (A) Getting acquainted with the basics of AI.
- (B) A crucial move which would require involvement of hospital administrations and novel hospital management policies to develop new departments within hospitals such as medical data analytics and health informatics/healthcare technology. This integrating and partnering with data scientists and engineers is essential to make AI surgical systems of real value. Considering the routine of a surgeon who is almost always scrubbed in an OT uniform and rotates between ward rounds, clinics, ICU, and operating rooms, it would be impractical to imagine surgeons heading to meet AI engineers outside the workspace and vice-versa. It would therefore be advisable to have all concerned professionals work under the same roof. Only then can inter-specialty understanding and knowledge cross-flow develop. Surgeons can impart their knowledge on complex anatomy, etiopathogenesis, pharmacology, disease clinical course, and surgical techniques to the AI engineering team while understanding the development needs of the technology team. This would be the fastest way to bring AI to the forefront of maxillofacial surgery.
- (C) A collaborative effort on the part of surgeons is required to form a surgical pool similar to biobanks and genomics. This could facilitate big data analysts to formulate a real-time, intraoperative navigation system something like a surgical GPS [14].
- (D) Triad for AI-assisted surgeries – Three main contributions of a surgeon toward development of AI-powered ORs/OTs:
 1. Provide access to comprehensive data – The operating room is equipped with multiple data devices right from diagnostic radiographs; the Boyle's apparatus; the ECG and vital statistics monitoring device; the cardiac monitor/electrocautery unit; the pulse oximeter; the blood pressure, blood glucose, and body temperature recording devices; the suction irrigation; the operating light; the ultrasound; and many more devices. All these devices are constantly recording patient data and can

- serve as sources of input data or sensors of data. It is up to the surgeon to acclimatize the AI team and aid in feeding all the sensor data into the AI system so as to develop a real-time context-aware AI tool.
2. Explain or interpret the surgical data for the AI system to learn and improve its performance. The raw initial data needs constant annotation by surgeons. These annotations can be in the form of classifying data (e.g., which type of tissue is visible in the images, blood, bone, fascia, soft vs hard tissue, skin vs fascia, blood vessels by diameter, nerves vs blood vessels, etc.), semantic segmentation (e.g., linking pixel resolution to organs in an image), and linear numeric regression (e.g., defining objects by size) [15]. Data annotation does throw up challenges to the surgical and AI teams. These would be dealt with in the next segment (i.e., “challenges in the path”).
 3. Work in tandem with the machine learning systems – As the AI system begins to understand the data, it shifts into deep learning. This means the surgeon supervises the learning so that the system can now retain and apply information used to perform a former task (e.g., identifying a bleeder in the surgical site) to execute a succeeding related task (e.g., forewarning of risk and target structures via tissue navigation to prevent bleeders).

Challenges in the Path

1. *Annotation Challenges* – As discussed in the previous section, the AI system requires constant annotations from the surgeon:

- Time constraint is the foremost challenge as surgeons often have packed work schedules that demand their full attention.
- Furthermore, the surgical data is vast, and annotation demands expert knowledge, thus making it an expensive and time-consuming activity.

- A greater challenge of patient confidentiality and privacy arises as data from across many hospitals will be required to provide sufficient information to be representative of the task to be learned by the AI system.
- Moreover, there is absence of any standardized data acquisition and annotation policies as of now and minimal data in digital formats.

Suggestions for Overcoming This Challenge

- Active Learning: Annotation with selectively significant data points from among vast data sets [16].
 - Crowdsourcing: A method of problem-solving wherein a task is delegated to a team of individuals rather than a single or few people. The large team may contain relative novices, but their lack of experience is compensated by the distributed wisdom of the group members. Thereby, this approach is advantageous in terms of flexibility, efficiency, and scalability. Crowdsourcing has successfully been applied in healthcare in the diagnosis of colonic and polyps and identification of malaria-infected red blood cells and holds promise in the field of maxillofacial surgery too [17].
 - Ontologies: Help maintain consistency in the vocabulary used by surgeons for annotation, making it easily readable by the AI system.
2. *Policy Challenges* – Regulation and reimbursement schemes will determine the on-the-ground AI access and availability.

Suggestions for Overcoming This Challenge

There is not much a surgeon can directly do in this direction. However, policy-makers will definitely count the surgeon’s inputs as priority for formulating guidelines. Therefore, maintaining detailed standard operating procedure flow charts and notes on advantages of AI in surgery which are backed by evidence will prove beneficial.

3. Algorithm Complexity and Bias Challenges – AI will remain a novel subject to medical experts for a while. Implementation of AI systems will not be under the direct jurisdiction of medical personnel. Nor is the doctor/surgeon's primary duty to know the nuances and functioning of the AI system. Therefore, there exists the possibility of corporate or other authorities in power to camouflage wrong intents like discrimination by misuse of the complexity of the AI algorithmic functioning. An example of this scenario was a claim made against the auto company Uber by Tim Hwang and Madeleine Clare Elish of non-profit organization Data & Society. The allegation is that Uber uses surge pricing algorithms as pretense and commits unfair pricing by depicting a fake appearance of demand to the end user [18].

Suggestions for Overcoming This Challenge

- Appoint a board or committee of people from different specialties so as to avoid vested interests and abuse of possible algorithmic bias.
- Be informed of the basic principles of AI so as to be vigilant against malpractice.
- Ensure strict legal blueprint and government laws to root out unethical leverage of AI for malicious profit.

Literature Speaks: An Overview of Current Applications with Potential for Harnessing AI in Maxillofacial Surgery

Maxillofacial Presurgical Imaging

Current

- AI is being used both in image acquisition and interpretation to enhance diagnostic, prognostic, and risk analysis in surgery. Digital radiography has already taken over conventional methods, and incorporation of AI into intraoral scanning devices has brought about an added and much needed direct advantage apart from AI data acquisition – that of reduced patient

radiation exposure. AI ensures high-resolution images with lower radiation doses by optimizing signal-to-noise ratio [19].

- Quantification of tumor phenotype and decision-making support with the aid of “radiomics,” a method of AI that can analyze vast amounts of radiographic images to then extract relevant quantitative features from them [20].

Potential

- Deep learning techniques can be employed to learn from a standard hierarchical representation of a specific image from several repeated regular examinations to then differentiate normal and abnormal radiographic findings.
- Convolutional neural networks along with deep learning have the potential to identify disease characteristic features from radiographic images to predict nature of lesion/disease entity.

Orthognathic Surgery

Current

- Automated lateral cephalometric analysis with integrated AI and machine learning. One might misunderstand this application as mere laziness on the part of the surgeon. However, the AI cephalometrics is beyond 2D analytics. A true biometric facial analysis of a 3D cone beam radiograph (CBCT) requires 100–200 craniometric points. AI has unmatchable ability to analyze so many parameters simultaneously and accurately [21, 22].
- Dynamic virtual setup software such as Cin Check and Insignia [23] are powered by machine learning and effectively replace the tedious tasks of plaster model mock surgery and lateral cephalometric analysis. They further enhance orthodontic-surgical team communication, patient education, and treatment planning by means of visual imagery of each treatment objective and outcome possibilities.

Potential

- To extend machine learning employed in cephalometric analysis software to the treatment of sleep apnea by the use of AI-based 3D

reconstruction and superimposition of multiple diagnostic modalities such as patient's intraoral images, digital photographs, and CBCTs.

- Development of ambitious AI systems with the integration of 3D CBCT images, planned digital mock surgery osteotomy cuts and robotic arms to make intraoperative precise osteotomies and check dynamic patient occlusion on the table, and thereby highly superior facial recontouring with minimal hospitalization and recovery time.

Implant Surgery

Current

- A pilot study of a robotic arm placing a zygomatic implant in a phantom skull showed higher accuracy than conventional surgical placement. The authors wish to augment their findings in the future by addition of tactile sensors and other AI tools [24].

Potential

- Bone mineral density and osteoporosis can be diagnosed by AI, and this is clinically relevant to implant surgeries. Panoramic radiographs have been used by AI models to distinguish between osteoporotic and healthy subjects. The AI algorithm can evaluate alveolar bone cortical width and erosion of the cortex to distinguish between osteoporotic and healthy subjects with 95% accuracy, sensitivity, and specificity. These initial studies have been in favor of application of such AI models into routine surgical planning in the time to come [25].

Temporomandibular Joint (TMJ) Surgery

Current

- Japanese researchers have developed a chewing robotic skull that functions with wires and motors. It employs artificial muscle

actuators (AMAs) to simulate dynamic masticatory muscle activity and chewing. However, this is a generalized system more applicable for training and research on TMJ surgeries and will be difficult to build to replicate every individual patient [26]. However, this certainly can form a basis for future research into musculoskeletal disorders by making customized robotic skulls of individual patients with measurements from their CT scans and facial photographs/impressions of the head and neck region. This can be particularly useful for management of conditions such as Myofascial Pain Dysfunction Syndrome (MPDS), trigger point muscle pains, correction of abnormal jaw movements induced by muscle laxity or hypo/hyper activity. These conditions are often challenging to diagnose because of their multifactorial etiology, association with dental occlusion and inter-relation with TMJ functioning in the head and neck region.

- Internal derangements of the TMJs have been enigmatic and complex dilemmas due to several interrelated factors like occlusion, visualization of intra-articular space, interrelationship of both the TMJs (right and left), etc. Clinicians have had to rely on external clinical evaluation modes, thus making it difficult to arrive at a definitive diagnosis and optimal treatment. Turkish researchers have used data such as patient clinical symptoms and subsequent diagnosis of TMJ internal derangements to train artificial neural networks. The results have been promising with improved diagnostic efficacy [27].

Potential

- The surgical anatomy and approach to the TMJ is tricky owing to the proximity to significant anatomic structures like the parotid gland, the facial nerve, and branches of the external carotid artery. Therefore, residents and novice surgeons find it challenging to perform surgery in this region. AI and deep learning tools can come to the rescue of surgeons as navigation, facial plane recognition, and nerve sensor devices.

- Total alloplastic joint replacements are an emerging option in TMJ ankylosis management. AI can be leveraged in the precise fabrication and placement of these joints to improve outcomes especially related to range of movement of the alloplastic joint which currently is limited to only rotational movement.

Oncosurgery and Reconstruction

Current

- IBM Watson is an AI-based cognitive system that leverages natural language processing and dynamic learning to offer clinicians' evidence-based treatment options after analyzing patient reports. IBM Watson for oncology has been trained by experts at Memorial Sloan Kettering Cancer Institute and is currently in use in hospitals around the globe.
- Reconstruction of jawbones after oncosurgical resection is challenging keeping in mind esthetics and functionality of the head and neck region. Determining normal predisease jaw morphology after radical tumor surgery has been attempted with promising results by CTGAN a deep convolutional generative adversarial network (DCGAN) [28].

Potential

- It is a known fact that oncological surgeries are extensive time-taking procedures requiring patients to be under general anesthesia for several hours. AI systems for effective intraoperative management of patient vitals like blood pressure will provide immense relief to the surgical-anesthetic teams as seen in early-stage randomized controlled trials [29].
- Intelligent surgeon's scalpel/knife that integrated rapid analysis by AI systems to distinguish between tumor margins, healthy tissue, borderline, and malignant tissue will greatly improve the quality of oncosurgery. The amount of tissue removal will be optimized, intraoperative frozen section and time delay can be minimized, and superior closure and reconstruction can be achieved.

Trauma Surgery

Current

- Machine learning algorithms have predicted the postsurgical short-term outcomes of open reduction internal fixation (ORIF) in ankle fracture fixation surgeries [30].

Potential

- The incidence of occult fractures in maxillofacial traumatic injuries is high and a matter of concern to treating surgeons. Missed fractures and associated fractures that are difficult to detect on conventional radiographs often haunt the clinician. Machine learning systems can be beneficial in detection and isolation of occult fractures [31].
- AI deep learning guided selection of the most suitable internal fixation from among various hardware options for a given facial trauma and personalized to each patient by analysis of patient radiographs, age, and medical history, correlated to medical literature, for example, the type of plate to be used, the number of screws, plate versus lag screw, and one-point versus two-/three-point fixation. This predictive intelligence will prevent complications like malunion and asymmetry due to inadequate or overzealous fixation.
- AI computer vision is particularly helpful in panfacial trauma (multiple facial fractures) and ballistic (high-energy avulsive trauma, blast-induced) facial injuries. The challenge of sequencing in panfacial trauma and diagnosis of occult trauma and extent of tissue (soft and hard) loss can be greatly enhanced with computer vision navigation surgical systems.
- Comprehensive orbital and ocular trauma AI tool would be of great help in synchronizing patient care between ophthalmological and maxillofacial teams, thereby enabling swift care. Orbital fractures usually occur in conjunction with naso-ethmoidal and/or zygomatico-maxillary complex. Furthermore, thorough ophthalmological evaluation in terms of visual acuity, visual fields, fundoscopic examination, papillary responses, and ocular motility is

necessary prior to surgical reduction of these fractures. An AI tool can be trained to accurately perform optic tests and be of great help to novice surgeons or trauma teams with limited access to ophthalmic devices.

Impacted Teeth and Minor Oral Surgery

Current

- Disimpaction surgeries are the most common procedure performed by maxillofacial surgeons. Injury to critical anatomic structures like the inferior alveolar nerve during impacted wisdom teeth removal has been a long-standing and highly studied aspect. Other minor oral surgeries like alveo-loplasties, tori removal, salivary mucocele excisions, etc. could also be improved with novel visualization and guided surgical systems. An augmented reality tool was developed and tested to visualize the inferior alveolar nerve (IAN) bundle through the mandibular bone by the use of a fiducial marker on an occlusal splint. A virtual image of the surgical site is created by 3D software analysis of patient's CT images.

An integrated image is then achieved by superimposition of the virtual image on the real surgical environment via the occlusal splint-fiducial marker assembly. The results were promising in enabling protection to the IAN and superior surgical outcomes [32].

- Prediction of postoperative facial swelling and edema which psychologically and physically affect a patient's recovery after minor oral surgery by artificial neural networks [33] has been far superior to traditional methods of prediction.

Potential

- Deep learning solutions to a commonly encountered challenge of management of medically compromised patients in oral surgery. The use of AI to evaluate relevant and current literature on precautions and protocols for management of patients on anticoagulants, antihypertensives, thyroid medication, and

other pharmacological agents will be highly assistive to maxillofacial surgery.

Miscellaneous

Facial Paralysis Gradation – Facial nerve paralysis due to trauma, infection, iatrogenic causes, and complications of surgery in parotid/TMJ regions resulting in unilateral facial palsy-/Bell's palsy-like condition. Management of such cases hinges on effective grading of the extent of neuronal injury. Currently there exists no objective dependable classification of facial nerve paralysis. The use of video footage of patients performing assigned facial movements to test nerve function can serve as data for artificial neural networks to effectively ascertain the degree/grade of facial nerve paralysis [34].

Pain Control – Maxillofacial surgery is particularly a bridge specialty of dental and medical fields, and its procedures routinely involve both local and general anesthesia and conscious sedation and ambulatory anesthesia. AI for optimal anesthesia delivery by automating drug delivery based on machine learning predictions of drug pharmacokinetics within the body has been reported. Neural networks have been used to predict recovery rates from anesthesia. Machine learning techniques are being tested to monitor conscious sedation and alert about levels of respiratory depression and automate classification of patients' preoperative ASA (acuity) status [35].

Watch List for Future Forward Maxillofacial Surgeons

Surgical Data Science

Large amount of annotated data for training the AI system is required. This has led to the emergence of a unique field of surgical data science. This involves the use of AI tools to capture, organize, and analyze which in turn will fuel the AI system to provide AI-enhanced operative room experience. Such AI systems would improve the quality

of surgical care by providing real-time decision support, context-aware assistance, and cognitive robotics [36].

Surgical Scene Analytics

Recent studies were focused on AI analysis of surgical tools to enable automated surgical (robotic) instrument usage. However, the future will see expansion of this methodology into entire surgical scene analytics. This could translate into anything from a virtual second assistant to a live intraoperative prediction device [37].

Surgical Control Tower (SCT)

Artificial intelligence developed by studying human detection poses estimation and surgical procedure monitoring via wall-/ceiling-mounted camera image data. The SCT will serve as centralized control for all round assistance to the surgical team. The ongoing OR status can be analyzed to provide smart decisions and automation of tasks and reduce errors in complex situations. The SCT can also serve as a video reservoir of data for training and evaluation [38].

Conclusion

The evolution of maxillofacial surgery has been shaped by time from the first accounts of mandibular fracture managements in the 2700 BC Egyptian *Edwin Smith Papyrus* [39] to the state-of-the-art “Fibula Jaw in a Day” maxillofacial reconstructions [40]. Fortunately the fraternity that emerged from medicine and merged with dentistry into a unique bridging specialty has been constantly upgrading and adapting to enhance practice. Training paradigms are now shifting from conventional modalities, and the most dominant influence has been that of technology. The scope of AI in maxillofacial surgery is poised to witness practical applications in every aspect of the field – right from AI-powered automation of dental extractions and robotic AI-enhanced surgical instrumentation to

machine learning-enabled decision support in diagnosis of enigmatic and challenging medical conditions such as genetic syndromes of the head and neck. The applications are infinite, and this chapter has delved into the current literature and guidelines for future potentials of AI integrated maxillofacial surgery.

Abstract

The steep rise of digital dentistry and technological advancements have opened doors for the development of artificial intelligence (AI). For the past few years, AI-based applications in dentistry have been constantly evolving as highlighted by the increasing number of studies, and now it is slowly entering the clinical arena. As healthcare professionals, dentists need to diagnose, plan, and make clinical decisions in order to provide an adequate treatment and care for their patients. All these phases are time-consuming, observer-dependent, and subjected to human error. Currently, the studies applying AI in many dental specialties have validated its application for the purpose of diagnosis and clinical decision-making. Thus, the objective of AI is to combine the professional expertise with the computer-assisted systems to automatize complex tasks, mimic

human cognitive skills, and retrieve information from digital data. Dental AI applications can be advantageous for all dental specialties including dentomaxillofacial radiology, restorative dentistry, oral and maxillofacial surgery, orthodontics, periodontics, prosthodontics, endodontics, and forensic dentistry.

Even though most researches and developments are still in an early phase, current results in the dental field are encouraging for future clinical applications.

This chapter provides an overview of the current state of the art of the AI applications in dentistry and its specialties.

Keywords

Digital dentistry · Presurgical planning · Cone-beam computed tomography · Intraoral scanner · Panoramic radiography · Radiological diagnosis · Tooth · Jaw · Face

Introduction

The daily routine tasks of a dentist involve gathering patient information, diagnostics, and planning and performing clinical treatment procedures. At the first visit to a dental office, the dentist needs to collect and annotate many pieces of information in a detailed manner. Afterward, the clinician initiates the diagnostic phase, combining clinical and imaging data, to arrange all information in a dental chart. All these tasks are time-consuming and completely dependent on the professional's attention to possible minor details. Furthermore, full integration of these multiple sources of information and data is crucial. Only after careful collection and integration of all information and diagnostic data, the dentist will be able to start further clinical treatment procedures.

During the past decade, technological advancements have already provided some solutions such as electronic medical and dental records, software applications to plan oral rehabilitation, and augmented reality to visualize the outcomes of the planned treatment. However, these solutions still depend on human intervention

and demand a lot of time. In this context, it would be important to develop more efficient software to allow reliable and automated actions for aiding the dentists in their assessments, treatment planning, and decision-making strategies. This is where artificial intelligence (AI) can jump in to facilitate digitalization and automation.

AI is rapidly evolving in dentistry with the number of studies and applications drastically increasing worldwide during the past few years. The storage of data and information in dentistry has always been a part of the daily clinical routine, as dentists are often collecting imaging data accompanied by general and dental history, systemic conditions, and medications in their patient's records. Nowadays, it has become much easier with digital data storage. This makes dentistry a suitable field for the implementation of new technologies such as AI and its subclasses, machine learning (ML) and deep learning (DL). The aid of technology may play a substantial role in terms of assessment, diagnosis, planning, clinical decision-making, and outcome prediction, consequently improving prognosis as well. Some studies indicate that the AI-based systems are able to surpass even the performance of dental specialists [1, 2].

In dentistry, facial and dental aesthetics are of a major concern. With the improvement of dental materials and techniques, patient's expectations in relation to the outcomes of the treatment have drastically increased. Therefore, accurate diagnosis and treatment planning are essential when dealing with tissues and anatomical structures that have an impact on people's appearance and also to provide personalized healthcare taking into account the patient's unique characteristics.

Thus, we must comprehend that AI is an advancing science that does not intend to replace dental specialists but to act as a powerful ally for attaining a better, faster, and more accurate assessment and diagnosis of the cases with the empathy and care given by the dentists. Finally, it intends to provide better outcomes for patients at lower costs. This combination of technology and dental practitioner is called augmented intelligence [2, 3].

The aim of this chapter is to give the reader an overview of the state-of-the-art AI applications in

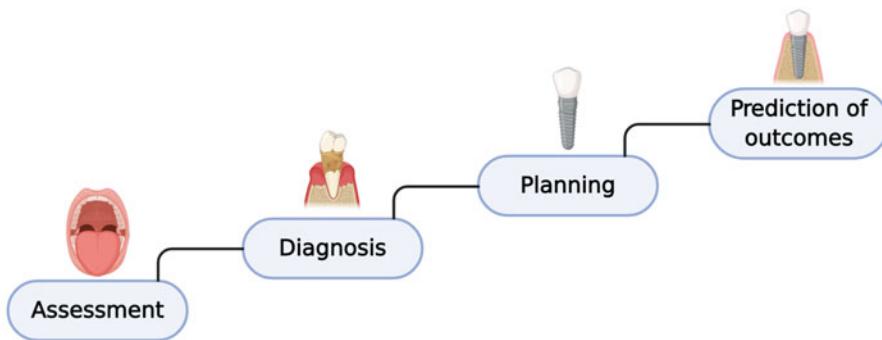

Fig. 1 Steps of the dental treatment where AI can aid dental specialists

dentistry, following a progressive timeline of dental treatments, in terms of assessment, diagnosis, planning, and prediction of outcomes in dentistry (Fig. 1).

AI for Assessment in Dentistry

Currently, one of the fields that has gained most attention for the use of computer systems aiming at improving tasks performed in dentistry is oral radiology. As the computer systems are able to extract and quantify features which the human eye cannot detect, thereby turning radiology into an objective science. In this context, AI and its subclasses have been excellent tools for serving radiologists to analyze the amount of information contained in different types of images. DL has been applied for many purposes such as optimization of images with low radiation dose and less scattering or artifacts, classification, image registration, segmentation, lesion detection, image retrieval, and image-guided therapy. It can also be applied for correcting technical positioning errors on panoramic radiographs and developing patient-specific imaging protocols [3].

Imaging-based data are also ideal for further development of AI-based applications, mainly for treatment, surgical planning, and follow-up. One of the first steps in order to train an automated tool is the segmentation of anatomical structures. This is usually a manual, time-consuming, and operator-dependent task, which is subjected to human error. Automation of this work may

improve diagnosis and treatment planning, virtual surgery planning, radiation therapy planning, and radiomics analysis [4, 5].

AI has been used for identification of teeth using different radiological imaging modalities. A variety of studies reported on the use of automated systems to effectively recognize and label teeth on periapical, bite-wing, panoramic, and cone-beam computed tomography (CBCT), and they achieved results comparable to those obtained by specialists [6–9]. Zhang et al [6], and Chen et al [7], applied DL algorithms for recognizing and labeling teeth position on intraoral radiographs and achieved high levels of precision. The former had 95.8% and the latter exceeded 90% precision. Tuzoff et al [8], also applied DL for teeth detection and numbering on panoramic radiographs and achieved a sensitivity of 0.99 and precision of 0.99 for detection and a sensitivity of 0.98 and specificity of 0.99 for numbering. Leite et al [9], used an AI-driven tool for tooth detection and segmentation on panoramic radiographs, and the system achieved 98.9% sensitivity and 99.6% precision for tooth detection. They also highlighted that the method was significantly faster, consuming 67% less than the time needed for manual processing. A panoramic radiograph is commonly requested for case evaluations because of the general overview provided. An example of an AI-driven tool for tooth detection and segmentation is presented in Fig. 2. Similarly, the application of AI for tooth recognition and segmentations has also been explored three-dimensionally using CT and CBCT devices

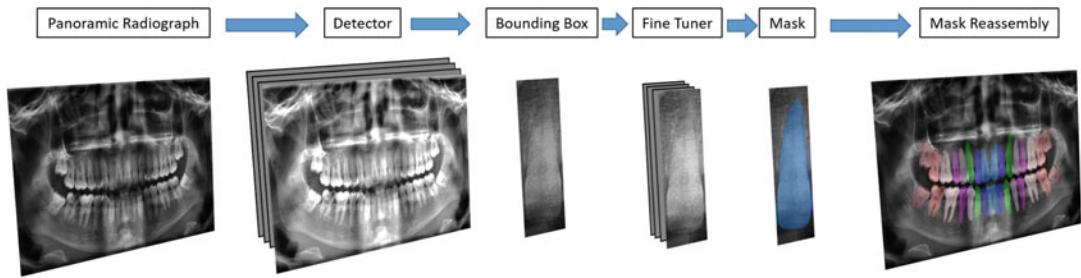

Fig. 2 Workflow of an AI-driven tool for tooth detection and segmentation [4]

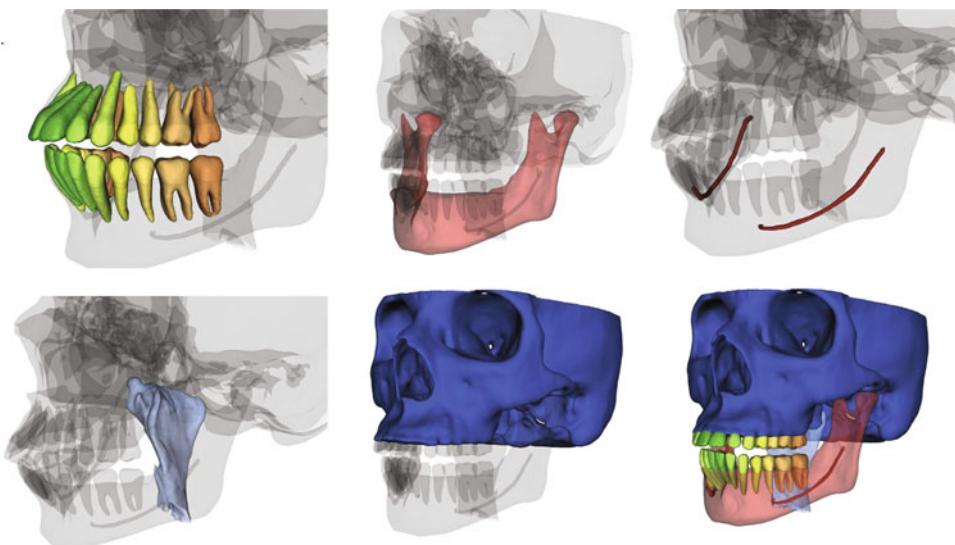

Fig. 3 Dentomaxillofacial structures automatically identified and labeled on a CBCT image (Relu BV, Leuven, Belgium)

[10–12]. Figure 3 illustrates an example of AI-based segmentation of dentomaxillofacial structures. All these results suggest that AI could be efficiently applied to recognize and label teeth on dental charts in a time-saving manner.

In the field of implant dentistry, the AI-based identification of dental implants may be another important task as they have been the treatment of choice for oral rehabilitation for more than 30 years. Since then, many different brands and systems have been developed. With the growing number of implants being inserted globally, the reports of complications have also increased. In order to solve a problem with a dental fixture, it is necessary to recognize the implant manufacturer and its prosthetic connection system. In some cases, the identification of implant is difficult

because the information may be lacking in the dental records or the patient is attending another professional that does not know the implant by its characteristics. Therefore, AI may be a useful tool to identify dental implants from radiographic exam [13–15]. Takahashi et al [13] applied DL in a pilot study to identify implants among six different systems manufactured by three companies. The results suggested that dental implants can be identified from panoramic radiographs. Hadj Saïd et al. [14] also applied DL to identify six types of implants from three manufacturers and achieved almost 94% diagnostic accuracy. Lee and Jeong [15] applied DL to recognize three similar conical dental implants from panoramic and periapical radiographs and compared the results with the performance of a periodontist.

Results showed that DL achieved an area under the curve (AUC) of 0.97 (95% CI, 0.96–0.98), while the professional values were 0.92 (95% CI, 0.91–0.93). The sensitivity and specificity were 95% and 97%, respectively, for the former and 88% and 87% for the latter. Even though the results of both studies were encouraging, they either relied on a small dataset or needed a data augmentation procedure. Therefore, if we need to apply these types of AI tools in a routine clinical practice, then their performance should be validated with all implant systems using multiple 2D and 3D imaging modalities and scanning parameters.

In relation to the implant placement in the lower jaw, a surgeon must be aware of the mandibular canal (MC) localization for determining the implant dimensions without damaging the nerve. The identification and segmentation of MC are normally carried out manually by the radiologists on 3D CBCT images. Jaskari et al [4] demonstrated that the use of DL to segment MCs significantly reduced the radiologists' time consumption for the task compared to manual delineation. Results in terms of accuracy were within 0.5 mm for about 90% of MCs. Toward the future, such AI-driven neurovascular canal detection and segmentation need to be trained with more anatomical variabilities and images derived from different CBCT units.

One of the most common conditions encountered in a routine dental practice is the impacted third molar, and the dentists are required to predict

whether the tooth will erupt in the oral cavity normally or would require extraction. The two important factors for predicting the potential eruption of these teeth are their angulation and the space between the distal side of the second molar and the anterior border of the ramus. These measurements can be performed on a panoramic radiograph by a radiologist. However, like every other task mentioned before, it is a tedious and time-consuming task. Vranckx et al [16] applied an AI-based algorithm for automatically segmenting and determining the angulation of the lower molars on panoramic radiographs. They measured the performance of the AI tool and the time required for the task versus an expert. Their results indicated that the AI tool had a good performance (Intersection over Union, 0.88) for segmentation and angulation calculation. Additionally, it was found to be twice as fast as the manual measurements. An example of the automated segmentation and angulation measurement of the lower molars on a panoramic radiograph is shown in Fig. 4.

When it comes to orthodontic treatment, lateral cephalometric analysis is routinely performed, and it consists of the identification of skeletal and soft tissue landmarks with the objective to assess various angles, distances, and ratios and to plan and predict the treatment outcomes. The tracing of these landmarks is a tedious activity, and manual identification still remains the gold standard. This task is observer-dependent and

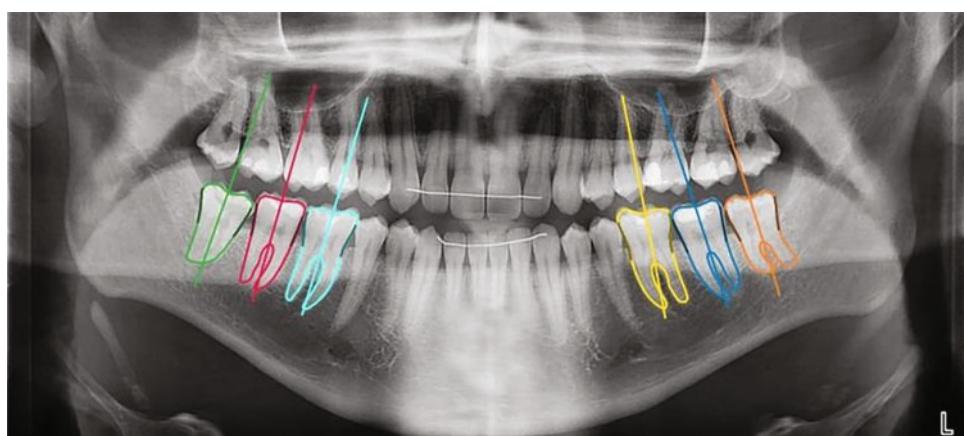

Fig. 4 Automated tooth angulation measurement on a panoramic radiograph [4]

varies depending on the experience level of an orthodontist. Inaccurate identification of the landmarks may lead to inappropriate decision-making for orthodontic therapy. It has been demonstrated that AI and DL algorithms have the potential to recognize anatomical landmarks and automatically detect the skeletal classification on cephalometric radiographs accurately [17–20]. During assessment of an orthodontic case, it is also crucial to determine the chronological age and to estimate the skeletal maturation of the patient. Both these factors are important for evaluating the remaining growth and development potential which can influence the orthodontic plan. Some studies have investigated the use of AI to perform these tasks [21]. All the aforementioned tasks such as radiographic analysis and identifying anatomical landmarks are time-consuming tasks for both clinicians and radiologists. Thus, the automation of these tasks would aid clinicians, as no manual intervention would be required when filling dental charts or elaborating radiographic reports.

In periodontology, periodontitis is one of the most commonly observed diseases in the oral cavity which can lead to alveolar bone loss and edentulism. This in turn can influence the patient's quality of life and impose higher healthcare costs, thereby requiring an early and accurate diagnosis. Evidence suggests only a few studies applying AI for the diagnosis of periodontal diseases. Krois et al. [22] and Kim et al. [23] proposed a convolutional neural network (CNN)-based network for detecting periodontal bone loss on panoramic radiographs. Both studies showed variable findings, where Krois et al [22] found higher accuracy in favor of the CNN (0.67) compared to the examiners (0.76) without any significant difference, whereas Kim et al. [23] suggested higher accuracy with CNN (0.75), and the average score of the dental clinicians was found to be 0.69. In another study, Lee et al. [24] developed a CNN algorithm for diagnosing and predicting bone loss on periapical radiographic images. They found the network to be as effective as an experienced periodontist. Recently, in another study,

Chang [25] et al. applied CNN for diagnosing as well as staging periodontitis based on panoramic radiographs. They demonstrated a high accuracy and stronger correlation between the CNN and an experienced radiologist compared to inexperienced ones, thereby confirming its effectiveness and reliability. As the 2D radiographs offer different levels of magnification and distortion, hence, there is a need to optimize the images further for training the CNN algorithms before employing these systems in a daily practice.

In endodontics, localization of the apical foramen is essential for determining the working length (WL) of the pulp canals accurately. Thereby, an inaccurate WL might either lead to an incomplete removal of the pulp or invasion of the periapical tissues. Saghiri et al [26]. conducted an ex vivo study and applied artificial neural network (ANN) for evaluating the position of a file tip in relation to the minor apical foramen and determining the WL on radiographs. They compared the AI performance with professional assessment and found that the AI-based network correctly determined the WL in 96% of the cases compared to the 76% achieved by the endodontists. Based on these findings, AI proved to be an excellent adjunct tool to locate the apical foramen and determine the WL.

A relatively new field where AI can play an important role is forensic dentistry. Sometimes, identifying victims of great disasters, such as plane crashes, is only possible with the analysis of the dental remains, and a forensicist has to spend a huge amount of time to identify and analyze the data. Similarly, another common task in forensic dentistry is the estimation of adolescent or young adult age by evaluation of the third molar development stage; however, this assessment is susceptible to human error and observer variability. The automated identification of the dental remains, the estimation of the third molar stage, and the identification of morphometric parameters based on panoramic radiographs may help to distinguish a person's identity, age, and gender. Some AI-based early phase studies have been carried out in the aforementioned areas,

thereby confirming that in near future, AI might be considered useful in the resolution of disasters and age estimation [27, 28].

AI for Diagnosis in Dentistry

The most beneficial impact observed with AI in the dental diagnostics has been the improvement in detecting lesions which might get misdiagnosed or overlooked by radiologists or clinicians on dental radiographs, such as caries, apical lesions, Sjögren's syndrome, sinusitis, extranodal extension of cervical lymph node metastases, and osteoporosis [3].

Dental caries is a common chronic infectious disease affecting many people around the world. Although the restoration methods to save teeth have significantly improved over the past few years, the same has not happened with the diagnostic methods. If a tooth cavity is detected at an early stage, the resolution prognosis is more optimistic. However, in the presence of deep fissures, tight interproximal contacts, and secondary lesions under restorations, the detection may be difficult. Even though dental radiography and the use of a dental probe could be considered as excellent tools for detecting dental caries, nevertheless, the final diagnosis tends to be based on empirical evidence. AI-based methods have been applied to detect dental caries, which may represent a vital shift to an objective way for diagnosing this type of lesion. Devito et al [29]. applied an AI model to detect proximal caries on bite-wing radiographs. The results suggested that AI was able to increase the diagnostic accuracy by 39.4% when compared with the mean of the examiners. Lee et al [30]. also applied a DL-based CNN to detect dental caries on periapical radiographs, and the algorithm achieved a mean AUC of 0.89. These results show how beneficial the use of AI can be for detecting one of the most common lesions seen by a dentist. Furthermore, allowing a change in the subjective diagnostic perspective which is completely dependent on the professional's experience to an objective one.

The correct diagnosis of crack or root fracture is crucial for making an accurate treatment strategy which may either involve tooth extraction or a more conservative approach. This task is difficult even on CBCT images where the fracture might not be visible to a naked eye, resulting in misdiagnosis and an inaccurate treatment approach. Some studies investigated the application of AI to detect root fractures effectively [31, 32]. Johari et al [31]. applied a probabilistic neural network to detect vertical root fractures (VRFs) on intact and endodontically treated teeth using periapical and CBCT radiographs. The results showed a high accuracy of 96.6%, and the authors concluded that the designed neural network can be used to diagnose VRFs on intact and endodontically treated teeth. CBCT images were more effective than periapical radiographs when evaluating the VRFs. Fukuda et al [32]. also applied CNN to detect VRFs on panoramic radiographs. The AI model achieved precision of 0.93, and it was found to be more effective than the specialists.

Some oral diseases can be life-threatening if not detected or treated early. Among such diseases, oral and maxillofacial cancer sits on the top of the pyramid having a high mortality rate. One of the most common oral malignancies is oral squamous cell carcinoma (OSCC), which presents with a high incidence rate worldwide, and most of the cases are diagnosed at an advanced stage, thereby reducing the survival rate of the patients. Aubreville et al [33]. evaluated an automatic approach for diagnosing OSCC by applying a DL approach to confocal laser endomicroscopy (CLE) imaging. They compared this approach against a textural feature-based ML method and obtained an AUC of 0.96 and a mean accuracy of 88.3%. The authors highlighted that this noninvasive method has the advantage of high magnification and better depth penetration allowing the diagnosis of the malignant tissue 100 μ m below the surface. The automated real-time identification of potential malignant sites in the oral mucosa may help to speed up the treatment and improve the prognosis.

Some jaw tumors vary in relation to the invasiveness and aggressiveness; however, they show similar radiological characteristics. Thereby, treatment is based on the differential diagnosis rather than an absolute diagnosis which might have a negative impact on the treatment plan. For instance, keratocystic odontogenic tumors (KCOTs) do not require radical jaw segmentation but enucleation like other cystic lesions. On the other hand, ameloblastomas require extensive surgical removal and reconstruction. Appropriate diagnosis and radiological differentiation between these two tumors can guide oral and maxillofacial surgeons to plan the treatment precisely. Poedjiastoeti and Suebnukarn [34] applied CNN for classification of KCOTs and ameloblastomas on digital panoramic radiographs. The results showed 83% in accuracy, which was comparable to the specialist (82.9%) but, however, much faster (38 seconds against 23.1 minutes).

AI for Treatment Planning

AI has also been useful for planning in dentistry. For orthodontic treatment, AI can be applied to decide if orthodontic treatment is needed or when to extract a tooth or not prior to the installation of fixed appliance [35–37]. In addition, orthodontic treatment might require surgical intervention such as orthognathic surgery to correct skeletal abnormalities of the maxilla and mandible and has to be carefully and assertively planned. It has been demonstrated that AI can decide between surgery and non-surgery cases based on lateral cephalometric radiographs [38].

In case of a surgical treatment, the advancements in technology have enabled combining imaging data with virtual models. This procedure requires an accurate superimposition of the data through the recognition of common reference points. Although some intrinsic and extrinsic registration methods have been proposed, nevertheless, it is time-consuming and requires

specific knowledge of certain software programs to achieve such a task. Meanwhile, registration can be achieved with AI in a user-friendly and time-efficient manner, thereby allowing accurate measurements and fabrication of digital splints for orthognathic surgery, oral and maxillofacial surgery appliances, dental implant insertion guides, navigated surgery, and many other applications.

AI for Outcome Prediction in Dentistry

One of the most important predictive activities would be certainly to detect a disease, such as oral cancer, in an early phase before it metastasizes, providing the patient with an adequate treatment and an excellent prognosis. DL can be applied for this purpose as it learns features from the training data to cast predictions on unseen data.

Patients frequently ask their dentists about the outcomes of the treatments which is a difficult answer to provide, as the predictive outcomes are influenced by a number of factors that would demand a certain amount of data and statistical analysis before giving the patient a proper response. However, some studies have focused on the use of AI to predict the outcomes of treatments such as postoperative swelling following the extraction of the third molar [39].

For orthodontic cases, depending on the circumstances during the mixed dentition phase, the orthodontist needs to save or open space for unerupted teeth. A study by [40] investigated the use of ANN to predict the size of unerupted canines and premolars of children with mixed dentition. The ANN selected the mandibular first molar and incisors and the maxillary central incisors for predicting the width of canines and premolars in the mandible and maxilla, respectively. The prediction error rates and maximum rates of over-/underestimation were smaller than the linear regression [40].

Orthognathic surgery aims at correcting severe dentofacial discrepancies that cannot be fixed

with conventional orthodontic treatment. Such procedures change the facial aesthetics which is of a major concern for the patients. AI-based approach has been applied to predict facial soft tissue changes in patients undergoing orthognathic surgery. Lu et al [41]. applied ANN to improve the prediction of facial changes on profile video images of post-orthognathic surgery patients. The ANN enhanced the prediction ability by more than 80%. An accurate prediction of surgical outcomes might improve the treatment planning and ability to provide patients with an accurate description of the changes following surgery.

AI has been widely implemented in conservative dentistry, dental implantology, and prosthodontics for predicting the longevity of restorations and their potential debonding, prediction of ceramic recipe in order to match the color of

natural teeth and implant treatment success rate and soft tissue transformations after rehabilitation with complete dentures [42–46]. The capability of predicting outcomes is based on many factors such as [1] characteristics of the restoration needed, [2] patient's personal habits, [3] dentist's abilities, and [4] properties of the restorative materials. A prediction of all these factors with AI might improve the decision-making process. The way forward is to implement these predictive AI-driven networks at a broader level as it has the ability to streamline dental care by reducing the laborious routine tasks of the dentists, predicting outcomes, and allowing an accurate treatment plan based on the AI-based prediction model.

A summary of the artificial intelligence applications reported in this chapter is provided in Table 1.

Table 1 Summary of AI applications in dentistry

Study	Field	Application
Zhang et al. (2018) [6]	Oral and maxillofacial radiology	Recognition of teeth on intraoral periapical radiographs
Chen et al. (2019) [7]	Oral and maxillofacial radiology	Detection and numbering of teeth on intraoral periapical radiographs
Tuzoff et al. (2019) [8]	Oral and maxillofacial radiology	Automatic teeth detection and numbering on panoramic radiographs
Leite et al. (2020) [9]	Oral and maxillofacial radiology	Automatic detection and segmentation of teeth on panoramic radiographs
Hosntalab et al. (2010) [10]	Oral and maxillofacial radiology	Classification and numbering of teeth on multi-slice CT images
Miki et al. (2017) [11]	Oral and maxillofacial radiology	Classification of teeth on CBCT images
Lahoud et al. (2021) [12]	Oral and maxillofacial radiology	3D segmentation of tooth on CBCT images
Takahashi et al. (2020) [13]	Implantology	Identification of dental implants on panoramic radiographs
Hadj Saïd et al. (2020) [14]	Implantology	Identification of dental implants on a radiograph
Lee and Jeong (2020) [15]	Implantology	Identification of dental implants on periapical radiographs
Vranckx et al. (2020) [16]	Oral and maxillofacial radiology	Measurement of mandibular molar angulation
Park et al. (2019) [17]	Oral and maxillofacial radiology	Identification of cephalometric landmarks
Kunz et al. (2020) [18]	Oral and maxillofacial radiology	Identification of cephalometric landmarks
Hwang et al. (2020) [19]	Oral and maxillofacial radiology	Identification of cephalometric landmarks

Concluding Remarks

The development of automated tools for many specialties in dentistry is still in early phase; nevertheless, the results are promising. Some of the AI applications are summarized in Table 1. Most of the studies show the capacity of AI to perform human activities equally or better than specialists and in a shorter time without the concern of observer variability.

Currently, we are seeing the AI creeping into the field of dentistry as a modern dental assistant. Many companies have been working on the development of AI-based solutions in dentistry (Table 2). In the future, systems trained with large datasets for a wide range of clinical situations will be able to recognize a variety of features from inputs, such as intra- and extraoral radiographs, photos, tomographies, and digital models. This will allow automatic assessment of the patient's oral condition, diagnose, and

Table 2 Companies developing AI solutions in dentistry

Company	Country	Description
BubblesEndo	USA	AI dental startup transforming endodontic diagnosis. The product called “Endogenie” is an AI-based endodontic application that helps clinicians to organize their findings during examination, analyzes dental radiographs, and highlights its findings. The application also combines the imaging analysis with the results from clinical testing to provide the most likely clinical scenario Website: https://www.endogenie.ai
CellmatiQ	Germany	This company mission is to extend complex image analysis beyond human capabilities and automatically detect and classify structural patterns, optimize processing time and quality of image-based workflows, and improve visual assessments with objective and validated methods. Among the dental solutions available are modules for cephalometric analysis and image modality classification. Currently, the company is developing solutions for pathology indication in dental panoramic radiographs, caries detection, and age determination by cervical vertebral maturation Website: https://cellmatiq.com
Dental Intelligence	USA	The goals of this company are to help dentists to provide more and better care and to improve the team’s collaboration and performance, raising the overall health and profitability of the dental practice. Their dental solution is a module that connects to the practice management software and tracks the activities and analyzes, finds, and signalizes opportunities, making sure that time is saved, more patients are helped, and production is increased Website: https://www.dentalintel.com
Dental Monitoring	France	This French company wants to reinvent the patient experience and revolutionize the way oral healthcare is provided, expanding the dental practice into the virtual environment. Among their solutions are applications that monitor patients’ treatments, AI technology to generate ultra-realistic smile predictions, and automation of repetitive tasks Website: https://dental-monitoring.com
dentalXr.ai	Germany	With the combination of machine learning, software engineering, and expertise in dental research, this company is committed to support dentists in making the best possible diagnostic and treatment decisions for their patients. Their technology supports dentists in detecting pathologies and restorations in dental radiographs Website: https://dentalxr.ai
Denti.AI	Canada	Cloud-based artificial intelligence applied to interpret dental images and developed to work as a “second opinion,” helping in the identification of undiagnosed conditions and fast elaboration of dental chartings Website: https://www.denti.ai
Diagnocat	Russia	Platform that allows uploading, storing, and sharing of dental images with a built-in AI technology that automatically detects common dental conditions and pathologies Website: https://diagno.cat
glidewell.io	USA	Company that promises to improve patient care and increase profit by offering solutions that use machine learning technology and AI algorithms to create customized crown proposals and ensure accurate scans with color coding to show the missed areas Website: glidewell.io
Kapanu AG	Switzerland	This Swiss company aims to help the dental community achieve a high-quality and multidisciplinary services and products. Among them, there are software applications for visualizing the possibilities for aesthetic dental makeovers with augmented reality and preview of the potential orthodontic treatment outcome Website: https://kapanu.com
MMG Fusion	USA	The MMG Fusion solution connects to the dental practice management software and helps in finding available time for filling the chair, increasing office production and revenue, reducing staff overhead, and creating great patient’s experiences Website: https://mmgfusion.com

Table 2 (continued)

Company	Country	Description
NovoDynamics	USA	NovoDynamics products transform large, disparate datasets into actionable information and insights that help organizations make better decisions with AI solutions addressing highly complex challenges. Among their products, there are solutions for radiographic analysis and enhancement and detection of anomalous claims submitted for dental insurances Website: https://www.novohealthdental.com
Orca Dental AI	Israel	The mission of this company is to provide dental practitioners the tools they need to make a breakthrough in patient care. It combines clinical experience and AI technologies to create diagnostic reports, treatment plan suggestions, and smart clinical predictions. Among their products, there are automated cephalometric analysis, airway analysis, mandibular nerve canal identification in CBCTs, and caries detection Website: https://www.orca-ai.com
Overjet	USA	This company incubated at the Harvard Innovation Labs is dedicated to solving the most challenging problems in dentistry. They have modules for insurance claims review, automation of administrative tasks, and identification of dental anatomy, oral diseases, and quality of restorations Website: https://www.overjet.ai
Pearl	USA	Founded on the notion that AI can be the dental assistant, Pearl aims to usher in a new wave of AI-powered tools, such as second opinion on every radiograph, management of dental practices, delimitation of indirect restoration margins, and automated insurance claims reviews Website: https://hellopearl.com
Relu BV	Belgium	Relu is a young and driven company that allies AI engineering and research expertise to develop clinical applications. Among their solutions, there are modules for automatic segmentation of teeth on CBCT scans, calculation of molar angulation to predict third molar eruption on dental panoramics, detection of the inferior alveolar nerve, and segmentation of the pharynx, mandible, and skull Website: https://relu.eu
Simplifeye	USA	Company focused on providing cutting-edge software technology and world-class service. They offer online solutions to reach patients anytime and anywhere and to access their information available in the cloud Website: https://simplifeye.co
VideaHealth	USA	The Boston-based company provides AI-driven tools for image analysis, diagnosis, treatment planning, and insurer claims processing Website: https://www.vedea.ai

suggest the best treatment options with the most optimal prognosis. Further, it will pave the way for predicting the outcomes based on the particular characteristics of each case.

Abstract

The holy grail in endoscopy examinations has for a long time been assisted diagnosis using Artificial Intelligence (AI). Recent developments in computer hardware are now enabling technology to equip clinicians with promising tools for computer-assisted diagnosis (CAD) systems. However, creating viable models or architectures, training them, and assessing their ability to diagnose at a human level, are complicated tasks. This is currently an active area of research, and many promising methods have been proposed. In this chapter, we give an overview of the topic. This includes a description of current medical challenges followed by a description of the most commonly used methods in the field. We also present example results from research targeting some of these challenges, and a discussion on open issues and ongoing work is provided. Hopefully, this will inspire and enable readers to future develop CAD systems for gastroenterology.

Keywords

Gastrointestinal endoscopy · Artificial Intelligence · Neural Networks · Hand-crafted features · Anomaly detection · Semantic segmentation · Performance

Introduction

Numerous abnormal mucosal findings, ranging from minor annoyances to highly lethal diseases, can be found in the human Gastrointestinal (GI) tract. For example, according to the International Agency for Research on Cancer, about 3.5 million luminal GI (esophageal, stomach, colorectal) cancers are detected yearly in the world [41]. These cancers represent a substantial health

challenge for society, with a mortality rate of about 63–65%, resulting in around 2.2 million deaths per year [19, 41]. Overall, Colorectal cancer (CRC) is the third most common cause of cancer mortality for women and men combined [104], and the other most frequently occurring GI cancers are stomach, liver, pancreatic, and esophageal cancers [18].

For diagnosis and treatment of GI diseases, GI endoscopy is the gold-standard procedure used to examine the tract for anomalies, and to a certain extent, the GI diseases may be prevented by improved endoscopic performance and high quality systematic screening in high incidence areas [19]. However, despite the substantial technical improvement of endoscopes over the last two decades, a major limitation of the endoscopic examinations is the endoscope operator variation, depending on the procedural skill, perceptual factors, personality characteristics, experience, knowledge, and attitude deficits [34]. This translates to a substantial inter-observer variation in the detection and assessment of mucosal lesions [64, 108]. This causes, for example, an average 20% polyp miss-rate during colonoscopies [52]. All these factors could potentially, to some extent, be alleviated by substantial educational efforts, but not eliminated [88].

In this context, assisted diagnosis using computers has for a long time been a holy grail. Developments in computer hardware have enabled computationally demanding yet promising technologies like AI, more specifically its sub-field Machine Learning (ML), to provide the clinicians with potentially highly accurate and efficient Computer aided diagnosis (CAD) systems, giving healthcare professionals the tools needed to provide quality care at a large scale [86, 102]. At its core, machine learning involves using algorithms to parse data, learn from it, and then make predictions, in the medical domain this means detect,

segment, assess or classify a disease. However, there exist several issues which need to be addressed, both for creating and improving automated diagnosis algorithms. Developing and assessing a computer's ability to diagnose at a human level are complicated tasks, and a potential success depends on various factors which goes beyond simply determining the accuracy of an algorithm. These challenges have been an active area of research for about a decade, and a large number of promising results have been published.

In this chapter, we describe current challenges on the way towards effective computer-based digital assistant systems. In particular, we focus on GI endoscopy. We provide examples of proposed methods and tools employing various techniques, identify current challenges, and give hints for future development and assessment of CAD systems.

GI Endoscopy

To examine the esophagus, stomach, duodenum (upper GI), and the large bowel and rectum (lower GI), a long, flexible tube is inserted into the mouth and rectum, respectively. A tiny video camera at the tip of the tube allows the doctor to view inside of the GI tract in real-time, where findings, as depicted in Fig. 1a and b can be found.

The small bowel is, due to its anatomical location, less accessible for inspection by such flexible endoscopes. To easier access these areas of the GI tract, Video Capsule Endoscopy (VCE) [22] has been introduced as an alternative examination method [25]. A VCE consists of a small capsule containing one or more wide-angle cameras. The capsule is swallowed by the patient, and it captures a video as it moves through the GI tract. The video is extracted, and a medical expert assesses it in a potentially tedious and time-consuming process after the procedure, searching for findings like the ones shown in Fig. 1c.

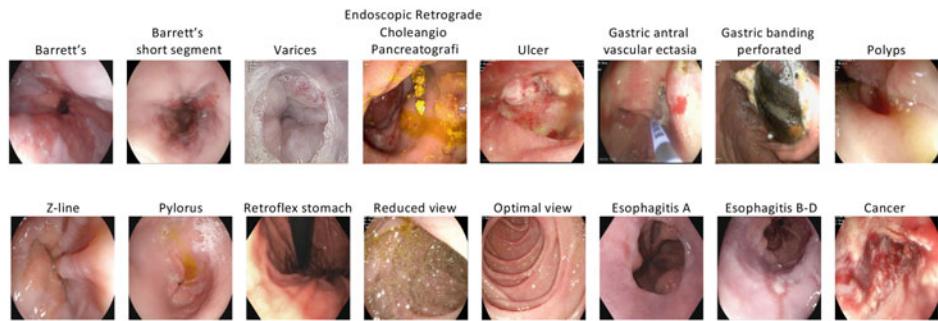

Even though these examination procedures allow clinicians to detect GI anomalies, there is still ample scope for improvements. Looking at the possible findings depicted in Fig. 1, it is obvious that it can be hard to detect and classify the various anomalies potentially found in the various

parts of the GI tract, either live during a gastroscopy or colonoscopy, or in a post-analysis of the VCE video. Moreover, there are large operator variations and anomaly miss-rates reported for both regular endoscopies [34, 52, 64, 108] and capsule endoscopies [20, 88].

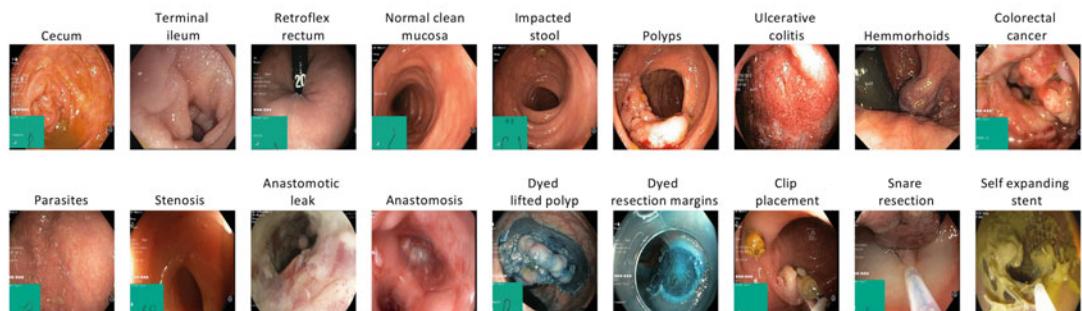

Hence, the hope is that automated analysis can assist medical experts in real-time anomaly detection, removing variations and increasing detection rates. Moreover, analyzing hours of VCE video, there is also a large potential in saving medical expert time, by analyzing the 4–12 h long videos in a few minutes by a fast computer, compared to the usual 45–60 min error-prone, fast-forward analysis performed by medical personnel today. From an analysis point of view, there are two important requirements for such CAD systems:

1. *High detection or segmentation performance* in the analysis is important in order to address the large human miss-rates and variabilities. It is often measured in terms of metrics like precision, sensitivity (recall), specificity, accuracy, F1 score, Matthews correlation coefficient (MCC) or similar [98]. This requirement aims at finding all anomalies correctly, i.e., detecting all findings without false positives or negatives. A more detailed discussion on metrics is given in section “Metrics and Evaluation.”
2. An often neglected requirement is *fast processing* in order to give real-time feedback during the endoscopy examination, or in the case of VCE, higher scale of the analysis and a faster feedback on the same amount of processing resources.

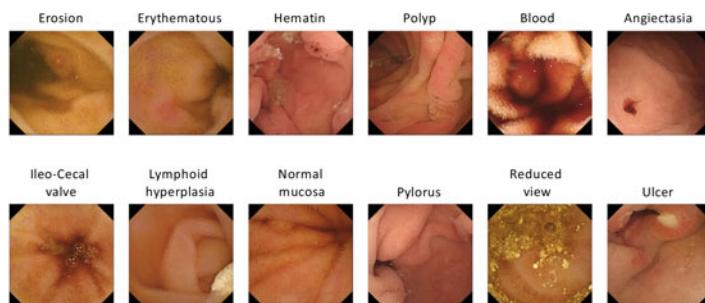

Furthermore, in order to be deployable in a clinical environment, all components need to be integrated in a pipeline capturing videos or frames from the endoscopy equipment, via an automatic analysis, to give the clinicians a visual feedback (and potentially also assisting in generating an examination report according to medical standards). The system must also be easily integrated into and usable with the current examination procedures, and of course, the various components must meet the medical privacy and security regulations.

(a) Upper GI tract, esophagus, stomach (Gastroscopy).

(b) Lower GI tract, large bowel (Colonoscopy).

(c) Lower GI tract, small bowel (Capsule endoscopy).

Fig. 1 Examples of various findings in the GI tract including anatomical landmarks, pathological findings, normal mucosa, therapeutic interventions and medical instruments [14, 96]

Existing Methods

As mentioned above, a large number of algorithms and models for automated analysis of GI video and images have already been proposed. In this respect, when we discuss CAD systems for the GI tract today, people often interchangeably

talk about detection, localization and segmentation. Here, we therefore first try to distinguish between the terms as follows:

- *Detection* is the operation of detecting whether an image belongs to a certain classification or not. This can be a binary “yes or no” for

Fig. 2 Various ways of indicating a finding (*left*: detection “just” showing the image; *center*: full segmentation mask showing in white all pixels part of the finding; and *right*: bounding box making a rectangle around the finding)

questions whether the image or video frame contains a polyp or not. It also includes systems that *classifies* the input into multiple classes.

- *Localization* is to point into the image where the object is located, e.g., using some type of point markers or making a bounding box around the object of interest.
- *Segmentation* is yet another step further where one determines pixel-wise whether the pixel belongs to a finding or not, e.g., generating an exact segmentation mask of the finding.

Figure 2 shows an example of detection, localization and detection. As localization is often mixed into both detection and segmentation, we here focus on detection and segmentation.

Hand-Crafted-Feature-Based Approaches

Automatic detection of GI anomalies has been a topic of research long before the success of AI and deep neural networks, using what is nowadays often called traditional computer vision and ML methods, as found in libraries such as *OpenCV* [16] and *LIRE* [69]. Already in 1998, Krishnan et al. [59] proposed detecting polyps using shape-features in a curvature analysis. In the subsequent decade, various approaches using a mix of shape, edge, texture, and color features appeared. For example, Alexandre et al. [2] detected polyps using a support vector machine (SVM) on color patterns. Further, using SVMs, Ameling et al. [5]

combined texture and colors, and Park et al. [75] used shape and texture features in a conditional random field classifier.

Two more recent approaches using hand-crafted techniques are Polyp-Alert [111] and EIR [85], where the authors also measured analysis time, with the goal of being able to give real-time feedback during the examination. The Polyp-Alert [111] system combines edge and texture features. The polyp edge detection algorithm mainly relies on edge features obtained from the part-based multi-derivative edge cross-section profile [110]. The EIR [85] system combines a content-based similarity search with statistical classifiers from the training data. A large number of image features are tested [87], ending up with a combination of the joint composite descriptor feature and the Tamura features, due to a good trade-off between the precision and sensitivity (recall), and the speed of the algorithm. A search-based classifier is then used to determine if an image contains a finding of a certain class.

A detailed overview containing earlier example approaches can be found in [85, 111]. However, lately, deep learning approaches have outperformed these hand-crafted approaches and replaced them entirely.

Deep Learning-Based Approaches

Already in 2001, Karkanis et al. [53] aimed for the detection of lesions in endoscopic video using textural descriptors on the wavelet domain supported by artificial neural network

architectures, albeit not using deep architectures. Such early approaches were tested on tiny data sets, in this case 8 images [53]. More recent approaches are usually based on deep learning architectures where Convolutional Neural Networks (CNNs) are clearly the most popular ones.

Where hand-crafted features rely on extracting predefined properties of an image, such as color, texture, or shape, CNNs are neural network architectures using convolutions and pooling operations to automatically learn which features are most relevant. CNNs perform well on many different tasks like image classification, object detection in images, and image generation [56]. Although they are mostly used for image analysis, they have also proven useful in timeseries research and video analysis. In medicine, architectures like U-Net [89] have shown promising results in areas like cardiology, colonoscopy, and radiology [74, 119, 122]. This also includes gastroenterology, where CNNs are currently state-of-the-art for analyzing colonoscopy videos. The most common application is the detection and segmentation of polyps, where many CNN-based approaches have shown excellent results [17, 50, 114]. These approaches have expanded to other findings as well, like detecting and segmenting ulcers [31]. Furthermore, due to limited access to medical image and video data, most approaches use transfer learning. In transfer learning, pre-trained models are used as a starting point, and refined for the given data set by retraining with some layers trainable and some frozen [82].

An automated CAD system for the GI endoscopic image segmentation is a step further than providing “just” detection of anomalies. A predicted segmentation mask (see Fig. 2) can help point out the area of interest in the images (frames) that need to be further examined. However, making such perpixel predictions is also a more complex task. In this respect, there has been a considerable amount of work done so far, especially targeting polyps [32, 45, 47, 48, 50, 71, 81, 100, 109], artifacts [3], and endoscopic instruments [90]. In general, CNN-based approaches perform well with the larger polyps. However, still the major challenges issues in the field are

related to adenomatous polyps or small and flat polyps. Recent studies are targeting smaller polyps [50, 63]; however, it is yet an open-challenge to solve.

Unsupervised and Semi-supervised Approaches

The above presented approaches fall into the category of supervised learning, meaning that we train the models on a data set with an existing ground truth. In this section, we give a glance at newly emerging unsupervised and semi-supervised methods.

Generative Adversarial Networks (GANs), which were introduced by Goodfellow et al. [30] in 2014, are becoming increasingly popular in the medical domain for generating synthetic data. Different advancements to the original GAN architecture, such as conditional GAN [72], pix2pix [43], CycleGAN [123], Style-GANs [54, 55], to mention a few, present different methods, ranging from domain transformation to high definition image generation. ML researchers in the medical domain can use GAN models to generate synthetic data to tackle challenges related to privacy, data deficiency, and data annotation. For example, Younghak et al. [93] use a conditional GAN architecture to generate synthetic polyp images to improve the performance of a deep learning system detecting polyps in the colon. This methodology is still in its early stages, and it has yet to be shown to which extent generated data can replace real data and help to improve performance and shareability.

Another emerging method in the field of medical image analysis, is semi-supervised learning. Here, the goal is to learn from a small set of labelled data combined with a larger amount of unlabeled data. Examples include [7, 67, 70, 116]. These models produce promising results, and could also help overcome the challenge of insufficient labelled data faced by many data-hungry methods. However, these approaches still struggle with challenges such as low accuracy and high entropy during early stages of the training

process. The models are also regularized towards high entropy predictions, making it hard to achieve a high accuracy [117, 120]. It will be interesting to see whether these challenges can be overcome, and how useful the results will prove to be in the medical domain.

Example Results

High detection or segmentation rates are important in order to be clinically relevant, and the typical way the performance is compared. However, due to factors like different data sets and different equipment, the pure numbers cannot be directly compared. Still, to give some indications of the state-of-the-art performance, we give a set of, by far from complete, examples using standard metrics like precision, sensitivity (recall), specificity, accuracy, F1 score and MCC for detection; and Dice similarity coefficient (DSC), Intersection over Union (IoU), precision and sensitivity for segmentation. A substantial overview of existing approaches can be found in [61], containing 138 different studies. An explanation of the different metrics is given in Table 1 and further discussed in section “Metrics and Evaluation.” Another source for exploring and comparing different approaches are the popular GI detection,

classification and segmentation challenges discussed in section “Competitions and Challenges.”

A selection of performance examples are given in Table 2. Looking at the numbers, we see that in the specific tested cases, the computer should be at the level of the best experts with scores above 90%, i.e., potentially being a helpful digital assistant during a GI endoscopy examination. Likewise, example results for lesion segmentation are provided in Table 3, and the numbers are again encouraging in terms of proving that the used models could be of use in a medical setting. However, while the results achieved are promising, there are still several open challenges, including generalizability, overfitting, cross data set testing and explainability of the results. Moreover, as indicated in the Tables, hardly any existing research report the speed of the system, meaning that it is hard to assess the system’s capability to provide a live analysis in the clinic.

Open Issues and Ongoing Research

Despite impressive results presented in many of the published papers, even exceeding what are reported as average detection rates from clinicians, there are still challenges and open issues.

Table 1 List of commonly used metrics. To define each metric, TP, FP, TN, and FN represent true positives, false positives, true negatives, and false negatives, respectively

Formula	Description
$\text{accuracy} = \frac{\text{TP}+\text{TN}}{\text{TP}+\text{FP}+\text{TN}+\text{FN}}$	Rate of correct classification. Ratio between correctly classified samples and all samples.
$\text{precision} = \frac{\text{TP}}{\text{TP}+\text{FP}}$	Proportion of retrieved samples which are relevant. Ratio between correctly classified positive samples and all samples classified as positive.
sensitivity (also known as recall) $= \frac{\text{TP}}{\text{TN}+\text{FP}}$	Proportion of relevant samples which are retrieved. Ratio between correctly classified positive samples and all positive samples.
$\text{specificity} = \frac{\text{TN}}{\text{TN}+\text{FP}}$	Negative class sensitivity. Ratio between correctly classified negative samples and all negative samples.
$\text{F1} = \frac{2 \times \text{TP}}{2 \times \text{TP} + \text{FP} + \text{FN}}$	Harmonic mean of the precision and sensitivity (recall).
$\text{MCC} = \frac{\text{TP} \times \text{TN} - \text{FP} \times \text{FN}}{\sqrt{(\text{TP}+\text{FP})(\text{TP}+\text{FN})(\text{TN}+\text{FP})(\text{TN}+\text{FN})d(\text{TP}+\text{FP}+\text{FN})}}$	Pearson’s correlation coefficient [23] for binary classification.
IoU (also known as Jaccard) $= \frac{\text{TP}}{\text{TP}+\text{FP}+\text{FN}}$	Similarity between sets from the size of the intersection divided by the size of the union.
$\text{DSC} = \frac{2 \times \text{TP}}{2 \times \text{TP} + \text{FP} + \text{FN}}$	Quotient of similarity of two sets. Semi-metric as it doesn’t satisfy the triangle inequality. Related to the IoU via $\frac{S}{2-S}$.

Table 2 Examples of **detection** performance from different approaches. The results show promising performance with numbers above 90%. Unfortunately, speed is not commonly reported

Paper/system	Data set used	Sensitivity (recall)	Specificity	Accuracy	Precision	F1	MCC	Speed (fps)
Boughorbel [17]	MICCAI-challenge data sets	86.3	–	–	73.6	–	–	–
Kundu [60]	30 Own data set	95.2	98.3	97.9	88.4	–	–	–

ResUNet++ [50]	Kvasir-SEG	81.3	79.3	70.6	87.7	–
Double-UNet [45]	CVC-ClinicDB	92.4	86.1	84.6	96.0	–

First, for example, Thambawita et al. [98] presented the issue of overfitting to specific data sets and a lack of generalizability. This means that a model that performs well on one data set may not perform at all on another. Furthermore, like other deep neural networks, CNNs are black boxes, and it is not easy to understand why one input gives a particular result. There is also a lack of large open data sets that contain annotations for uncommon abnormalities and rarely documented findings to support data-hungry algorithms like CNNs. Here, we elaborate on a few of these open issues.

Limited Data Availability

Available medical data is scarce. However, modern deep learning approaches usually require a lot of data to perform well, and often, the more variations in the data, the better the model gets, especially for supervised learning models. Table 4 shows the data sets available in the field of GI endoscopy. Evidently, the number of images used for training and testing is small when compared to the data set from the natural images. This is because it is difficult to obtain data from the medical domain. The data is often protected and

Table 4 Summary of available endoscopic data sets. A further discussion about data sets are found in [14, 96]

unavailable due to legal restrictions and lack of medical personnel for the tedious process of manually extracting and labeling training data. This calls either for better data sharing processes and culture, or methods more capable of handling small amounts of data.

This gives rise to several basic challenges: The amount of data is too small to train a robust model, and the presented results might appear deceptively good due to overfitting. Moreover, it is hard to compare results if all experiments are performed on different data, and practically impossible to reproduce them. Thus, it is almost impossible to conclude whether one model is better than another. We must therefore aim for more and open data sets. Table 4 contains an overview of known available data sets at the time of writing, making a good starting point for future experiments. Still, more data is needed, especially data containing pathological outcomes.

Generalizability

One of the open issues in the field is the GI endoscopy is the generalizability of ML models, i.e., their ability to perform well on previously unseen data regardless of source, equipment, etc. Such data can be from either the same distribution as the model was trained on, or from a different distribution. Which of the two a new data sample represents, is not always clear [101, 103]. Although some recent studies address generalizability of ML models for polyp classification [45, 112], this must be addressed for any model or system to be deployed into clinical practice.

Evaluating whether a model is reliable for real world use also requires cross data set testing, to avoid accepting a model which coincidentally works well on one specific set of data. The model developers should in general not have access to the final test data, to avoid bias during testing and development. This process, known as data blinding, is an important tool in many fields of research, including medicine [80]. Ideally, the

model should be tested for robustness on data collected separately from the data used during model development and testing.

Furthermore, distinction should be made between data annotated by medical experts, referred to as *soft ground truth*, and data labelled based on a medical test, referred to as *hard ground truth*, e.g., pathological examination of a polyp. The quality of soft ground truth data is limited by how well the medical annotator is trained, and such data is most useful for training models intended to automate processes. On the other hand, data with hard ground truth labels can also be used for automating processes, with the added benefit of avoiding annotator error or bias into the model, but it can furthermore be used for obtaining new knowledge. Note that while, as mentioned above, annotating each image is time consuming, collecting hard ground truth data is even more demanding, resulting in a scarcity of such data sets.

In current endoscopy practices, different hospitals use different endoscope system for diagnosis and therapy. The most common globally available endoscope systems are Olympus (Japan), Pentax 90i series (Japan), Fujinon (Japan), and Karl Storz (Germany) [57]. Moreover, different medical institutes have different protocols. Therefore, designing generalizable CAD systems is essential for performing well on a variety of institutes. Such systems should always be tested on several data sets. Discussions regarding challenges and advantages associated with cross-dataset testing can be found in [98].

Metrics and Evaluation

Evaluating performance is an important step when creating models for clinical use, and depends strongly on the choice of metric. As shown in Table 1, commonly used metrics are precision, sensitivity (recall), specificity, accuracy and F1 score. Some papers also report AUROC (area under the receiver operating characteristics). There are several reasons for going beyond the aforementioned metrics [98]. One challenge

frequently encountered in association with medical data sets, is their tendency to be imbalanced between classes, often having far more normal images than images with lesions. Because of this, certain metrics can provide an overly optimistic impression of the actual performance. For instance, a binary classifier can achieve a high accuracy on a data set containing few negative instances, by assigning all instances to the positive class. The AUROC is also known to be deceptive for imbalanced classification [91]. In such cases, the correlation coefficient between the true and predicted classes can be more informative [15], although no single metric is universally informative or suited for any imbalanced data problem. Moreover, for detection purposes, it is also a question whether one report per-frame performance, i.e., giving a decision for every frame in the video, or per-lesion, i.e., giving a correct prediction for at least one of the frames in the video sequence. Looking at the results from a technical point of view, a per-frame analysis of often desired, but from the medical point of view, a per-lesion analysis is often sufficient to notify the clinician of the finding once.

For segmentation performance, commonly used metrics are DSC and the IoU, also known as the Jaccard index. In clinical use, medical experts are usually interested in pixel-wise detail information about the potential lesion. DSC and IoU can be used to compare the pixel-wise similarity between the predicted segmentation maps and the ground truth. In addition, precision and sensitivity are used to evaluate under-segmentation or over-segmentation, where under-segmentation implies that the model predicts less relevant content in some portion of the image compared to the ground truth, and over-segmentation that the predicted image covers more pixels than the ground truth.

As observed in Tables 2 and 3, little research has until now focused on the required real-time capabilities in order to provide live feedback to clinicians during the endoscopy examinations. However, there seems to be reported systems that analyze data faster than the frame-rate threshold, and it has also been given attention in some of

the arranged competitions (see section “Competitions and Challenges”). Nonetheless, it is often a trade-off between speed (model complexity) and detection performance, indicating that this is still an important issue in future research and development of CAD systems.

Automatic Report Generation

After the endoscopist finishes an endoscopy, a high-quality report should be generated. This often a time-consuming process, where research shows that approximately one-sixth of U.S. physicians working time is spent on administrative tasks, taking time away from direct-patient care and lessening job satisfaction [115]. Moreover, there are large variations in endoscopists’ interpretations of findings as well as reporting styles. This can, and often does, lead to inconsistencies in the final decision [37]. Hence, automated report generation could both save clinical time and help standardize endoscopy reports, and recent development in natural language processing is expected to open up new possibilities in automatic report generation [86].

A method proposed by Jing et al. [51] uses neural image captioning to create reports from x-ray images. In [121], images are analyzed by a neural network, and example images of findings similar to the one at hand and attention maps are combined to reports. Most approaches focus on image analysis as a basis, and combine this with additional information [24, 33, 118]. This of course depends on access to a database containing correct information which can be used in combination with the images. A significant challenge is different reporting standards between countries or even hospitals, making it practically impossible to create a widely adoptable software.

However, for medical experts, automatic text creation might not even be the most crucial feature of such a software: A more important aspect is their ability to understand the reasoning and decision of the underlying model, enabling them to include it in their assessment. This is discussed in the next section.

Explainability

A well-known challenge associated with deep learning based CAD systems, is limited explainability due to their inherent complexity [4]. This property has caused their notoriety as black boxes whose decision-making processes are unknown, especially to end-users [35]. The need for understanding and explaining how the systems work and which roles the different data features play in the decisions, addresses different needs in the different stages of the system's development and use. The developer of the system needs to understand how data and methods are working together, as understanding and interpretability of the output helps to determine errors in the data as well as enabling targeted failure analysis. Particularly, in the context of this AIM, the medical experts require an explanation of the system's decision to assure that it concurs with the relevant medical knowledge.

Deep learning based systems, such as CNNs, have no inherent ways of providing explanations, meaning that they must either be extended to contain explanation generators, or explanations must be obtained post hoc [1, 38, 39]. A brief overview of approaches to model explanations is shown in Table 5. Models can be designed to provide justifications for their decisions as an additional task, e.g., via a text justification generator as part of the model architecture [62]. Given a model without such a design, different approaches are available: Those which explain the properties of the decision making system itself, and those which treat the system like a black box and

provide explanations based on its emergent behavior, referred to as model dependent and model agnostic approaches, respectively. One example of the former is displaying the values of the Deep Neural Network (DNN)'s internal parameters as a heat map superimposed on the classification instance [35]. Interpreted correctly, this can provide an understanding of the system's internal decision making process. Such an approach can also be extended to include information regarding the system induced decision uncertainty (meaning the part of the uncertainty not associated with the data collection and selection process), see [113].

Among the model-agnostic methods, the explanation concept LIME (*Locally Interpretable Model-agnostic Explanations*) approximates the black-box model using an interpretable model, such as a linear model, decision tree, or falling rule list [84]. This is done in the neighborhood of the instance to explain, making the resulting explanation a local one, given that it applies to a single outcome and is based on the particular instance's characteristics, as is also the case for the aforementioned model-dependent explanations.

In contrast, global explanations capture and explain the model at large, such as feature importance ranking. One class of methods capable of producing global explanations, are those based on the game-theoretic concept of Shapley values [92], which are currently enjoying a surge of interest in the statistics and machine learning literature [27, 40, 44, 66]. Shapley values are obtained by evaluating the model using all

Table 5 The different model explanation approaches regarding when they are applied: During the model development (in-model) or after the model is finished (post-

model). Explanation methods provide insight into model behavior either locally (around a particular prediction) or globally

Category		Description	Ex.
In-model		Justification text generator as part of model architecture	[62]
Post-model	Model dependent	GradCam: Display DNN activations on image	[35]
	Model agnostic	LIME: Yields a locally interpretable model approximating the full model	[84]
		SHAP: Shapley decomposition of a conditional expectation function of the full model	[68]
	Model independent	Global non-parametric Shapley decomposition	[28]

possible combinations of the data features. Hence, the computational complexity increases with the number of features $|f|$ as $2^{|f|}$, and the calculation involves re-training the model for each subset of features. The latter is problematic as re-training would result in different model parameters, highlighting that Shapley values are merely model agnostic, not *independent*. The widely used SHAP (*SHapley Additive exPlanations*) package [68] circumvents these challenges in different ways for various model architectures, by calculating approximate values using background samples from the data, and for deep architectures using a similar approach as the per node attribution rules from DeepLIFT [94]. The Shapley decomposition can be computed both globally and locally, and can be formulated [68] as a special case of LIME. Shapley values can also be used to obtain model-independent explanations [28].

Competitions and Challenges

There have been a series of different challenges related to automatic analysis of endoscopy data [9, 36, 79], where CNN-based approaches have been the top performing methods for the last few years. The various tasks given have been to benchmark and develop automated systems to accurately detect, localize, and segment the abnormalities inside the GI tract. These challenges targeted different tasks from detection, localization, and segmentation of GI anomalies, colorectal polyps to artifacts presence in the GI tract (see

Table 6). These regular competitions can help the research community in the field to find to find common standards for evaluating models, benchmarking state-of-the-art methods and tools, and finding new directions to bring the field forward together.

Clinical Verification and Emerging Commercial Systems

Many research groups have presented promising research results and good performance indicators, and several AI-based commercial systems have emerged, some of which are listed in Table 7. The status of these are mostly unknown, but, for example, the GI Genius system is CE marked, but still lacks US Food and Drug Administration (FDA) approval, and EndoBRAIN-EYE is approved only in Japan. For CAD systems to be deployed for real-time examinations in clinical examination rooms, or to be used for VCE data post analysis, clinical verification is strictly necessary. Still, at the time of writing, such studies are very limited. In August 2020, Repici et al. [83] presented a randomized multi-center trial, concluding that the AI-based CAD increases the adenoma detection rate (ADR), i.e., the percentage of patients with at least one histologically proven adenoma or carcinoma, demonstrating the potential of such systems. They examined 685 patients: 341 patients using the CAD system and 344 patients using only the traditional manual examination. The system achieved an ADR of 54.8%, and the control group 40.4%. This

Table 7 Emerging commercial products

Product	Vendor	Year	URL
GI Genius AI	Medtronic/Cosmo Pharma	2019	https://www.cosmopharma.com/products/gi-genius
EndoBRAIN-EYE	Cybernet	2020	https://www.cybernet.jp/english/documents/pdf/news/press/2020/20200129.pdf
CAD-Eye	Fujifilm	2020	https://www.fujifilm.eu/eu/cadeye
Ai4Gi	Ai4Gi	2016	https://ai4gi.com
UltiVision	DocBot	2018	https://www.docbot.co/gastroenterology-and-health
DISCOVERY	Pentax	2020	https://www.pentaxmedical.com/pentax/en/95/2/DISCOVERY-new
ENDO-AID	Olympus	2020	https://www.olympus.no/medical/en/Products-and-Solutions/Products/Product/ENDO-AID.html
SOMA	Augere Medical	2018	https://augere.md

demonstrates that AI-based systems can help detect adenomas, but that further improvements are required to increase detection rates, and to detect a larger number of sessile serrated lesions (at all). Considering the limitations of the study as well as the presented performance, it is clear that there are still improvements to be made, and more clinical studies are in order.

Despite significant interest from the industry, proper standards regarding evaluation methods and reproducibility are widely lacking. In addition, industry applications seem not to have focused on model explainability or model output interpretability. These are all crucial ingredients of trustworthy applications, and industry development will hopefully follow current research trends and focus more on these in the future.

Finally, when a high-performing (research) prototype has been built and tested, meeting the requirements above, it must be approved for medical use. Robust evaluation of AI based software before implementation is needed to reduce patient and health system risk, establish trust to facilitate wide-spread adoption. The common term used for such products is AI based software as a medical device (SaMD). Regulators of the SaMD applications, including the FDA in the United States, have been guided by the Global Harmonization Task Force and International Medical Device Regulators Forum (IMDRF). The IMDRF has proposed four different risk categories for SaMD each with a different set of requirements for assessing scientific and clinical validity of the technology [42]. Within gastroenterology, CADe

and CADx technologies have not yet been classified. The current FDA process for SaMD is derived from its approval process for medical devices and will be categorized into three risk categories: Classes I, II, and III (highest risk) [105]. After risk classification, premarket submission as a 510(k) pathway or de novo pathway might be relevant to GI-based AI technologies similar to Osteoidetect [107]. Moreover, given that the AI algorithms are rapidly iterative and continuously learning, it can pose a challenge to the current regulatory process. The FDA proposed a new system of regulation for AI technologies in its Digital Health Innovation Action Plan, focused on AI technologies that rely on continuous learning and adaptation [106]. Regulators around the world have also recognized the challenges involved with AI algorithms when applied to medicine and most countries have initiated efforts to develop policies tailored for SaMD. Many of them share the core principles of designation of risk, review clinical evidence to demonstrate efficacy and safety, practices to incorporate evolving AI systems.

Summary and Conclusions

In this work, we have introduced the application of automated data analysis for GI endoscopy, and presented an overview on detection and segmentation based approaches to tackle challenges like large lesion miss-rates and interobserver variability. Recent studies have shown that deep computer

vision-based approaches seem to have the potential of improving the accuracy and overall performance in GI endoscopy by providing fully automated CAD systems acting as an additional digital eye. Nevertheless, there are still several open issues and challenges which need to be addressed before automatic analyses can be usefully integrated into clinical practice. These should be regarded as issues requiring research attention in the field.

Acknowledgments This work is funded in part by the Research Council of Norway, project number 282315 (AutoCap).

Abstract

Artificial intelligence (AI) is revolutionizing the way medicine is practiced. In this context, the application of AI algorithms in endoscopy is gaining increasing attention so that modern endoscopy is moving towards more and more assisted/automatic solutions. Several approaches have been carried out in order to improve accuracy in diagnosis and surgical procedures. In this chapter, a general overview of the main contributions in the field is surveyed. Four main categories of applications were identified, namely, (i) detection and diagnosis during endoscopic procedure, (ii) informative frame selection, (iii) mosaicking and surface reconstruction, (iv) augmented reality systems for intraoperative assistance and surgeon training. Discussions on future

research directions and implementation in clinical practice are provided.

Keywords

Endoscopy · Artificial intelligence · Machine learning · Deep learning · Computer-aided detection · Computer-aided diagnosis · Informative-frame selection · Mosaicking · Augmented reality

Introduction

Endoscopy is a minimally invasive procedure performed to examine internal organs of the human body: a flexible tube with a light and a camera attached is inserted into the patient body to observe details of internal organs and tissues (Fig. 1). Endoscopy can also be used to carry out other tasks including minor surgery. To this aim, the endoscope can be equipped with surgical tools through the so-called *working channel*. Physical examination for diagnosing specific diseases in the small intestine can also be performed through Capsule Endoscopy (CE), a camera-embedded pill-shaped device that passes through the gastrointestinal tract, captures and transmits images to an external receiver [1]. As the capsule travels through the digestive tract, it takes thousands of pictures, which are transmitted to an external receiver.

Endoscopy is useful for investigating many anatomical districts: respiratory tract, including nose (rhinoscopy) and lower respiratory tract (bronchoscopy); the urinary tract (cystoscopy); the esophagus and the stomach (gastroscopy); the colon (colonoscopy); abdominal or pelvic cavity (laparoscopy), interior of a joint (arthroscopy), organs of the chest (thoracoscopy and mediastinoscopy) [2]. With its origin in the late 50s, modern endoscopy procedures have become the most important methods to diagnose and treat a wide variety of diseases and injuries inside the human body [3].

Endoscopy is generally considered a relatively safe procedure, and it is typically performed while the patient is conscious. However, it can be a

burden for the surgeon, whose performance could be altered by fatigue, stress, or limited experience [4]. With the rise of artificial intelligence (AI) in medicine, including recent advances in computer vision, a number of researchers have been carried out in order to improve performance in the field, so that modern endoscopy is moving toward more and more assisted/automatic procedures.

AI-assisted endoscopy is based on computer algorithms that mimics human cognitive function. The idea is based on the algorithm ability to rationalize and take actions that have the best chance of achieving a specific goal. In particular, among the variety of AI techniques which have been successfully applied in the field of endoscopy, the most significant achievements can be attributed to machine learning (ML). ML is a class of generic algorithms used to recognize patterns in data. ML algorithms learn from the experience without being explicitly programmed, improving their abilities in a trial-and-error iterative process. In this context, a significant breakthrough was Deep Learning (DL), a fast-growing subset of ML algorithms, biologically inspired by the human brain. In particular, Convolutional Neural Networks (CNNs) have been proven to be well suited for image and video processing tasks. CNNs leverage the multiple network layers (consecutive convolutional operations performed on image patches) to extract the key features from an image and provide a final classification through the fully connected layers as the output. Such a relatively simple idea has allowed to achieve impressive results in computer vision, including endoscopy-related tasks.

Several applications of AI in endoscopy can be found in literature. An overview is illustrated in Fig. 2. Among the most effective applications, detection and diagnosis tasks are one the most studied. In particular, the research interest seems to be mainly related to the gastrointestinal tract with polyp and detection and classification, lesion patterns identification, benign and precancerous polyps differentiation being the most diffused applications [5]. By naive searching the words “Artificial Intelligence,” “Machine Learning,” “Deep Learning” and “Endoscopy” on Pubmed,

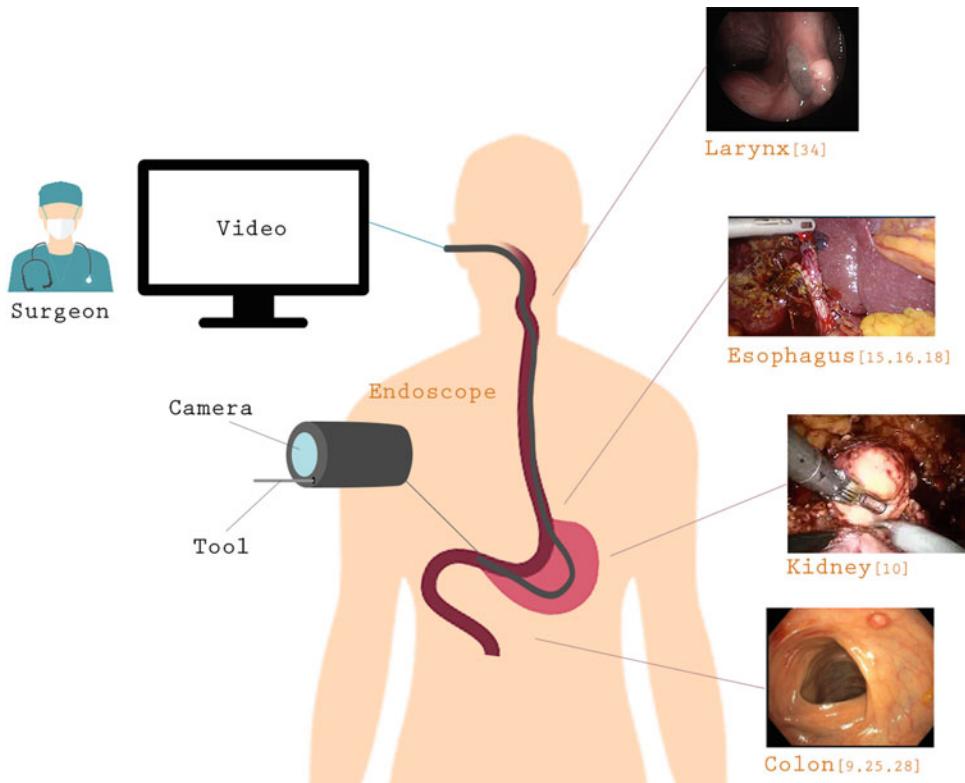

Fig. 1 Endoscopy procedure: the endoscope is inserted into the patient body and used to observe details of internal organs and tissues. It can also be used to carry out other tasks including minor surgery

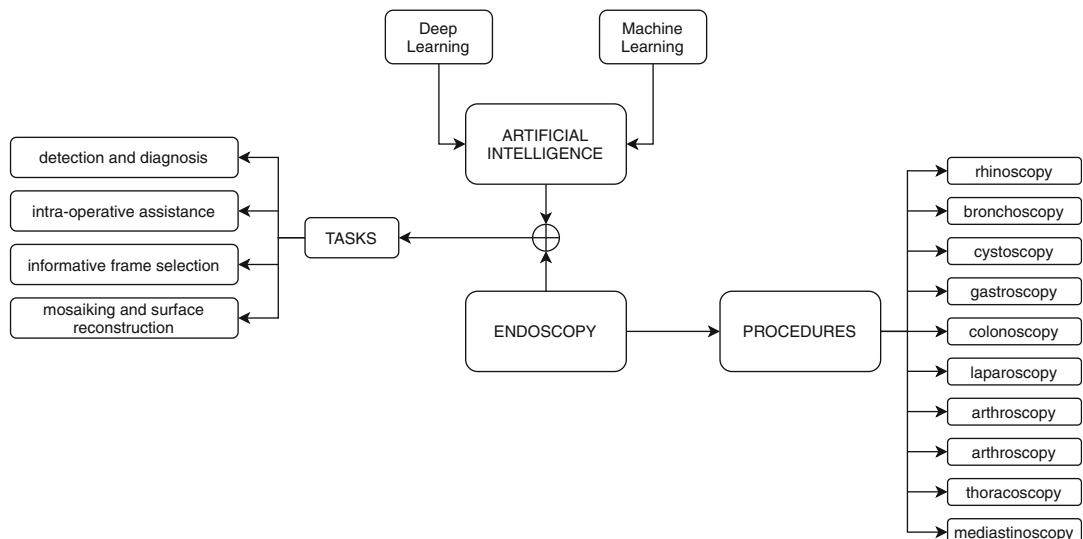

Fig. 2 Overview on applications of Artificial Intelligence in Endoscopy

indeed, about 220 results have been added in the latest 20 years, with 70 related to “diagnosis,” “detection” and “characterization” and more than 80 studies investigating the gastrointestinal tract. However, either fast-growing and milestones applications still exist. This includes real time applications of computer-aided systems, informative frame selection in video endoscopy, mosaicking and surface reconstruction.

In this chapter, those contributions will be investigated in detail. An overview of the most well studied tasks will be provided, with focus on classical methods and recent trends. Existing challenges will be analyzed to collect insight for future work.

Applications of Artificial Intelligence to Endoscopy Practice

In the following, a general overview of the main topic related to AI in Endoscopy will be provided.

Detection and Diagnosis During Endoscopic Procedure

Medical applications of AI have made significant progress during the past several years. In the field of Minimally Invasive Surgery (MIS), computer vision systems are nowadays a trendy subject. Among the possible tasks, computer-assisted detection (CADe) and computer-assisted diagnosis (CADx) systems have received particular attention from the Surgical Data Science (SDS) community [3]. CADe systems offer assistance for locating elements inside the field of view, and several techniques have been proposed to assist endoscopists to mark conspicuous structures and sections both in real-time and offline applications. Usually, this is achieved by placing a bounding box surrounding the region of interest over the image. Alternatively, a *segmentation* task can be performed where the contour of the target element is delineated [6]. Eventually, instead of just detecting the region of interest, CADx systems are used to characterize and classify elements during standard screening and

surveillance (e.g., to assess the stage of a particular form of cancer or diagnose certain infections) [4].

Several techniques have been applied from the ‘90s, initially based on image processing techniques (region growing, thresholds, etc.) and handcrafted features [7, 8], then combined with more sophisticated ML algorithms in order to improve performances [9]. However, a significant breakthrough was achieved with the rise of DL, where features can be automatically extracted from classic endoscopic images without the need of magnifying Narrow Band Imaging (NBI), Flexible spectral Imaging Color Enhancement (FICE), or Blue Laser Imaging (BLI), which are clinically useful in discriminating cancerous areas from noncancerous areas [10]. Both single frame analysis or video sequence processing approaches have been proposed. One of the most studied applications has been in computer-aided detection and computer-aided diagnosis of polyps [11]. Polyps are an abnormal growth of tissue projecting from a mucous membrane. Polyps in the colon are the most common, but it is also possible to develop polyps in other anatomical districts, including stomach and uterus. Despite most polyps being harmless (benign), some of them can eventually develop into cancer. Automatic polyp detection and classification has been an active research topic during the last 20 years and different approaches have been proposed [12, 13]. However, applications for routine patient treatment are very limited [9]. Real-time constraints, great variation of polyps appearance, the presence of other elements such as folds, blood vessels and lumen can impact on performance, and make development of CADx and CADe systems very challenging [9].

AI has also been used to develop diagnostic and detection systems associated with several diseases in several parts of the body, including the esophagus, stomach, small bowel, and colon. For example, optical diagnosis of early dysplasia relating to Barrett’s esophagus (BE) can be currently precisely done only by experts [10]. Barrett’s esophagus is a determinant condition for the development of esophageal adenocarcinoma, and automated identification of

dysplastic change in BE is one of the popular trends studying CADe gastroscopy. Nevertheless, several AI-based techniques have been developed, which achieved promising results [12, 14]. In this context, early work considered appearance features (color, vasculature and surface pattern) to train classic classifiers such as Support Vector Machines (SVM) [15]. Van der Sommen et al. [16] proposed a method based on specific texture, color filters, and machine learning for neoplasia detection. One-hundred images from 44 patients were considered in the study, achieving a sensitivity and specificity of 83%. To the same aim, Swager et al. [17] tested an AI model on 60 near microscopic resolution scans from 19 patients. Results showed a sensitivity and specificity of 90% and 93%, respectively. Recently, advanced DL techniques have been proposed with the joint of objective of increase performance and avoid the time-consuming step of manually specifying features [15]. De Groof et al. [18], proposed a DL CADe system, suitable for use in real time in clinical practice, to improve endoscopic detection of early neoplasia in patients with BE. The method was tested using 1704 unique esophageal high-resolution images derived from 669 patients, achieving more than 90% of accuracy.

Identification of esophageal squamous cell carcinoma (SCC) has also received particular attention [14]. Squamous cell carcinoma is the most prevalent esophageal cancer worldwide occurring most often in the upper and middle portions of the esophagus [19]. Guo et al. developed a real-time DL system for diagnosis of precancerous esophageal lesions [20]. The model creates a probability map indicating suspected areas of neoplasia and noncancerous areas. It was tested using more than 6000 NBI images, obtaining a sensitivity of 98.04%. Ohmori et al. used neural networks for esophageal lesions detection and differentiation [21]. More than 10,000 endoscopic nonmagnified images were used, achieving sensitivity, specificity, and accuracy were 90%, 76%, and 81%, respectively.

AI can offer valuable assistance in the management of stomach diseases. Among those applications, detection of gastric cancers and recognition

of Helicobacter pylori (HP) infection are widely studied. HP-associated chronic gastritis can cause mucosal atrophy and intestinal metaplasia, both of which increase the risk of gastric cancer [22]. In Itoh et al. [22], a CNN was used to accurate diagnosis of HP infection. The system was tested using 179 upper gastrointestinal endoscopy images obtained from 139 patients. The sensitivity and specificity of the CNN for the detection of HP infection were 86.7% and 86.7%, respectively, and the area under the ROC was 0.95.

Several studies have also demonstrated applications of AI in wireless capsule endoscopy (WCE). WCE is a technology developed for the endoscopic exploration of the small bowel [23, 24], with cases for which WCE proved useful increasing significantly over the last few years. A major challenge of WCE for clinicians is the time-intensive nature of reviewing the images [25]. For this reason, ML, and in particular DL, represents a remarkable perspective and contributes to broadening the range of applicability. According to recent related reviews, indeed, ML has been used to enhance WCE analysis in a wide range of studies, including detection of GI bleeding, detection of small intestinal ulcer and erosion, detection of GI angioectasia, among others [23].

Finally, CAD systems, in particular CADe, are not only limited to disease detection and characterization. Considering the number of elements which can be present in a traditional endoscopy procedure, several researchers started to develop systems to detect and track other objects outside anatomical tracts [26]. Instrument detection, segmentation, tracking and pose estimation are some examples in this context. However, illumination levels, variations in background and the different number of tools in the field of view, pose difficulties to algorithm and model training [27].

Informative Frame Selection

AI is aiding in improving or monitoring endoscopic quality. In this context, informative frame selection systems have been implemented to

monitor the quality standards and reducing the amount of information to process, for example, indicating degrading factors such as noise, acquisition errors, glare, blur, and uneven illumination which can lead to diagnostic errors [28]. Manual revision of endoscopic videos, indeed, is costly and time-consuming. In WCE, for example, a typical recording is composed by more than 50,000 frames and about 45–90 min are required for reviewing it [29]. To minimize these amount of data, a possible step is to eliminate the frames with no diagnostically relevant information, which only serve to degrade the accuracy of video analysis [30]. Such solutions are already having a larger impact on clinical outcomes and are therefore likely to increasingly become a field of interest in endoscopy [31].

In Alizadeh et al. [32], a multi-stage method including active contour, color range ratio, adaptive gamma correction method, canny color edge detection operator, and morphological processing [33] was proposed to discriminate between internal mucosa (informative) and uninformative regions (sensitivity and specificity of 81% and 92%). In Moccia et al. [34], a set of intensity, keypoint-based and textural features, and multi-class SVMs are used to classify informative and three classes of uninformative frames in laryngoscopic videos in NBI (mean AUC of 91% tested on a balanced set of 720 images from 18 different laryngoscopic videos).

Recently, it has been shown that deep-learning algorithms may outperform standard learning approaches for image analysis. Patrini et al. [35] presented a novel approach toward the selection of informative frames in laryngoscopic, also

showing the potential of *transfer learning* in the field. SVMs and CNN-based approaches were used to classify frames as informative and uninformative ones such as blurred, with saliva or specular reflections, and underexposed. The system was tested on a dataset of 18 NBI endoscopic videos, referring to 18 different patients affected by squamous cell carcinoma, achieving Area under the ROC curve of 0.98.

Mosaicking and Surface Reconstruction

Endoscopic procedures have the advantage of providing a minimally invasive intervention implying less burden for both patients and surgeons in order to guide the endoscope and be aware of its position inside the body. However, for the latter, such techniques require a high degree of coordination and fine motor abilities to guide the endoscope and be aware of its position inside the body. Among the causes, a very limited field of view provided by the endoscope and the absence of a direct relation between the displayed image and the physical environment [2]. These problems have raised the interest of researchers and industries in providing methods for assisting the endoscopist by creating an enhanced field of view.

Mosaicking (also called stitching) refer to the process of combining several (partially overlapping) frames from a video sequence of endoscopic images to create a broader field of view or panorama image with a wider perspective. In a typical pipeline (Fig. 3), images are acquired during the endoscopic procedure and pre-processed in order to clean and reduce the amount of input

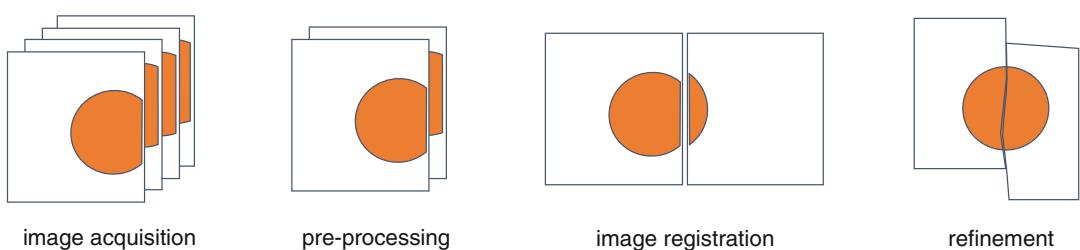

Fig. 3 Typical workflow in image mosaicking

data (e.g., subsampling the number of subsequent images in the video stream which may contain redundant information) [36, 37]. Then, image registration is performed, which is the task of aligning images representing physically connected components [2]. Common approaches include pixel-based or feature-based alignment methods. The first, consider the entire pixel group within the overlapping regions, while the latter extract higher-level features and uses their similarity to compute the match [38, 39]. Often, a further optimization process is performed on the obtained reconstruction to improve the accuracy of the final result [2]. Several techniques, originally developed by the photography and photogrammetry community, have been applied for each step. A comprehensive survey is provided in Szeliski [40], Bergen and Wittenberg [2].

Mosaicking can be applied either by projecting the images onto planar surfaces or, if the scene observed in the images has a significant 3D structure and the camera performs any translational motion, onto an higher dimensional space. Here, mosaicking and 3D surface reconstruction intersect and can be regarded as involving similar problems. In this context, existing works have proposed a software solution to reconstruct the 3D structure of a target organ (e.g., colon, liver, and larynx) with the estimated endoscope poses from an endoscope video. The methods are ranging from shape-from-shading (SfS), structure-from-motion (SfM), visual simultaneous localization and mapping (SLAM) [41, 42]. SfS attempts to retrieve the 3D structure of the human tissue surface by considering variations in illuminations and surface reflectance. Despite its simple assumptions (e.g., all visible surface points will receive the same amount of light from the same direction [43]), this method has provided promising results in endoscopy applications [44, 45]. However, SfS techniques alone may not be appropriate for scenes in which the illumination conditions drastically change during the operation. For this reason, researchers have started to combine SfS methods with SfM methods to simultaneously exploit shading and feature information for the reconstruction of surfaces from endoscopic images [46] and with

SLAM, to also exploit the endoscope trajectory in real-time [47, 48]. Bergen et al. [2] provided a detailed overview of the milestone techniques used for mosaicking and surface reconstruction, surveying relevant applications based on medical branches and anatomical structures.

Recently, DL techniques have been started to catch the interest of the researcher community. Turan et al. uses DL to 3D surface reconstruction methods for endoscopic capsule robots [49]. A particular interest has been observed for the task of predicting depth information in endoscopy from 2D images, where several deep learning approaches have been proposed with promising results [50–52]. However, several work has been conducted concerning homography estimation [53, 54] and fetoscopic mosaicking [55].

Augmented Reality Systems for Intraoperative Assistance and Surgeon Training

Endoscopic simulators are used to virtually reproduce real-life clinical settings. This is particularly important, since both physical and mental burdens for the surgeon may be reduced in the operating room, and trainees may acquire technical proficiency by practicing directly on a live patient [56]. Several possibilities are offered by Augmented Reality (AR), Virtual Reality (VR) systems: from one hand, surgeons can exploit enhanced view during surgery. On the other hand, they allow trainees to experience simulated clinical scenarios by practicing on virtual patients, test their response and benefit from CAD systems in real-time [57]. In AR the users real world is *augmented* by combining live video input with immersive display technology (e.g., computer-generated 3D objects superimposed on the video frames). The objective is to provide the surgeon with additional information about the patient while looking onto the patient. This differs from VR, where the basic elements of the environment are entirely simulated by a computer in an effort to simulate their existence [58]. Despite its long history, which can be dated back in 60s, its only in recent years that AR has started to be used

for medical practice. Localization of specific anatomical structures within the human body was one of the first applications [58, 59]. Bertrand et al. [60] proposed a technique which overlays a deformable preoperative model semi-automatically onto a laparoscopic image using a new software called Hepataug. Their analysis reported the feasibility and the potential interest of using Hepataug to achieve AR with a deformable model in laparoscopic liver resection. Hussain et al. [61] developed and assessed the performance of a video-based augmented reality system, combining preoperative computed tomography and real-time microscopic video. Virtual endoscopy image was registered to the microscope-based video of the intact tympanic membrane based on fiducial markers and a homography transformation was applied during microscope movements. In particular, the system provided additional visual information on the middle ear structures and the surgical instrument with submillimetric precision, compatible for middle ear surgery.

However, since the introduction of wearable headup displays, there has been much interest in the surgical community adapting this technology into routine surgical practice. In a recent survey by Yoon et al. [62], among 74 published articles that evaluated the utility of wearable headup displays in surgical settings, many of them were related to endoscopic surgical procedures. Recently, in Al Janabi et al. [63] the Microsoft HoloLens has been evaluated as a feasible alternative to conventional endoscopic monitors, showing that the device facilitated improved outcomes of performance and was widely accepted as a surgical visual aid by the study participants. In Qian et al. [64], the authors introduce ARsist, an augmented reality application based on an optical see-through head-mounted display, to help the first assistant perform tasks his/her task more efficiently, and hence improve the outcome of robot-assisted laparoscopic surgeries.

Discussion and Perspectives

The use of AI in endoscopy is gaining growing interest because it has the potential to increase the quality of endoscopy at many levels. Real-time and offline detection and diagnosis during

endoscopic procedure have achieved promising results. However, various issues and challenges still emerge before their effective use in clinical applications and medical routines. The first major limitation relies heavily on algorithm generalization capability. As already pointed-out in recent related work [11, 12, 23], multicenter studies should be performed in order to avoid any bias related to the machine used to acquire data. Furthermore, validation should be also focused on nontrivial instances (e.g., high quality frames or sequences, with low variability) to not overrate performances. In this context, limitations of the study should be mentioned in papers, and suggestions for an effective use in clinical settings should be included to help understanding future steps [31]. Also, interpretability of the model (especially DL) should be improved in order to increase algorithm reliability. Nevertheless, some AI products already exist that have obtained regulatory approval, and could be available for clinical use in the next future. For example, *EndoBRAIN* (Olympus, Tokyo, Japan), an AI system to support the diagnosis of colorectal polyps obtained regulatory approval and is now delivered in combination with the endocytoscopy system, therefore facilitating realtime *in vivo* characterization of the tissue [65]. A deep learning solution (GI Genius; Medtronic, Minneapolis, Minn, USA) for the improvement of polyp detection rate on ileocolonoscopy has been released [25]. CAD systems, thus, could represent a significant support for the next future of endoscopy. Novel and promising tools are about to be developed. However, careful guidelines should be provided to endoscopists to help them understand the potential of such novel technologies [31, 66, 67]. This will be crucial to determine the future of detection and diagnosis during endoscopic procedures. Furthermore, AR in endoscopy surgical practice is a valuable field of research which may significantly improve the quality of operations in the next future. The use of wearable headup displays are worth investigating, since they usually result in improved ergonomics compared to traditional procedures in which the surgeon is required to turn his or her head repeatedly to shift visual focus between the surgical field and the imaging monitor [62]. In this direction, reducing the size of

the screen as well as holographic projections represents areas of improvement.

Concerning mosaicking and surface reconstruction, several challenges can still be observed. First, improving algorithm processing time for real-time applications represents an important objective. Some applications have still reached valuable results in providing a panoramic view to be used in clinical settings, while acceleration up to real-time capability still represents an issue [2]. Finally, few work has been successfully conducted on reconstruction and mosaicking of nonrigid structures [68, 69] which achieved valuable results. However, room for improvements and novel ideas should be considered for this task which can be seen as a challenge that has not been solved yet [41]. A framework for dealing with respiration deformation, cardiac motion, organ shift and tissue tool interaction is needed. To this aim, DL solutions could be considered a valuable field to explore where models can be trained at simulating the deformation model [70, 71].

Conclusion

In conclusion, this chapter outlined the current status of research and development and the prospects for application of AI in endoscopy. Such techniques have opened up new possibilities and may become effective in clinical practice by helping physicians, but not by reducing their relevance.

Introduction

Problem Statement

Esophageal cancer is the eighth most common cancer and the sixth leading cause of cancer-related death worldwide [1]. Despite vast improvements in image quality of endoscopes over the years, detection of early lesions fails frequently when surveillance is carried out by general endoscopists who must undertake the bulk of surveillance [2]. Additionally, 80% of all cases occur in less-developed regions, which have less access to experienced physicians as well as specialized equipment. These factors highlight the need for a reliable, cheap, and universal solution for the detection of cancer in the esophagus.

The majority of esophageal cancers can be subdivided into two main histological subtypes: esophageal adenocarcinomas (EAC) and esophageal squamous cell carcinomas (ESCC). A pre-existing condition called Barrett's esophagus (BE) is typically the origin of EACs. BE develops in the lower third of the esophagus when the normal mucosal cells lining the lower portion of the esophagus are replaced with acid-resistant cells that are normally only present in the small intestine and large intestine. In contrast, SCC occurs mostly in flat cells lining the upper two-thirds of the esophagus [3]. Unfortunately, the prognosis for both EACs and ESCC is poor, since the lesions are predominantly identified at an advanced stage. Early detection is paramount as randomized trials have demonstrated that low-morbidity endoscopic treatment (e.g., endoscopic eradication of dysplasia via ablation or resection) reduces the risk of developing late-stage cancer significantly [4, 5]. Endoscopic resection of esophageal cancer at an early stage (i.e., limited to the mucosa or muscularis mucosa) can achieve >90% cure rates without the need for esophagectomy, which carries substantial morbidity [6, 7].

The Case for AI in the Esophagus

The quality of imaging in gastroenterology has increased dramatically in the last few decades.

Current state-of-the-art endoscopy devices are capable of capturing high-definition footage with white light endoscopy (WLE) and several optical chromoscopy techniques. This has caused a paradigm shift in the field of endoscopy from visualization to emphinterpretation. At the same time, the field of computer science has developed at a rapid pace to a point where current computational hardware can be employed to develop sophisticated AI systems for a huge variety of applications [8, 9], including endoscopic imaging [10, 11]. These two factors combined have paved the way for effective use of artificial intelligence in the esophagus. Especially advances in the field of deep learning have had a tremendous impact in the number of such systems [12].

Properly designed and tested AI systems are extremely valuable for the field of endoscopy. The most obvious use case is the early detection of cancer. Both EAC and SCC are especially deadly diseases, since many early lesions are missed, which then progress to cancers for which endoscopic treatment is no longer possible [13]. Despite advances in therapy, the prognosis for patients diagnosed with esophageal cancer remains poor with population-based studies showing a 5-year survival rate of <20% [14, 15]. Prognosis of esophageal cancer depends largely on the stage at the time of diagnosis. Unfortunately, the majority of cancers are only found at an advanced stage [16, 17]. Since most endoscopies are performed at peripheral hospitals, where specific expertise on – and familiarity with – the visual representation of early lesions is typically not present, a computer-aided detection system could save countless lives when performance of the AI is comparable to experts.

Visual identification of early cancer in the esophagus is extremely difficult and a highly subjective task that requires significant effort and experience. Even experts score a sensitivity of only 48% using the most common WLE modality [18]. For this reason, the Seattle protocol was introduced [19], in which biopsies are taken every 1–2 cm in four quadrants. In practice, however, adherence to the protocol is low and research has found that endoscopists systematically undersample patients with long-segment BE

[20]. This leads to more missed lesions and progression to cancer. A biopsy-indicator algorithm could alleviate these problems significantly.

The effectiveness of AI systems is highly dependent on the quality of the endoscopic inspection [21]. A given computer-aided system with perfect accuracy theoretically solves many problems. However, if a lesion is not properly imaged, such systems cannot be used to their full potential. For this reason, patients can greatly benefit from automatic quality inspection of surveillance endoscopies as well. Patients are generally only partially sedated so the esophagus is not impeded from moving during routine endoscopies, especially when inexperienced doctors perform the operation, and patient reflexes cause contractions which may lead to missed lesions. AI can help physicians in this context by either providing feedback about video quality or by automatically selecting the best frames for further analysis.

While artificial intelligence is on the rise in many research and clinical areas, including gastrointestinal imaging, many challenges remain. Simultaneous integration of the technical and medical aspects of these types of studies is often difficult and physical implementation of these systems is much more strenuous than in other fields that are not bound by privacy laws [22]. This work attempts to showcase the research that has been done pertaining to AI in Barrett's esophagus which will help with bridging this gap.

AI for Barrett's Esophagus

Barrett's esophagus (BE) is a medical condition where the normal mucosal cells lining in the lower portion of the esophagus is replaced with acid-resistant cells that are normally only present in the small and large intestine. BE is considered a premalignant condition since the disease is associated with a high incidence of the often-deadly cancer, esophageal adenocarcinoma (EAC). Patients suffering from BE have a 30-fold increased chance of developing EAC. When detected at an early stage, cancer in BE can still be endoscopically treated and has an excellent

prognosis [23]. However, in many cases, early stages of EAC go undetected as routine endoscopic procedures are performed by endoscopists who are unfamiliar with the early visual signs of the disease [24]. Therefore, the recommended protocol entails taking evenly spaced biopsies throughout the esophagus. Unfortunately, studies have shown that the current biopsy protocol is prone to sampling error which leads to missed lesions. As a result, relatively easy-to-treat early cancer develops into late-stage cancer where invasive surgery and radiochemotherapy are the only available treatment options. In the following sections, we will discuss the use of AI systems in Barrett's esophagus. A succinct overview of relevant references is shown in Table 1.

BE Cancer Detection Using White Light Endoscopy

Prior to the deep learning revolution, many researchers attempted to classify dysplasia in Barrett's esophagus using conventional machine learning techniques. Van der Sommen et al. [25] used Gabor filters to extract features from patches of BE images in overview. These features were then used to train a support vector machine (SVM) classifier to make predictions on new patches. A segmentation could then be created from combining the patch scores. Similarly, Souza et al. [26] also employed an SVM to classify dysplasia in BE, but extracted features using color co-occurrence matrices. Others attempt to bridge the gap between deep learning and a handcrafted feature approach by incorporating both in the same model. In the work by Ghatwary et al. [27], Gabor features were combined with features extracted from a DenseNet architecture [28] to perform classification on the Kvasir dataset [29] and a dataset from an endoscopic vision challenge [30]. Van Riel et al. [31] did employ CNNs but used so-called CNN codes. With this approach, a pretrained CNN (generally pretrained using the ImageNet dataset) is used, where features are extracted from the penultimate layer. In this work, Alexnet [32], VGG [33], and GoogleNet [34] were used as feature extractors, and SVM and

random forest [35] were used to further classify the images.

Mendel et al. published the first preliminary results for adenocarcinoma detection using CNNs in the esophagus [36]. In this work, the same endoscopic vision challenge dataset was used by fine-tuning a ResNet model [37] on patches of the full-resolution images. The same group has done more research on WLE images using deep learning since then. In their most recent deep learning WLE study, Ebigo et al. [38] developed a new algorithm with more advanced deep learning techniques, such as spatial pyramid pooling [39], and a state-of-the-art decoder [40]. It is noteworthy that the algorithm is not trained and tested on WLE images in overview but on zoomed in lesions/healthy tissue. Therefore, this algorithm cannot be used for primary detection, however the system shows excellent performance with an overall accuracy of 89.9%. In more recent work of this group, the use of Generative Adversarial Networks (GAN) [41] is proposed to increase the variation of data augmentation [42]. Fake images of Barrett's esophagus are generated alongside real examples in order to increase the variation in the dataset. Results showed that generating artificial patches of BE increases the classification performance compared to using the original dataset alone.

A different group performed an extensive evaluation of many existing deep learning architectures for the detection of early esophageal adenocarcinoma. In work by Ghatwary et al. [43], several object detection frameworks such as Regional-Based Convolutional Neural Networks [44] (R-CNN), Fast R-CNN [45], Faster R-CNN [46], and Single-Shot Multibox Detector

(SSD) [47] are implemented and evaluated on the data from the endoscopic vision challenge. The results from this work show that even with limited data, deep learning can outperform traditional machine learning methods for the detection of cancer. The same group also recently proposed a system for the automatic detection of endoscopic abnormalities from endoscopic video [48]. In this work, a 3D CNN is combined with a convolutional long short-term memory (LSTM) to efficiently learn short- and long-term spatio-temporal features. The learned feature map is then utilized by a Region Proposal Network in order to produce bounding boxes that indicate cancer in the videos. The aforementioned publications regarding endoscopic cancer detection in BE employ relatively little data compared to other deep learning research, which generally perform better with more data. In 2020, Hashimoto et al. [49] published a study with considerably more data (nearly 1,000 images) compared to earlier studies by other groups that only had access to smaller datasets (several hundred). The dataset contained both WLE and NBI images (including zoom imagery). A CNN algorithm was pretrained (on ImageNet) and subsequently fine-tuned to perform binary classification. An additional object detects on algorithm with the goal of drawing bounding boxes surrounding the dysplastic regions. An impressive result of 95% accuracy for classification and mean-average precision of 0.7533 for detection was obtained with real-time performance. However, the algorithm was trained on a limited amount of patients (100 total).

De Groof et al. [50] and Van der Putten et al. [51] recently demonstrated the benefits of using a

very large dataset of endoscopic images ($\approx 500,000$) to *pretrain* a convolutional neural network. Subsequently, a several BE-specific datasets are used to fine-tune the model, each time getting closer to the target domain. They compared their CAD results to 53 physicians in four different skill levels and the results show that the AI algorithm outperforms every doctor by a convincing margin [50]. In later studies, the same algorithm is evaluated live in the clinic with excellent results where 90% of patients get correctly classified by the algorithm [52, 53]. The same group also investigated challenges and opportunities of AI with respect to endoscopic video [54]. A CNN trained on WLE images of EAC was tasked to find lesions in endoscopic video as well. While the results are promising, noninformative frames prove to be a problem. A second problem is how to determine the diagnosis of an entire video when only a small section is actually cancerous, false positives make this a difficult problem. Lastly, a study was conducted into the so-called “field effect,” which theorizes that nondysplastic tissue in dysplastic BE exhibits similar characteristics that are not as obvious as the actual lesion, but might be perceptible by AI. In a study by Verhage et al. [55], a CNN is employed on nondysplastic patches of dysplastic images and compared to patches of a nondysplastic Barrett's esophagus. Results show a statistical difference between the two which indicates the potential presence of a visual field effect.

BE Cancer Detection Using Narrow-Band Imaging

While white light endoscopy is the de facto choice for endoscopic imaging [56], technological advances have led to several alternative imaging modalities with the aim of improving cancer detection and lesion characterization. Narrow-band imaging (NBI) is based on narrowing the spectral transmittance of white light using optical filters with the aim of improving the sensitivity of detecting superficial esophageal cancer [57]. This is often combined with the zoom modality of newer endoscopes aiming to characterize the

cancer (as opposed to primary detection for WLE). Several NBI (non-AI) classification schemes have been proposed in the last decade using a variety of criteria but are still suboptimal [58–60]. Recently, the combination of artificial intelligence and narrow band imaging has been used extensively in other closely related fields such as colonoscopy [10, 61, 62]. For BE, however, the use of NBI data is limited.

In 2009, Rajan et al. [63] used WLE, NBI, and a third modality called acetic acid chromoendoscopy (AAC). Washes of acetic acid are commonly used in colonoscopy to highlight dysplastic areas and thereby enhance the ability to obtain targeted biopsy specimens. This technique can also be used to identify small islands of residual specialized columnar epithelium and thus enhance mucosal pit patterns during endoscopic imaging. In their paper, three classification algorithms (SVM, K-nearest neighbors, and boosting) are used in combination with the three mentioned modalities to classify lesions. Results from the study show that NBI and AAC outperform WLE on their dataset.

NBI can also be combined with WLE to maximize the information extracted from both modalities. Van der Putten et al. [64] uses a small paired dataset of WLE and NBI images (images were taken sequentially with as little camera movement as possible). Regular affine registration was employed to ensure a better match between the two modalities. Two CNNs were trained on the two modalities and results showed that a composite prediction increased the localization performance of the algorithm when compared to only the WLE algorithm. Later, the same group performed a characterization study on a NBI video dataset [65, 66]. The CNN was pretrained on a large endoscopy-specific dataset (same dataset as in [50]) and trained on 183 NBI-zoom videos. The results showed that endoscopic pre-training outperformed natural image pretraining (ImageNet) as well as training from scratch. Additionally, the algorithm was able to run in real time.

Other studies mentioned previously ([26, 36, 49]) also employed NBI images in their datasets. However, in these studies, NBI data was either added to the training data or evaluated separately.

NBI data was not used as a means to enhance the WLE predictions in these cases.

BE Cancer Detection Using Endomicroscopy

Due to the difficulty in detecting early cancer using conventional optical methods such as WLE and NBI, new methods have been developed based on long-wavelength lasers that can penetrate the skin and visualize the subsurface tissue in order to potentially find early lesions in these tissue layers. Endomicroscopy is a technique for obtaining histology-like images from inside the human body in real time, a process known as “optical biopsy.” These methods are unique in the sense that they permit *in vivo* histologic analysis of esophageal mucosa, which is not possible with traditional methods.

1. Probe-based confocal laser endomicroscopy:

Probe-based confocal laser endomicroscopy (pCLE) comprises a fiberoptic bundle that can be inserted into the accessory channel of modern endoscopes. The probe-based system has a fixed focal length, limiting the scan to a single plane. Probe-based CLE is able to obtain very high-magnification and high-resolution images of the mucosal layer of the GI tract. The system operates by detecting reflections of the fluorescence of light through a pinhole [67]. While research has shown that pCLE can lead to an increased specificity for identifying high-grade dysplasia, the associated sensitivity is still low compared to conventional methods.

Grisan et al. [68] introduced a computer diagnosis method in 2012 for classification between intestinal metaplasia (IM), gastric metaplasia (GM), and neoplasia mucosa (NPL) with an overall accuracy of 84%. Feature extraction was performed on an image basis and further processed with a two-stage classifier. First, images were classified as NPL or not. Second, the non-NPL images were further classified as either IM or GM. Leave-one-out cross-validation was used to evaluate performance on 336 CLE images. Later,

Veronese et al. [69] proposed a hybrid approach of image and patch-based feature extraction using intensity distribution values, geometric characteristics, and local binary patterns to determine if an image is IM or not in a similar two-stage approach as prior work [68].

In 2017, Hong et al. [70] investigated whether machine learning models may improve screening accuracy via pCLE and recognize features that may have eluded human visual analysis. A small CNN consisting of four convolutional layers and two max-pooling layers was followed by several fully connected layers. While results look promising, the imbalance in size of different subcategories caused low accuracy for predicting the minority class.

Ghatwary et al. [71] proposed a classification model that discriminated between the IM, GM, and NPL on CLE images. The model was divided into three phases: the first phase was improving the image details by using an ad hoc filter and the second phase was extracting different features, such as intensity features, wavelet features, gray-level co-occurrence matrix (GLCM), fractal dimension, and fuzzy LBP. Later, aiming to improve this result, Ghatwary et al. [72] proposed to use a specific preprocessing filter followed by traditional machine learning techniques. The extracted features were used to train a model, which was subsequently tested on a dataset consisting of 557 images of four different histopathology grades from 96 patients. The model obtained excellent scores (accuracy of 96%) and showed that preprocessing with a discrete wavelet transform improved model performance.

In work by Pulido et al. [73], pCLE *videos* are classified into the same three classes as in [70]. Two video models are introduced that classify frames from a dataset compiled from 78 patients with 10–15 videos per patient examining different areas of the esophagus. Results show high specificity and increased sensitivity when using the proposed model.

2. *Optical coherence tomography:* Optical coherence tomography (OCT) is an emerging optical technique using near-infrared light to generate

high-resolution images of tissue structures, providing noninvasive, subsurface, high-resolution imaging of biological microstructure [74]. The conceptual idea of OCT is comparable to ultrasound, but instead of using the reflection of acoustic waves, OCT uses the scattering of near-infrared light to generate images. Subsequently, consecutive 2D images generated by pullbacks can be reconstructed to 3D structures.

The work by Qi et al. [75] has shown promising results for the detection of dysplasia using endoscopic OCT and texture analysis. Center-symmetric autocorrelation features such as gray-scale texture covariance, local variance, between-pair variance, and within-pair variance were calculated and PCA was used to obtain classification results. An AUC of 84% was obtained with this method. Later, the same group improved on their previous result by using more complex Fourier domain fractal analysis and classification trees [76]. Perfect classification scores (100% accuracy) were achieved with the proposed method.

3. *Volumetric laser endomicroscopy*: Volumetric laser endomicroscopy (VLE) is a second-generation OCT application with a significantly higher image quality compared to standard OCT. The tissue penetration depth of the VLE scan is 3 mm with an axial resolution of $7\text{ }\mu\text{m}$ and a lateral resolution of $40\text{ }\mu\text{m}$. Even though endoscopic OCT can ensure histopathology correlation between the scan and the tissue, only a small portion can be imaged at a time. In contrast, VLE can capture the complete circumferential and longitudinal Barrett segment in a single scan with a much higher image quality. In 2015, Rodriguez-Diaz and Singh et al. [77] presented an algorithm for image interpretation of VLE images using gray-level co-occurrence matrix statistics of the first wavelet components of the image, followed by a naive Bayes classifier. An impressive sensitivity and specificity of 86% and 93%, respectively, were reported for computer-aided classification between dysplastic and nondysplastic BE tissue. Swager et al. presented a computer-aided detection

algorithm where two clinically inspired quantitative image features specific to VLE were developed based on the VLE surface signal and the intensity histogram of several layers. Scheeve et al. [78] also employed a clinically inspired approach where quantitative image features were developed based on gland patterns in the submucosal tissue visualized by VLE. In 2018, Van der Sommen et al. [79] investigated a large variety of imaging features such as GLCM, local binary patterns, and histogram features. Multiple classifiers such as SVM, random forest, KNN, and logistic regression were used to assess the discriminative power of the extracted features. While results were promising, the tissue of interest had to be extracted by hand prior to classification. Work by Van der Putten et al. [80] attempts to solve this problem by creating a deep learning-based segmentation model. The decreasing signal-to-noise ratio in deeper layers of tissue was used to improve the segmentation performance. Resulting segmentations were indistinguishable from experts when compared to interobserver variability of different experts. Fonolla et al. [66, 81] employed an ensemble of CNN models to obtain an AUC of 0.96 on an independent test set in a multicenter study. The study also investigates the most relevant regions of the image by using class activation maps. Finally, Van der Putten et al. [82] proposed principal dimension encoding as a means to incorporate the inherent scanning properties of the VLE modality to improve classification results. First, the region of interest segmentations from earlier work [80] was used to extract relevant tissue. Then, scan lines were encoded one by one prior to classifying with several classification algorithms such as SVM and random forest.

AI for Quality Assessment in the Esophagus

The vast majority of AI research in the gastrointestinal (GI) tract is primarily focused on detection of diseases, often using heavily curated datasets.

While this type of research can lead to algorithms that are extremely useful in clinical practice, the problem remains that you cannot classify what is not properly visualized. In recent years, several algorithms have attempted to improve the quality of endoscopies by detecting informativeness of frames, detecting specific artifacts, or assessing missed regions in the esophagus. For clarity, not all references in this section pertain to the esophagus exclusively, quality assessment of videos and images in other regions of the gastrointestinal tract such as the small intestine are applicable to BE as well in this case.

Early work for the quality assessment in the GI tract was based on traditional feature engineering. In work by Hwang et al. [83], blurry frames are classified based on the number of discontinuing edges on that frame, motivated by the observation that a sharp image typically has fewer isolated edges compared to a blurry image. In later work [84], the same group improved on the classifier by computing eigenvalues of the Fourier spectrum of the frames and using K-means to detect blurry frames. A different group [85] uses a handcrafted “Ring Shape Selective” filter to detect ring shape bubbles in the image. Similarly, Pietri et al. [86] detect bubbles in still frames with four traditional features. For specular reflection detection, Akbari et al. [87] combined RGB and HSV color space features to detect highlights in an image with an SVM classifier. For BE specifically, Van Dongen et al. [88] distinguish frames between informative and noninformative based on a variety of features. Discrete cosine transform-based features, color features, and blur-based features are used in combination with a regression tree to classify frames.

As with most other medical imaging applications, deep learning has also been extensively used for artifact detection in the GI tract. In 2016, Tajbakhsh et al. [89] performed a large study to determine whether fine-tuning outperforms full training. In one of the experiments, informativeness of endoscopic video frames was analyzed and showed that the pretrained network using a large set of labeled natural images provides a better accuracy than a CNN trained from scratch. Islam et al. [90] used CNNs to classify noninformative frames in colonoscopy videos as well. In this study, distinctions were made

between blurry images, and images containing water or bubbles. A very efficient architecture was proposed that traded processing speed for a small decrease in performance. Other methods focus on reconstructing a virtual colon from colonoscopy frames to ensure all areas of the colon have been visualized [91]. A depth-from-intensity technique was proposed to estimate the distance of each fold from the camera using the brightness intensity of selected pixels around fold contours.

For Barrett’s esophagus specifically, Van der Putten et al. [92] employed a CNN to classify individual video frames of BE pullbacks as either informative or noninformative. A hidden Markov model was subsequently used to incorporate temporal information, which helped to improve results. Later, the same group improved on their work by replacing the hidden Markov model by a recurrent neural network [93]. This allows training with video sequences end to end instead of two stages. In other related work, Boers et al. [94] employed a similar recurrent model to detect time sequences in endoscopic pullbacks which contained tissue that could potentially contain Barrett’s cancer with the aim to decrease the amount of false positives.

The body of work on quality assessment in endoscopic video is very large and we only cover a subset of all available publications. For a more complete review of all existing work in this field, we refer to a recent review of De Groen [21], which addresses different aspects that need to be considered when using artificial intelligence to improve adequacy of inspection in gastrointestinal endoscopy which goes deeper into this aspect.

Discussion

The current sampling protocol for surveillance Barrett’s endoscopies is error prone and heavily dependent on the skill of the endoscopist. For this reason, artificial intelligence that can mitigate these problems could be extremely valuable in the fight against esophageal cancer. The technologies that have emerged so far have attempted to replace random biopsies that often claim extremely high accuracies on in-house datasets or highly curated datasets with a nonnegligible

selection bias. However, performance in clinical practice is often never tested. While pilot studies and initial experiments are a natural part of the development process, clinical studies with new images/videos from unseen patients are necessary to properly validate how these algorithms translate to the clinic. Fortunately, there seems to be a paradigm shift in the literature placing higher emphasis on proper validation [22, 95]. The most recent studies [38, 52, 53] have also started testing promising algorithms in the clinic. This is a vital step where interdisciplinary knowledge and resources are of paramount importance.

Other modalities such as NBI and VLE have shown to be beneficial or complimentary to existing WLE algorithms. While the reported performance of these methods is extremely good, none have been evaluated in live endoscopies so far. This might be explained by the fact that white light endoscopy is the standard imaging modality and available to all endoscopists. NBI and VLE on the other hand are much rarer and require expensive specialized equipment. Considering that, when aiming for an improved detection, these methods are to be mainly used in periphery hospitals, sufficient funds might not be available to purchase these devices. This limits the applicability of these techniques, especially if standard white light endoscopy provides similar performance.

Given that dysplasias in Barrett's esophagus are nonpolypoid, a higher skill level is required of the endoscopists in order to achieve a good detection rate. Unfortunately, most practicing endoscopists have suboptimal detection and miss lesions despite being detectable by an expert endoscopist. A second problem is the relatively low prevalence of BE dysplasia, which inhibits an extensive training program. If the performance (90 + % accuracy) of the models in the clinical pilot studies prove to hold true, most endoscopists in peripheral centers will likely perform much better when assisted by AI. Another factor that compounds the problem is that endoscopists tend to specialize in one specific disease according to the prevalence specific to the country. In contrast, given a dataset of sufficient size, AI can be trained to classify any number of diseases. This is showcased by high accuracies on a large amount of different diseases that use very similar models (CNN with residual connections).

The research on quality assessment of endoscopies is broadly acknowledged to be very promising. Many of the proposed algorithms present high accuracies for either detecting non-informative frames in a video sequence or detection of unwanted artifacts such as bubbles or specular reflections in endoscopic images. Interestingly, no studies have been performed so far that combine the quality algorithms with cancer detection algorithms to improve cancer detection performance. Additionally, to the best of our knowledge, these algorithms have also not been tested in the clinic to improve cancer detection by endoscopists. One opportunity for future work would be to combine quality assessment algorithms with cancer detection algorithms that can be trained and evaluated on data that is not heavily curated. A second opportunity for future work that would have tremendous value would be to use quality assurance algorithms in the clinic with nonexpert endoscopists to assess whether their detection rate improves compared to nonexperts that do not use these algorithms. A third avenue that has not yet been explored is the effect that AI has on the user. On the one hand, human performance may improve by the mere fact of being watched by AI (the Hawthorne effect), on the other hand the sense that AI is watching and there is less need to carefully inspect the tissue may cause the endoscopist to produce suboptimal videos. Unfortunately, even the best AI cannot compensate for poor input quality.

In this review, developments of AI in Barrett's esophagus have been discussed. While it is evident that a lot of research is focused on computer-aided detection and segmentation of cancer in BE, most algorithms are not ready for clinical implementation. Regardless, the current research is very promising and developments in the field will provide many opportunities for the future of AI in Barrett's esophagus and ideally improve patient care.

Abstract

Colorectal cancer (CRC) is one of the leading causes of death worldwide. Fortunately, its early detection and treatment highly improves the survival rates and reduces costs. In this regard, screening programs and colonoscopy

play an essential role. Artificial intelligence (AI) and deep learning (DL) have arisen with great success and been widely applied to medical imaging for the last few years and efforts have also been placed to develop methods to improve the adenoma detection rate in colonoscopy. In this chapter, polyp detection, localization, segmentation, and classification using colonoscopy are addressed. Works on these tasks have shown an exponential growth in the last few years. In the first place, the elements required for applying supervised DL methods for colorectal polyps in colonoscopy are introduced. The focus is placed on the model architecture, the dataset, the loss function, data augmentation, and metrics. Next, the currently openly available datasets that might be useful for future research are presented, before discussing methods for polyp detection, localization, segmentation, and classification.

Supplementary Information: The online version of this chapter (https://doi.org/10.1007/978-3-030-64573-1_308) contains supplementary material, which is available to authorized users.

Lastly, some challenges and future trends in these fields are commented. This chapter about AI and DL for colorectal polyps in colonoscopy put forward the wide range of applications and research lines that can be further investigated with promising results as shown by the already currently published works, and always with the ultimate goal of assisting the endoscopist to improve CRC detection and diagnosis, which would eventually lead to better patient outcomes.

Keywords

Colorectal polyps · Detection · Localization · Segmentation · Classification · Colorectal cancer · Artificial intelligence · Deep learning

Introduction

Colorectal cancer (CRC) is defined as a carcinoma, most commonly an adenocarcinoma, located in the colon or rectum [1]. It is estimated that the number of incident cases and number of deaths will double from 2018 to 2040, reaching over one million deaths yearly [2], even though early detection of CRC highly improves the 5-year survival rate up to 88.5% if detected in an initial stage [3], which also implies a high reduction of costs [4]. In this regard, screening programs and colonoscopy play an essential role. Colonoscopy is the visual exploration of the colon and rectum by inserting a flexible endoscope through the anus [5]. During the procedure, precursor lesions of CRC can be detected, so the most convenient strategy can follow. This might range from leaving the lesion and scheduling a surgical intervention for its removal if it is an advanced stage, to the strategies of “diagnose and leave behind” or “resect and discard” of diminutive polyps that present a low risk of developing CRC, as long as their histopathology can be assessed in real time with high accuracy [6]. Nevertheless, the most common and traditional approach is to remove the lesion during colonoscopy and send it for pathological analysis. In any case, the removal of pre-malign lesions, if deemed

necessary, is associated with the reduction of CRC mortality [7]. The adenoma detection rate (ADR) of the endoscopist is defined as the percentage of colonoscopies performed with at least one adenoma identified. It is shown that the higher the ADR is, the lower the rate of detecting CRC after screening examination [8]. This is also known as interval CRC and that can be defined as a CRC “diagnosed after a screening or surveillance examination in which no cancer is detected, and before the date of the next recommended examination” [9].

Computer-Assisted Detection (CADe) and Computer-Assisted Diagnosis (CADx) have the potential to improve colonoscopy on three key areas: (1) adequacy of mucosal inspection, (2) polyp detection, and (3) optical biopsy [10]. This chapter is focused on the last two. Moreover, artificial intelligence (AI) and deep learning (DL) have arisen with great success and been widely applied to medical imaging for the last few years, obtaining a similar performance to experts in many fields. Undoubtedly, efforts have also been placed to develop AI and DL methods to improve the ADR in colonoscopy, although more randomized controlled trials are still necessary [11]. These methods can be designed to fulfill one or more of the following tasks related to CADe and CADx for colorectal polyps (Fig. 1):

1. Polyp detection: In this case, the aim is to label the frame, indicating whether a polyp is shown or not in it, without further information. In this chapter, image and frame will be used indistinctly, as images are actually frames from a video or can be considered as such.
2. Polyp localization: In this task, the position of the polyp is given within the corresponding frame, either by a bounding-box, a circle, or the center coordinates.
3. Polyp segmentation: In the frame, a precise delimitation of the polyp area is obtained.
4. Polyp classification: For a given polyp, the objective is to label it as benign/malign or as a category of any classification schema, such as Paris [12], Kudo [13] or NICE [14]. This can be considered as “optical biopsy,” as it allows for an *in situ* diagnosis.

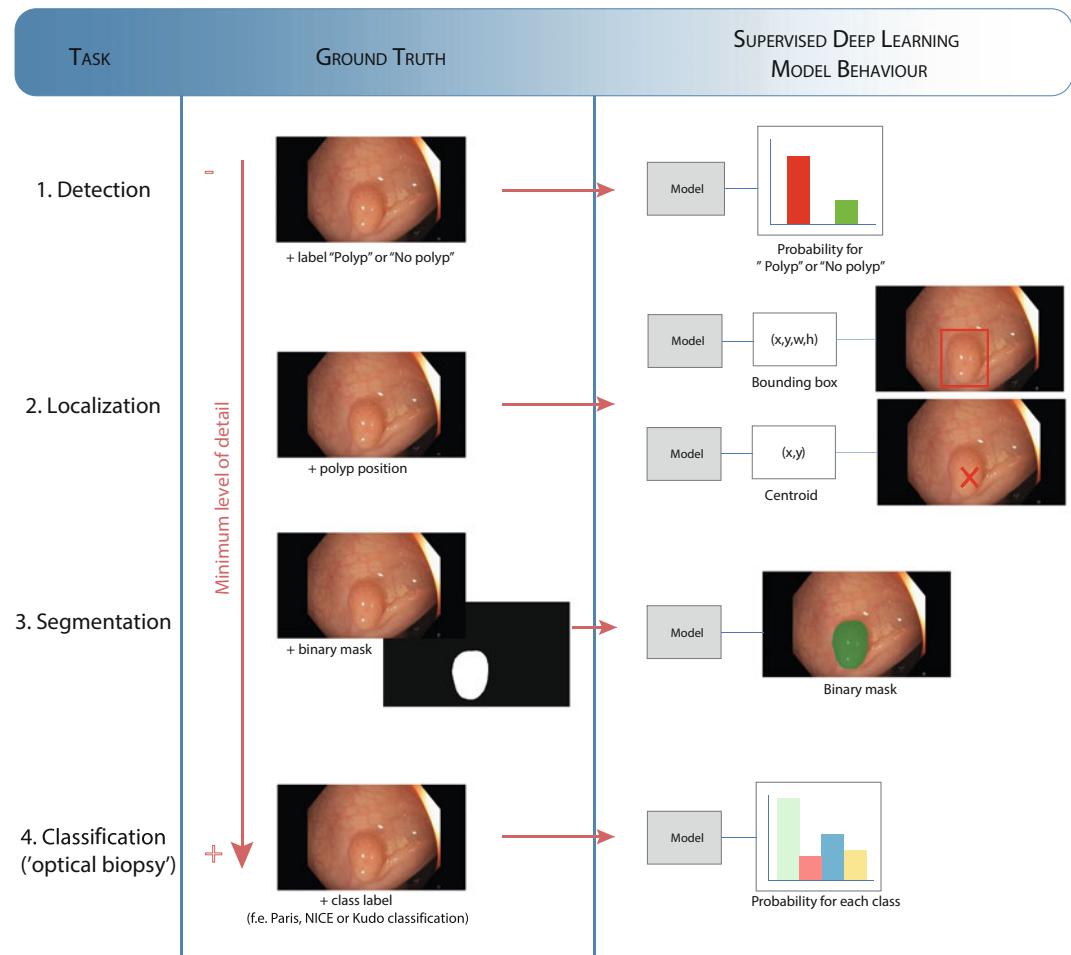

Fig. 1 Tasks considered in this chapter. Ground truth and model behavior for the four tasks are also included

Several recent reviews gather the wide spectrum of methods for detection, localization, segmentation, and classification of colorectal polyps [15–18]. These fields have had great success for the last few years. A quick search only on the Web of Science using the search string “deep learning” AND “colorectal” AND “polyp” AND (detection OR localization OR segmentation OR classification) shows the exponential growth in the field of this chapter (Fig. 2). It is clear that the increasing technical capacities, together with the high impact on mortality that early detection of CRC has, are essential to keep moving forward in this field. Currently, some of the published methods have already been deployed into the market, such as GI Genius module from Medtronic, CAD EYE from

Fujifilm, or AI4G from AI4GI and Olympus [19]. Lastly, it is also worth mentioning the value of AI for the diagnose-and-leave strategy, as it saves cost of unnecessary polypectomies and pathologic examinations, meaning an estimated reduction between 6.9% and 18.9% of the gross annual reimbursement for colonoscopies upon the country [20].

This chapter is organized as follows: Firstly, the elements required for applying supervised DL methods for colorectal polyps in colonoscopy are described. The currently openly available datasets that might be useful for future research are presented, to then further discuss methods for polyp detection, localization, segmentation, and classification. For the sake of the chapter extension,

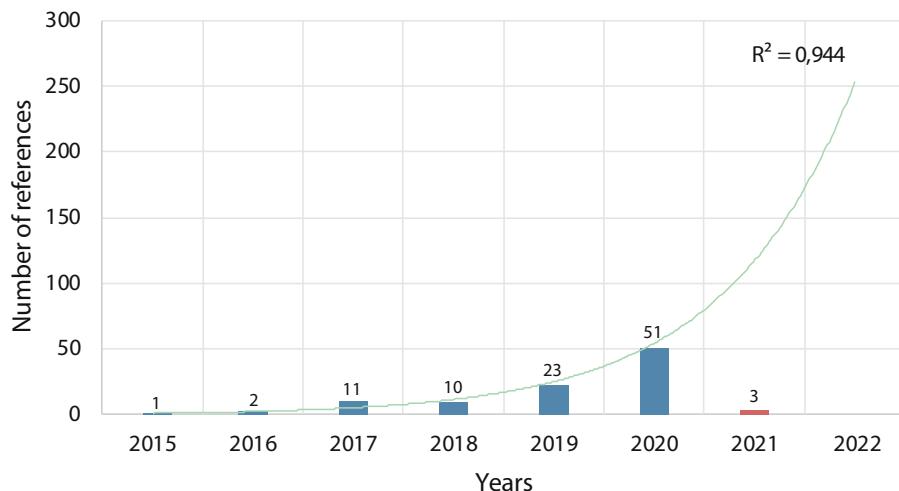

Fig. 2 Trend for publications in the fields of detection, localization, segmentation, and classification methods for colorectal polyps using deep learning (search performed on 25 January 2021)

detailed references to reviews are included, and the reader is encouraged to peruse them for further description of the AI and DL methods. Lastly, we comment on some challenges and future trends in these fields.

Components for Developing DL

Before going into detail, the components that should be considered when developing a DL model for colorectal polyps are briefly revised (Fig. 3):

1. An annotated dataset of colorectal polyps is needed. To this end, a proprietary dataset or any of the openly available datasets presented in the following section can be used. As indicated in Fig. 1, ground truth information might have different level of detail that should be directly related to the desired task to accomplish, but in any case, it should be provided by a clinical expert. For instance, at least the position of the polyp would be necessary for its localization; as labels would not be enough. It is also possible to take advantage of larger datasets not related to colorectal polyps, such as ImageNET, MSCoco, or PascalVOC, by using them to pretrain either the encoder/

classification network or the whole model, which will be then fine-tuned with the dataset of colorectal polyps. When splitting the dataset into training, validation, and test set, patient independence between sets must be assured. Each set is intended to be used at a different point during the process.

2. Strategies to overcome scarce and/or weak annotations might also be needed [21]. Medical imaging datasets are usually limited in size, so one of the most common strategies is data augmentation that consist of an artificial increase of the training set by transforming the original image. Among the possible transformations, they can be classified depending on the level at which they are applied into [22]:
 - (a) Image-level: such as width and height shifts, rotation, or shear. In these cases, the image is modified, and while this does not alter the label assigned to the image, it requires that the binary mask, if available, is modified in the same way.
 - (b) Pixel-level: such as changes in brightness and contrast. These modifications do not alter the label or the mask, as they only affect the pixel values of the RGB channels.
 - (c) Problem-based: these transformations mimic particularities of the endoscopic

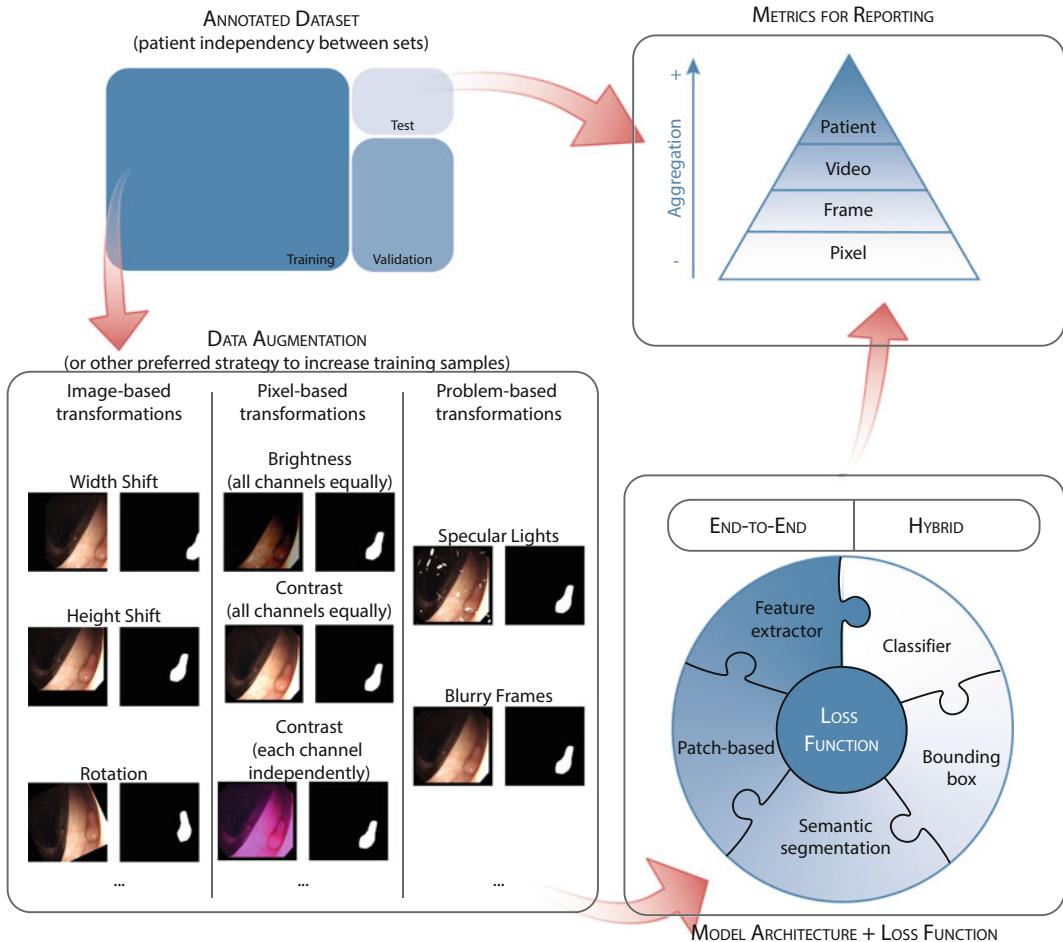

Fig. 3 Schematic setup of DL methods for colorectal polyps and necessary elements

images, such as the presence of specular lights or blurry frames.

3. An appropriate model architecture matching our objective task should be selected, created, and/or modified. In a previous work, a two-level classification scheme was defined [15]. In the first level, methods are classified into end-to-end, if one single DL approach is used to accomplish the task, and hybrid methods, if a DL approach is combined with other hand-crafted method. On the second level, we defined five approaches depending on their use of the DL architecture (Fig. 4):
 - (a) Feature extractor: The model is used to automatically create a feature vector that

is the input of a traditional classifier, such as Support Vector Machine.

- (b) Classification: A classification network is used in detection tasks to label an image as containing a polyp or not, without positioning of the polyp, or in the classification task to assign the most probable class of the classification scheme.
- (c) Patch-based: The presence of polyp is obtained for each image patch or tile, so the location of the polyp might be obtained based on the patch location.
- (d) Bounding-box: The location of the polyp through a bounding-box (coordinates of the upper right corner, height, and width)

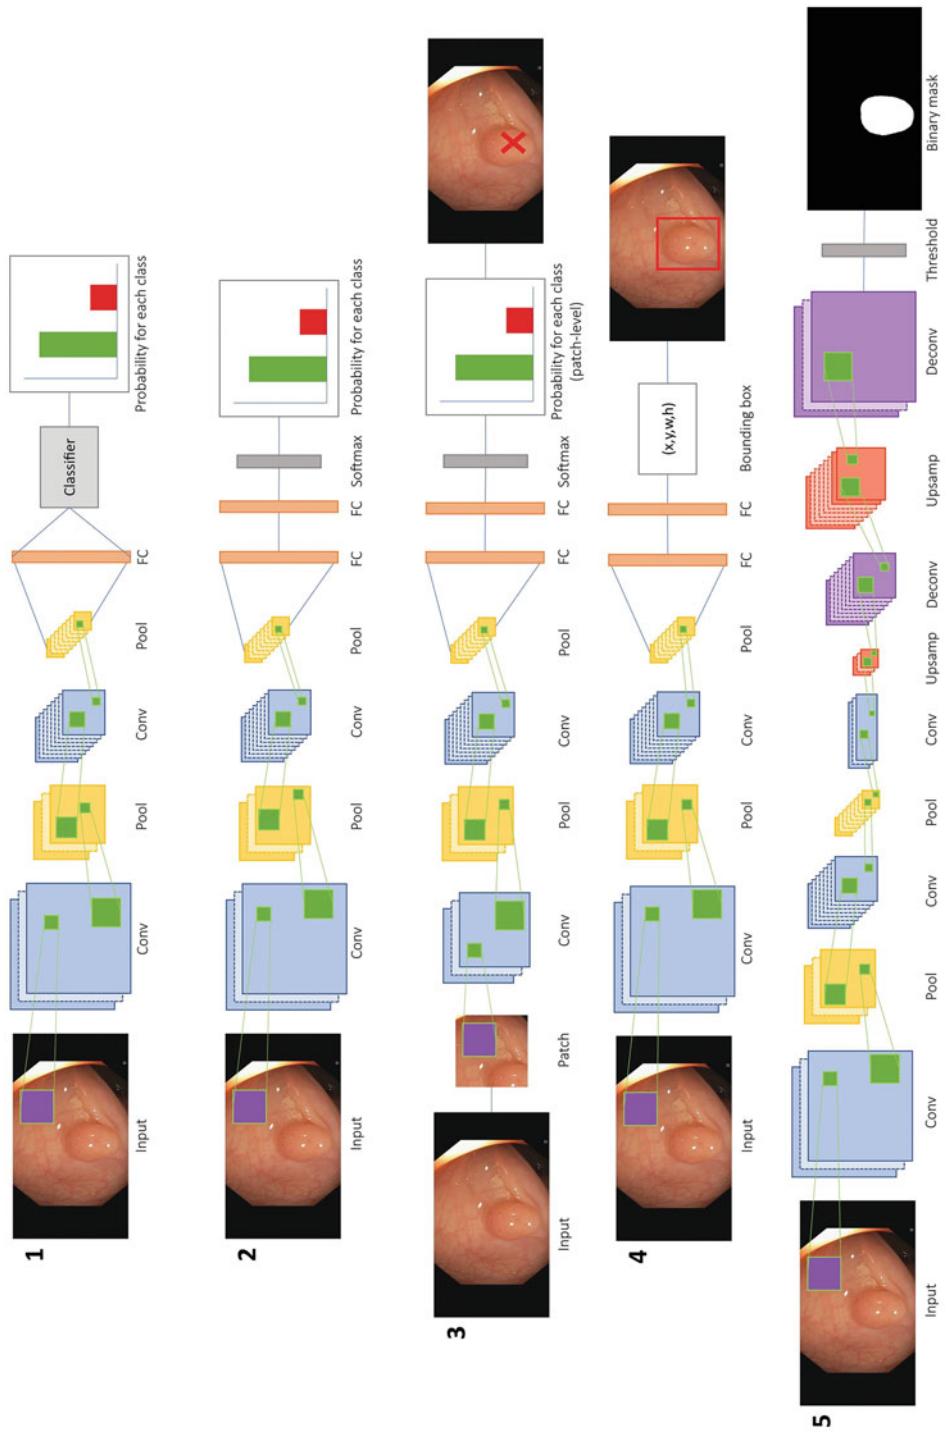

Fig. 4 Schematic representation of different approaches for polyp detection, localization, segmentation, and/or classification. From top to bottom, (1) feature extractor, (2) classification, (3) patch-based, (4) bounding-box, and (5) semantic segmentation. Each type of layer is represented by a different color: convolutional layer (conv), pooling layer (pool), fully connected layer (FC), upsampling layer (upsamp), and deconvolutional layer (deconv). The receptive field is marked with a green square. (Reproduced from [15] under Creative Commons License CC BY-NC-ND 4.0)

Fig. 4 Schematic representation of different approaches for polyp detection, localization, segmentation, and/or classification. From top to bottom, (1) feature extractor, (2) classification, (3) patch-based, (4) bounding-box, and (5) semantic segmentation. Each type of layer is represented by a different color: convolutional layer (conv),

is given by the DL method, generally using a regression layer.

- (e) Semantic segmentation: The image is labeled at a pixel-level either as polyp or background. Encoder-decoder networks are usually selected for this task. While encoder or first half of the layers encode the image description highlighting the discriminative features, the decoder or second half is responsible for mapping the low-resolution encoding into full input resolution feature maps.

End-to-end methods are surpassing hybrid ones, thanks to the increasing computing capacity of systems. Convolutional Neural Networks (CNNs) are the most used DL architectures for detection, localization, and classification, while Fully Convolutional Networks (FCNs) are preferred for segmentation tasks [15, 18]. Other architectures, such as Recurrent Neural Networks (RNNs) or Generative Adversarial Networks (GANs), can also be found in the literature for some of the considered tasks in this chapter. Classical architectures as AlexNet, VGG16, or VGG19, and GoogLeNet are widely used as backbone/feature extractor/encoder in our field. These FCNs can be initialized from the weights of a classification network (encoder) that acts as a feature extractor.

4. A suitable loss function should be employed, bearing in mind the target task. In this regard, we can use either widely known loss functions, such as binary cross entropy and Jaccard loss function for classification and segmentation, respectively, or custom-made loss functions [23]. When selecting the loss function, it is advisable to take into account the distribution of the dataset, i.e., the distribution of polyp/no polyp images, the proportion of pixels labeled as polyp or no polyp, or the proportion of examples for each class in a classification task. With balanced datasets, a traditional loss function might suffer; otherwise, a specific loss function might be necessary to overcome the imbalance toward the positive class.

5. Selection of reporting metrics, which will compare the obtained result of the model with the ground truth in any format (label, bounding-box, and/or binary mask). In most cases, they are based on the confusion matrix: true positives (TN), true negative (TN), false positives (FP), and false negatives (FN), such as accuracy, precision, recall, and specificity as well as combination of these, such as F1-score and F2-score. Furthermore, widely used overlap measures, such as the Jaccard index or Dice index, can also be determined based on the confusion matrix elements. It is highly recommended to report results in more than one single metric [18]. Although this issue might seem irrelevant, a poor selection of metrics might result on artificially increasing the DL performance and failing to show if the model works correctly and in the best way. For polyp detection, localization, segmentation, and detection, several reviews [15, 16, 18] identified the wide range of metrics used, which makes more difficult to fairly compare methods. Furthermore, the same metric can be calculated at different levels: pixel, frame, video, or patient-level, for a different level of aggregation. Depending on the task, one or another might be more convenient. Figure 5 illustrates different casuistries for a segmentation task, where six frames from three polyps compose the test set. While the accuracy, which includes TN in the numerator, reaches values above 0.750 in all cases, the Jaccard index, as overlap measure, penalizes both FP and FN, showing differences between the different frames A to F. The analysis of metrics per polyp instead of considering all frames together, regardless of their origin, lead also to different results. In this example, polyp 3 is much worse segmented than polyp 1 in average, but this cannot be identified if the test set is analyzed as a whole; therefore a per polyp analysis could give further information on which ones are poorly detected and/or segmented to further improve the DL method in those particular cases. Similarly, and assuming detection if the Jaccard index is above the 0.5 threshold, differences can be also observed

		POLYP 1			POLYP 2			POLYP 3			
		Frame A	Frame B	Frame C	Frame D	Frame E	Frame F				
TP	20	15	17	17	5	5	5	Average			
TN	80	75	78	58	80	70					
FP	0	5	5	10	0	15					
FN	0	5	0	15	15	10					
Accuracy	1.000	0.900	0.950	0.750	0.850	0.750		0.867			
per polyp	0.950			0.800				0.833			
Jaccard	1.000	0.600	0.773	0.405	0.250	0.167		0.532			
per polyp	0.791			0.208				0.468			
detection ($J > 0.5$)	1	1	1	0	0	0		0.500			
per polyp	1			0				0.333			

Fig. 5 Comparison of metrics. TP: True Positives. TN: True Negatives. FP: False Positives. FN: False Negatives. Accuracy is calculated as $(TP+TN)/(TP+TN+FP+FN)$, while

Jaccard is calculated as $TP/(TP+FP+FN)$. Dashed line indicates the polyp ground truth

between the analysis per polyp or per frame, decreasing the capacity of detection from 50% to 33%.

It is also important to highlight that some features of the endoscopic images might have an impact on the image processing analysis [17], which is the basis of any AI or DL method. On one side, features derived from the acquisition process, such as color artifacts or interlacing and, more importantly, the presence of specular lights due to the perpendicular incidence of the endoscope light source onto a shiny surface. On the other side, there are also features derived from the endoscopic image per se, such as a wide variety of polyp appearances.

Datasets

The limited size of datasets for medical imaging analysis using AI and DL is one well-known challenge to address. Having to annotate and/or segment the images, videos, or studies is a cumbersome, time-consuming task. Furthermore, this process must be done by clinical experts with

wide knowledge and experience, who usually lack time for these tasks. Therefore, there is still a need to create larger, publicly available datasets in a collaborative manner. Nevertheless, there are currently different public datasets that can be used to train DL models in the field of colorectal polyps in colonoscopy:

1. CVC-EndoSceneStill [24] is a manually segmented dataset compiling and improving two other datasets, CVC-ColonDB and CVC-ClinicDB. It includes 912 images from 44 video sequences from 36 patients. Annotations include a binary mask for the lumen, specular lights, polyp, and void areas. Furthermore, division into training, validation, and test sets is provided by the owners.
2. CVC-VideoClinicDB [25, 26] gathers 18 video sequences showing a polyp. In this case, annotations are binary masks showing ellipses that approximate the polyp area. This way, annotated frames come to 9.221 polyp frames, out of a total of 10.924 frames.
3. ETIS-Larib [27, 28] provides 196 white light (WL) images from 34 sequences showing

- 44 different polyps. The provided ground truth is binary masks manually annotated.
4. ASU-Mayo Clinic [29] provides binary masks for 20 annotated videos as well as other 18 videos for testing for which ground truth is not available. Frames include both WL and narrow band imaging (NBI).
 5. Kvasir-SEG [30] provides a manually delimitated binary mask for 1.000 polyp images, together with the corresponding bounding-boxes in a JSON file. It is also part of a larger dataset for gastrointestinal endoscopy called HyperKvasir [31].
 6. PICCOLO WL and NBI colonoscopic dataset [32] comprises 3.433 polyp frames from 76 lesions from 40 patients, also divided into training, validation, and test sets assuring patient independence between them. This dataset also provides clinical metadata of the lesions, including size, Paris and NICE classification, and histological diagnosis.
 7. Mesejo et al. [33] provide WL and NBI videos for 15 serrated adenomas, 21 hyperplastic lesions, and 40 adenoma.

Furthermore, Nogueira-Rodríguez et al. [16] provide an extensive summary of proprietary datasets, which have been used by several authors when they had access to such clinical information.

Depending on the aimed task, one or another dataset might be more convenient, depending on the ground truth provided. In any case, they might also be used in conjunction, both public and proprietary, to increase the number and variety of samples, either for training or to assure transferability at testing phase. In this regard, three public datasets, CVC-EndoSceneStill, Kvasir-SEG, and PICCOLO datasets have been compared, finding that PICCOLO shows better generalization capabilities [32].

The datasets should gather all range of polyp variability. While this is the ideal situation, it is still far from being accomplished since flat polyps are usually underrepresented in those public datasets. Flat polyps are the most difficult ones to detect [32], so CADe systems would play an essential role to assist endoscopists to reduce their miss rate. A joint global initiative would help

(1) to collect a larger sample of abnormal cases like these flat polyps, which are usually less frequent; (2) to have good quality annotations; and (3) to increase variability of the acquisition devices, which would eventually result in more robust AI and DL methods.

One last remark is the need for a common reporting framework. In order to perform a fair comparison of the different methods, the same images and metrics should be used. Therefore, it would be advisable to establish a set of criteria and guidelines for the authors to follow. Patient independency between training and reporting sets must be assured in any case, so it is highly encouraged that the dataset owners establish a distribution into training, validation, and test sets or the definition of a bootstrapping methodology.

Polyp Detection and Localization

Detecting and locating a polyp is the trigger event for CRC diagnosis. Therefore, this is directly related to improving the ADR, as DL models will help endoscopists to ensure that no lesions are missed during the colonoscopy procedure that would eventually develop CRC. Therefore, these DL methods have a highly important clinical implication and the eventual increment of the ADR, will lead to a reduction of interval CRC and its associated mortality. In this regard, subtle lesions are prone to be missed even for trained endoscopists, so CADe systems would play an important role. In this regard, Guo et al. [34] have analyzed a YOLOv3 CADe system, which achieved a similar sensitivity to experts and superior to physicians in training, using 50 short videos showing one or two polyps of mean size 3.5 ± 1.5 mm. This fact emphasizes the utility of AI and DL for diminutive, subtle lesions that might be missed even by more experienced endoscopists.

There are several reviews that summarize the state of the art of detection and localization methods either from a technical or a clinical point of view. From a more clinical approach, Barua et al. [35] analyzed five randomized trials and concluded that the number of small adenomas

(≤ 5 mm) found in colonoscopy assisted by AI methods was higher than without AI assistance, while the number of large adenomas (> 5 mm) remained similar. On the other hand, placing the focus on the technical aspects of DL methods, Sanchez-Peralta et al. [15] systematically reviewed the state of the art and found 26 works related to detection and localization. They found that end-to-end and hybrid methods have an equal presence, but the trend is toward the use of end-to-end methods. In a similar approach, Nogueira-Rodríguez et al. [16] included 21 works for detection and localization in conventional colonoscopy, identifying those able to detect multiple polyps in real time. In a more extensive manner, Pacal et al. [18] reviewed polyp detection and localization in different imaging modalities, including 35 works that use colonoscopy.

Nevertheless, most papers gathered in those presented reviews are focused on still frames from the datasets, either public or proprietary. In this situation, the temporal coherence of the presence of a polyp in a video cannot be exploited. Since the polyp would not abruptly disappear from one frame to the next one, the use of videos instead of still frames would allow the inclusion of this temporal dependency. In this line, a recent work by González-Bueno Puyal et al. [36] proposed a 2D/3D CNN for segmentation where five consecutive frames are considered as compromised between new temporal information and detection speed. Another relevant aspect is the reduction of frequent false positives since they may lead to operator burnout and/or diminished trust in the system. Qadir et al. [37] proposed a two-stage method that combines a CNN-based detector with a false positive reduction unit to overcome this situation. In this regard, Holzwanger et al. [38] recommended a time-based threshold of 2 s to maximize specificity and accuracy.

Regarding metrics, analysis of results for polyp detection and localization is usually done at image or frame-level, as either the presence or absence of polyps is indicated individually. Metrics based on the confusion matrix such as accuracy, precision, or recall are useful as they show the proportion of correct or incorrect labeled frames, and although

they are all widely used, recall has been found in a larger number of works [15]. Nevertheless, it would also be advisable to report detection per-polyp, establishing a threshold, such as Misawa et al. [39], who established that a polyp is correctly detected if the model identifies it more than 75% of the time it appears in the video. In the case of localization, and as long as a bounding-box is available as ground truth, overlap measures could be used, similarly to the task of polyp segmentation.

Polyp Segmentation

Once the presence of a polyp is confirmed in a given frame, it might be useful to determine the area that is considered to be lesion, for assisting on its removal if necessary. If this is done, a safety margin should also be taken into account. Therefore, for this task, segmentation methods should be applied to determine the precise contour of the polyp. Endoscopists will benefit from a precise polyp segmentation to assess the resection margins. In this case, it is essential to remove completely the lesion without leaving behind any part of it that could reproduce or evolve into CRC.

Similarly to the methods for detection and localization, segmentation models have also been reviewed in 2 works [15, 18] but their presence is not so wide as the former, finding 10 and 14 works, respectively. This might be due to the lack of widely annotated datasets, as it is less time consuming to label one frame than manually annotate the polyp area in an image. To overcome this, different solutions are provided for medical image in general [21]. Out of those, data augmentation is one of the most common techniques addressed for polyp segmentation [15, 16], although there is no consensus on the most beneficial transformations and they are mainly selected on a trial and error basis, and based on the researcher experience. In this regard, the effect of different transformations on two publicly available datasets has been studied [22] and it has been determined that, while polyp segmentation using CVC-EndoSceneStill benefits from pixel-based

transformations such as changes in brightness and contrast (even if they are not commonly used), if Kvasir-SEG is employed, then image-based transformations are recommended, especially rotation and shear. In any case, it is important to remark that including more intense data augmentation does not always lead to an increased performance [40].

For polyp segmentation, the combination of end-to-end and semantic segmentation models are the most commonly used methodology [15]; this means that the task is accomplished as a whole. Therefore, the use of encoder-decoder architectures is preferred. While the encoder transforms the input image into a feature vector capturing the context information, the decoder recovers the spatial information lost in the previous process. These encoder-decoder architectures can be based on off-the-self networks or designed on purpose for polyp segmentation. As an example of the first case, four different models are created by combining two backbones or encoders (VGG-16 [41] and Densenet121 [42]) with two different ways of joining the encoder and decoder (U-Net-based [43], so information is either concatenated, or added, if it is LinkNet-based [44]) to analyze the influence of the loss function on polyp segmentation [23]. On the other hand, Mahmud et al. [45] have designed the PolySegNet. Although it is based on U-Net, it incorporates three major building blocks to overcome initial limitations for polyp segmentation, so it achieves a Dice score over 84% in all the four public datasets used.

For polyp segmentation, overlap measures are generally taken into account. Either the Jaccard index, also known as Intersection over Union (IoU), or the Dice index are widely used, but despite this, it would also be advisable to further include distance metrics valid for small segments, such as Hausdorff distance or Mahalanobis distance [15]. Since semantic segmentation can also be seen as detection at pixel-level, by labeling each pixel as either belonging to the polyp or no polyp class, the metrics indicated in the polyp detection section might also be applied as long as they are calculated at pixel-level. In this case, it is important to emphasize that due to the

unbalanced situation, as the polyp area is generally much smaller than the background class, metrics including true negatives, such as the specificity, might obtain high values even when the polyp is poorly or not detected at all.

Polyp Classification

Lastly, classification methods allow for polyp characterization or an “optical biopsy” or “optical diagnosis,” that is, giving a clinical diagnosis in real time without the need of removing the lesion and sending the sample for histological analysis [46]. This way, patient safety might be increasing by not removing lesions without malignancy capacity, while time and costs are reduced. The strategy of “diagnose and leave behind” would benefit from real-time, in-situ accurate diagnosis, as long as the methods surpass the minimum value of 90% for the negative predictive value (NPV) requested by the American Society for Gastrointestinal Endoscopy [6].

Although polyp detection can also be seen as a classification between healthy tissue and lesion, in this section we refer to the determination of the type of lesion once it is detected. Reviews [16, 18] consistently found much less works for polyp classification based on WL images from colonoscopy, which possibly is due to the lack of clinical information in most of the publicly available datasets. This situation hinders the wider development of CADx systems by the scientific community and puts forward again the need for joint collaboration to create such datasets. Besides, this lack of methods is also due to the use of other imaging modalities, such as NBI, confocal endomicroscopy, or magnifying chromoendoscopy, for polyp characterization [46, 47].

Therefore, these classification methods might use any of the different classification approaches for colorectal lesions, but in most cases, they rely on NBI image rather than WL images [16], since in the clinical setting, WL is normally used for detection and once the lesion is detected, the imaging modality is switched to NBI, when available, for diagnosis, as this image modality highlights patterns useful for diagnosis. For example,

Patino-Barrientos et al. [48] used a pretrained VGG model as feature extractor to classify polyps according to the Kudo's pit pattern schema. They obtained 83% accuracy and F1-score, and their method outperformed traditional techniques where features are manually extracted. On a different scale, Rodriguez-Diaz et al. [49] classified previously segmented lesions into neoplastic (including tubular adenomas, tubulovillous adenomas, and adenocarcinomas) or non-neoplastic (including hyperplastic polyps and polypoid-appearing normal colonic mucosa). In this case, the NPV equaled 0.91 but the model is limited to near-focus NBI polyp images. More recently, Jin et al. [50] go a step further and included interpretable explanation to the optical diagnosis by overlapping a heatmap showing the probability within the image.

Metrics for polyp classification are usually calculated at frame level, although it would be more convenient to establish a diagnosis per polyp such as Byrne et al. [51], who trained a CNN to classify NBI frames into type 1 and 2 of the NICE classification, achieving an accuracy of 94% in 106 diminutive polyps.

Conclusions and Future Trends

Undoubtedly, AI and DL have come also to improve colonoscopy and polyp detection, localization, segmentation, and classification. The large amount of works over the last few years show that AI and DL methods have the potential to improve CADe and CADx systems in order to increase CRC early diagnosis and eventually reduce its associated mortality.

This potential is well recognized, and the American Society for Gastrointestinal Endoscopy has recently published a White Paper, where polyp detection and diagnosis are included as priority clinical use cases for developing AI algorithms [52]. There are also key research questions that remain unsolved. Ahmad et al. [53] followed a Delphi approach and determined guidance for future research on performance metrics, clinical trials design, and end points; technological developments,

clinical adoption, and integration into endoscopy; data (access, sharing/privacy, curation, and annotation); and regulatory approvals. Among these questions, it is worth to highlight the need to improve performance of more challenging and advanced lesions, such as subtle, flat lesions and sessile serrated lesions, as well as the need to reduce false positive rates to avoid the “alert fatigue,” and the need for real-time systems with minimal latency. Similarly, Hoerter et al. [54] also identified current challenges in terms of standardization of outcomes, training and testing datasets, real-world application, as well as regulatory approval and reimbursement. In all cases, it is clear that further studies are still necessary until a wide application of AI and DL methods for colorectal polyps in the clinical daily practice of colonoscopy. Furthermore, prospective clinical trials should be further carried out, in order to determine the actual impact of CADe and CADx systems in the ADR.

From a more technical point of view, this chapter has focused on supervised DL methods, and most of them include CNNs in their approaches. Therefore, there is still room for further research to apply more recent developments, initially applied on natural images. In this regard, semi-supervised or even unsupervised approaches could be considered. In these cases, the need for annotating images by experts would be reduced, so the creation of larger datasets would be easier. Up to now, there have been no efforts on semi-supervised methods for detection, localization, and segmentation [55]. For polyp classification, just recently Golhar et al. [56] applied a semi-supervised learning to improve classification into neoplastic/cancerous and non-neoplastic, which overcome the fully supervised approach, especially when few data are used.

Also, the use of Generative Adversarial Networks (GANs) could be further exploited. Its raise in natural images will for sure quickly evolve into a wider application for colorectal polyps in colonoscopy. So far, GANs are used for detection and localization [57], as well as for data augmentation [58], but the presence of these networks is

practically inexistent in the current reviews [15, 16, 18]. Doubtlessly this situation will change in the upcoming years, as other medical imaging modalities are already benefitting from the capabilities of GANs.

Furthermore, the use of synthetically created images to overcome the limited size of datasets could be analyzed. Initial efforts have already been done by Shin et al. [58] to create polyp images from normal colonoscopy images, although the ranges of color and texture of the created polyps is limited, or by De Almeida Thomaz et al. [59] to “copy and paste” polyps from one image to another in a convenient location. In any case, these efforts lead to determined polyps, and thus, the potential of synthetic images could still be further exploited to create non-deterministic polyps and cover the full range of clinical variability.

Therefore, this chapter about AI and DL for colorectal polyps in colonoscopy puts forward the wide range of applications and research lines that can be further investigated with promising results as shown by the already currently published works, and always with the ultimate goal of assisting the endoscopists to improve CRC detection and diagnosis, which would eventually lead to better patient outcomes.

Abstract

There is little doubt artificial intelligence (AI) will define ENT and healthcare as a whole in the near future. Advances in AI in recent years have allowed investigation of a broad selection of ENT datasets including radiological images, sound recordings, neural signals, mechanical measurements, photography, videography, and complex clinicopathological data, among others.

It is important for otolaryngology and head & neck surgeons to appreciate the fundamentals of AI so they can effectively evaluate studies in this field. AI has clear limitations, and yet is subject to marketing hyperbole. A good knowledge base allows otolaryngologists to work through the hype and recognize areas of opportunity in this rapidly growing field. Increasing literacy in data science and machine learning will help with clinical integration of algorithms and promote early adoption of AI tools once safe and effective. It will enable better cooperation with data scientists to direct clinically relevant research. Furthermore, it will facilitate the much-needed multicenter collaboration to take ENT AI research into the future.

This review aims to provide this foundation, illustrated with ENT-specific examples, while highlighting AI's potential benefits, limitations, challenges, and future direction. We discuss a variety of applications in otolaryngology along the main subspecialties from head & neck

Introduction

Artificial Intelligence (AI) in medicine has seen a paradigm shift in recent years through the merger of technological advancements in powerful graphic processing units, a shift to accessible electronic clinical data and improved multicenter collaboration. Through the automation of tasks previously thought only possible by humans, AI has huge potential to revolutionize healthcare [1]. It is predominantly focused on narrow skills such as prediction, perception, classification, and decision making, with the aim of matching or superseding human level performance.

Within otolaryngology, it is important for clinicians to appreciate the fundamentals of AI so they can effectively evaluate studies in this field.

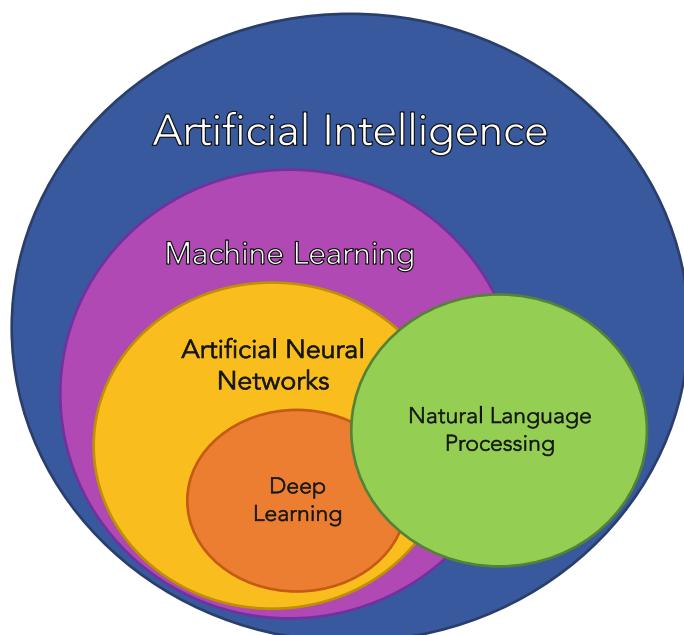

Fig. 1 Artificial intelligence as an area of research includes both NLP and ML. Deep learning is an advanced technique within ML that can also be applied to NLP

AI has clear limitations, and yet is subject to marketing hyperbole. A good knowledge base allows otolaryngologists to work through the hype, recognize areas of opportunity, and contribute positively to research in this rapidly growing field. This review aims to provide this foundation, illustrated with ENT-specific examples while highlighting AI's potential benefits, limitations, challenges, and future direction.

AI encompasses a large area of research, but primarily includes natural language processing (NLP) and machine learning (ML) (Fig. 1). The field of NLP works toward human-level language interpretation and so far is used in personal AI voice assistants and foreign language translation. While the progress in NLP has huge potential in digesting large volumes of unstructured medical text records and interpreting patient speech, ML is the workhorse of current medical AI research.

A Brief Introduction into Machine Learning

Machine learning refers to a group of data orientated, computing and mathematical techniques that enable predictions on new information based on previous experience or data. It enables

learning without explicit programming. The complexity of these algorithms, their ability to self-optimize alongside absence of programmed human knowledge allows the detection of patterns often imperceptible to humans [2]. This makes machine learning one of the most exciting areas of development within medical research.

The basic template for ML involves obtaining a suitably large dataset, preprocessing this data, and dividing it into training and testing parts (Fig. 2). The training data is inputted into the model and through multiple iterations the algorithms' parameters are optimized. This "trained" algorithm is then validated against the unseen testing dataset. While not always undertaken, external validation on data independent to the research center(s) is highly desirable. The three key paradigms within machine learning are supervised machine learning, unsupervised machine learning, and reinforcement learning:

Supervised machine learning involves the development of a predictive model using labeled data, that is, data with known outcomes. The paired input and outputs allow the learning algorithm to optimize by minimizing the mismatch in prediction between inputs and its label, done through many iterations. This algorithm or "function" can then make inferences based on previously unseen data. Supervised learning in medical-based AI is predominantly focused on classification or on regression. A common example is in the classification of images, for example,

cat versus dog, or in medical diagnosis, cancer versus benign [3]. A key component of supervised learning is the "ground truth" used for these labels. The more objective a measure of "truth," such as final histology, the more opportunity for an algorithm to accurately map the real world and make better predictions.

Unsupervised machine learning involves unlabeled data. The algorithm self-organizes without a predefined outcome to discover commonalities and subsequently define "clusters" within data. This clustering may be used to identify previously undefined subgroups of patients in large multivariable datasets. These populations may demonstrate similar prognosis or responses to certain treatments, which in the future may benefit more specific or directed management.

Reinforcement learning is less commonly employed in medical AI research, but after a series of actions, uses a "reward/punishment" type approach depending on final outcome. It is limited due to the real-time nature of the algorithm improvement process, high data volume requirements, and usually slower results. It is frequently used in autonomous game-based AI and was the principle algorithm for AlphaZero, the famed and successful boardgame program. Reinforcement learning has been used in a hybridized approach, alongside supervised learning for developing "dynamic treatment regimes" in graft versus host disease [4]. It has promise in surgical robotics and in clinical decision support-based algorithms,

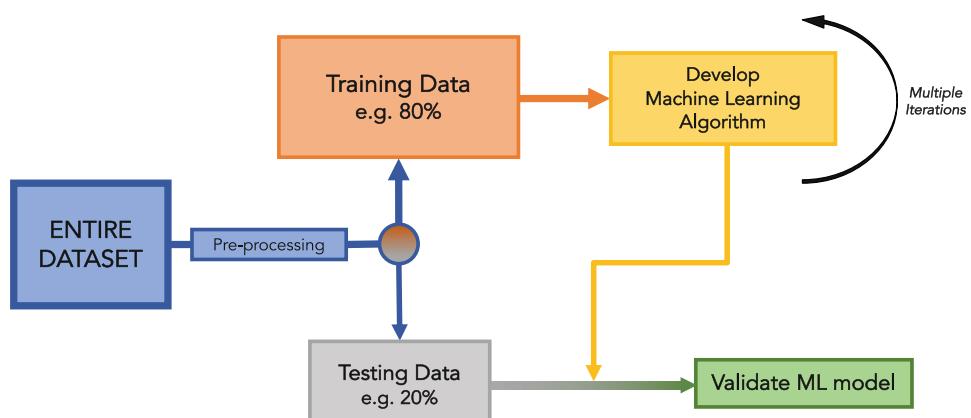

Fig. 2 A simplified overview of the development of an effective machine learning algorithm

especially in critical care [5]. Due to the innate exploratory nature of reinforcement learning as seen with AlphaZero, it has huge potential in uncovering truths and methods in medicine that are not limited by human level cognition nor knowledge.

Perhaps the most promising technique within ML is deep learning (DL) through “deep neural networks” (Fig. 1). A prerequisite to deep learning is the construction of artificial neural networks (ANN) which are inspired by the neural networks of the brain (Fig. 3) [6]. These are highly adaptable systems with good application in interpreting complex heterogeneous data in a highly precise manner. These systems comprise of input and output layers composed of nodes or neurons with bridging “hidden” layers. The complexity of an ANN is in general dependent on the number of hidden layers and a “deep neural network” (DNN) refers to an artificial neural network with multiple layers. Information travels through these nodes with each connection representing a synapse and are attributed a random “weight” or “bias.” These weights or biases are progressively adjusted through multiple iterations to improve the performance of the algorithm. In supervised neural networks, this is achieved through

involved mathematical techniques such as “back-propagation” to minimize error by comparing actual and expected outputs. Across many nodes and millions of connections these algorithms become unfathomably complex but can achieve human or super-human processing capabilities. An important tool in DL is the convolutional neural network (CNN), which are frequently used as an effective device in medical image processing.

Machine learning and specifically deep learning-based AI has demonstrated its utility in medical imaging. Key highlights in this area include: mammogram interpretation in breast cancer [7], skin cancer detection [8], and retinopathy assessment and grading [9] – all at levels comparable or better than medical experts.

Artificial Intelligence in ENT

In otolaryngology, a vast and broad landscape of AI-based research has taken place with number of publications exponentially increasing in recent years (Fig. 4). Machine learning has been employed to detect, classify, diagnose, predict, categorize, and enhance. These successes have

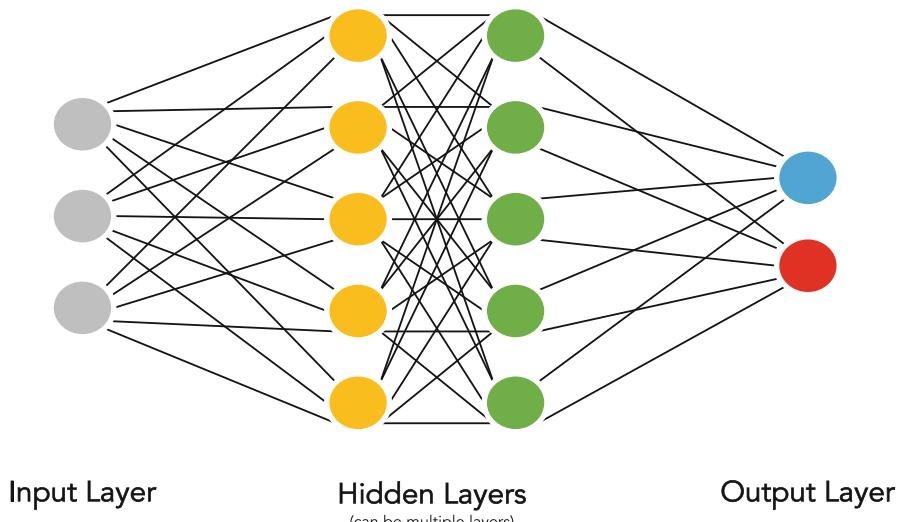

Fig. 3 Modeled on the brain, data passes from the input layer (preprocessed training data) through (multiple) intermediate or hidden layers through connections. Information eventually passes to an output layer and by comparing

actual and expected outputs the weights and biases of these connections are adjusted to improve predictive capacity

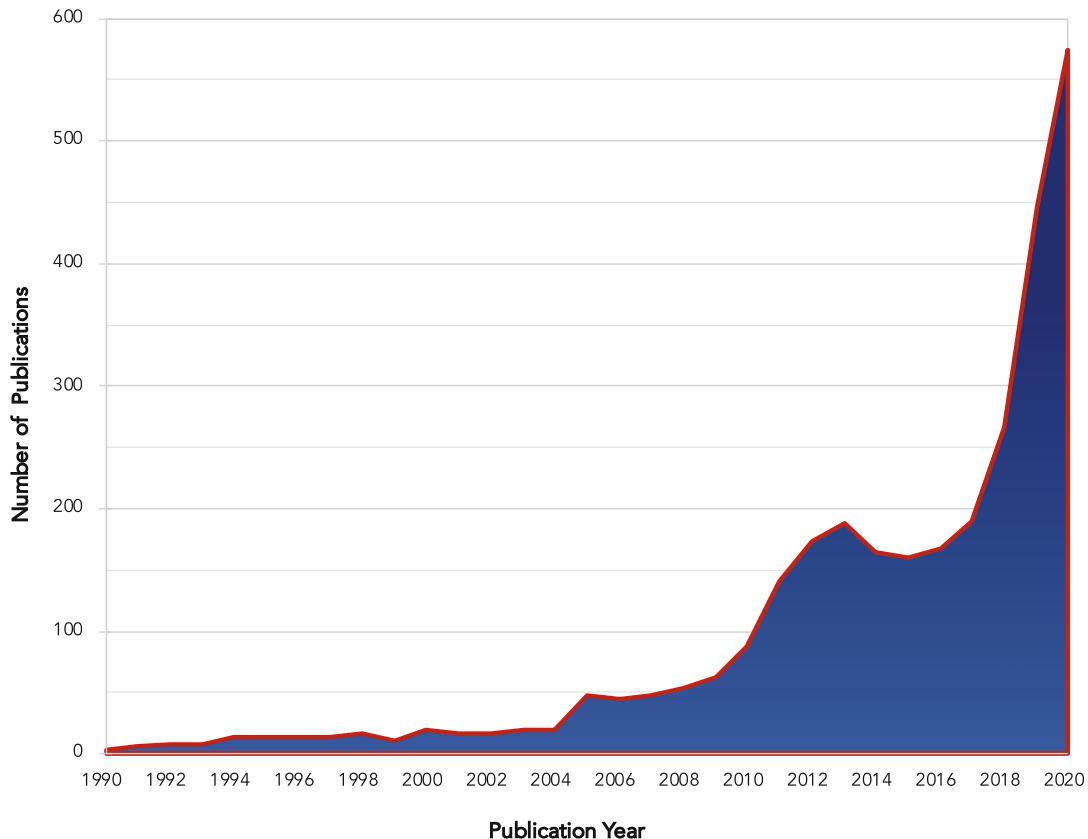

Fig. 4 Publications by year within Medline related to [ENT, Otolaryngology, Head & Neck Cancer, Thyroid, Otology, Rhinology OR Laryngology] AND [Artificial Intelligence, Machine Learning OR Neural Network]

been undertaken in a huge variety of single and hybrid datasets from imaging, genomics, clinicopathological data, sound recordings, neural signals, and mechanical measurements. This review will divide discussion along the main subspecialities within ENT: Head & Neck cancer, Thyroid & Endocrine, Otology, Rhinology, and Laryngology.

Head and Neck Cancer

AI research in Head & Neck cancer is presently the principal area of investigation within Otolaryngology. Large amounts of accessible data in imaging, pathology, genetics, and proteomics lend itself to an ML-based research approach.

Radiomics

Radiomics refers to the extraction of a large number of features from radiographic medical images and has now developed into a leading area of AI

investigation. Multidimensional medical images contain far more information than is detectable by humans. These imperceptible patterns may represent “image biomarkers” which may correlate with characteristics of the disease process, predicting both diagnosis and prognosis.

Predicting Outcomes: The largest area of AI research in head and neck cancer is in radiomics-based prognostication including survival, locoregional recurrence, and metastasis prediction [10]. With wildly varying survival rates in this heterogeneous population of tumors, better predictive tools are highly desirable. In the last 4 years, over 50 studies have been conducted in this area, investigating differing imaging modalities and distinct subsets of head and neck cancer. Shen et al. found a hybridization of MRI-based radiomic models with staging and EBV tumor status best predicted progression free survival in nasopharyngeal cancers [11]. Liu et al. demonstrated a superior

predictive power of overall and disease free survival when combining pre- and posttreatment PET-CT radiomic modeling with clinicopathological features in head and neck squamous cell cancer [12]. This predictive success however has not always been demonstrated in published MLA radiomic-based studies [13]. With more accurate prognostication, better-informed patients and clinicians may opt for more or less aggressive treatment in a personalized management approach.

Predicting Treatment Response: Related to prognostication is the assessment of treatment response. Response to chemotherapy in sinonasal and nasopharyngeal cancers has been predicted using algorithms trained on pretreatment MRIs [14, 15]. Zhai et al. using a neural network trained on a combined dataset of clinical and radiomic features, was one of the first groups to predict individual lymph node failure pretreatment [16]. Models such as these may allow better pretreatment planning and subsequent intensified or directed therapy, which may include neck dissection or higher dose radiotherapy.

Prediction of Pathological State: Automated staging and prediction of tumor histological features have also been researched extensively in HNSCC. Multiple studies have been able to predict histological features, grade, and degree of differentiation in both CT [17, 18] and MRI [19].

Overall, developing head and neck cancer radiomics may result in superior prediction in survival, treatment response, and earlier pathology diagnosis. This may in turn result in more effective individualized management for these cancer patients.

Radiological Staging

MLAs have been able to accurately stage advanced laryngeal tumors at T3 versus T4 through a contrast enhanced CT image data set [20]. Romeo et al. in a smaller subset of CT images for oral cavity SCC, through machine learning classifiers was able to demonstrate autonomous staging of both T and nodal status [21]. Tomita et al. recently trained a deep learning neural network to identify cervical nodal metastasis on CT in oral SCC [22]. They showed an AUC significantly better than that of the radiologist

comparator. A similar, but older, study in preoperative HNSCC was able to diagnose pathological nodes and was the first to detect extranodal extension on external validation with a high AUC of 0.91 [23]. Both of these studies highlight the important role deep learning algorithms may have in radiology support for preoperative diagnosis, risk stratification, and directed management. In the near future AI tools with high sensitivity can flag certain high-risk scans for earlier review by an experienced radiologist and thus streamline diagnosis.

Clinical Head and Neck Oncology

Predicting Treatment Toxicity: Post radiotherapy toxicity of the head and neck can manifest in a multitude of ENT symptoms: dysphagia, hearing loss, osteoradionecrosis, and xerostomia. Risk of xerostomia in particular has been examined in multiple studies; Jiang et al. used supervised machine learning methods on a combined dataset of sociodemographic, clinicopathological features, and radiation dose distribution [24]. They were able to accurately predict risk of xerostomia and also identify which salivary gland regions correlated most with this complication.

Auto-segmentation: In head and neck clinical oncology, deep learning networks have been used to automate segmentation of specific anatomical structures of interest to facilitate radiotherapy planning [25].

Nearly all studies examining the value of machine learning models in radiomics for head and neck cancer focus on a single modality. It is possible if not probable that combination of multiple imaging modalities may further improve accuracy of prediction. In late presenting and difficult to access tumors such as skull base and sinonasal, a highly accurate radiomic-based diagnostic and prognosticating algorithm would be invaluable in managing these patients.

Histopathology

Much like in radiology, histopathological images can be interpreted using CNNs. Halicek et al. digitized whole slide pathological images of head and neck SCC and interpreted a test set with a high AUC of 0.92 [26]. Each slide was

broken down into multiple small “image patches” to enable reliable training and subsequent interpretation. Results however were limited by image artifact including out of focus regions on the whole slide photograph. Additionally, due to “image patch” size, minimum interpretable SCC size was no larger than approximately 10 cells.

Ultimately, the use of computer diagnosis in histopathology, through deep learning methods, may rapidly speed up diagnosis. In the near future it may augment the histopathologist rather than replace them by flagging “high-risk” specimens for earlier formal review. Later, once more reliable and robust algorithms are produced on large volumes of multicenter data it may serve as diagnostic fail safe.

Multispectral Imaging

Multispectral or hyperspectral imaging has emerged as a tool to enhance issue identification via assessment across a broad range of both invisible and visible light. Combining the data images from different wavelengths multiplies the amount of information available and applying artificial intelligence to this dataset may uncover associations not obvious to the human eye or brain.

In a relatively small sample size, a team from Stamford University through a supervised learning “naive Bayesian” classifier demonstrated reasonably accurate identification of oropharyngeal malignancies on multispectral images taken from flexible nasopharyngoscopy [27]. Use of deep learning algorithms to identify normal tissue type on fresh frozen human cadaveric specimens has been undertaken with success. A model developed from multispectral imaging on operating microscope photography was superior to otolaryngology residents in diagnostic accuracy (82% vs 70%) [28]. This algorithm was also significantly better than one built on white light alone and in the future may enhance real-time intraoperative tissue assessment. In another study, head and neck surgical specimens containing marginal tumor tissue had hyperspectral images taken within 2 h of excision. These were analyzed with a machine classification model. The final algorithm successfully distinguished cancer from normal tissue in a variety of

head and neck malignancies at an accuracy of 90% [29].

ENT widely uses image representation devices including rigid and flexible endoscopes, microscopes, and robots. These algorithms may improve automated detection in malignancy, and further development may allow real-time assessment of tumor margins during surgery. Ultimately these systems may enhance intraoperative surgical vision in other ENT subspecialties through better visual definition of a variety of tissue types.

Genetics and Molecular Markers

Large genetic and molecular data sets are suitable for MLA application. Complex and as yet unknown or unknowable associations between genes and or proteins may code for tumor biology and behavior.

Gene Expression: Some fascinating AI genetic prediction models have been developed in head and neck cancer. Stepp et al. developed a 40 gene model from the genomics of the primary tumors of HPV+ve oropharyngeal SCC [30]. This algorithm, based on the gene expression of these tumors alone, was able to successfully predict nodal metastasis with an AUC of 0.93. An earlier study looked at combined datasets of clinicopathology and genomic data. They applied feature selection and machine learning to develop a model that improved prognosis prediction in oral cancer beyond clinicopathological features alone [31].

Molecular Markers: Carnielli et al. used protein and peptide biological signatures to predict lymph node metastasis in oral SCC [32]. They did this with an accuracy above 74%, validated on a test set. Using a support vector machine learning algorithm Bohnenberger et al. were able to identify “proteomic diagnostic biomarkers” to differentiate between primary lung SCC and HNSCC metastases. This model, based on the analysis of over 1000 proteins, demonstrated an accuracy of approximately 87% on an independent validation set [33].

Unique protein and gene expression combinations may represent definite subgroups of cancer patients. These specific patterns may identify patients with more aggressively behaving tumors or those with lymph node metastasis irrespective

of imaging. A more accurate stratification would guide more or less aggressive treatments.

Thyroid and Endocrine Surgery

Thyroid Cancer

In a diagnostic sense, thyroid cancer differs from most other head and neck cancers primarily due to the frequent indeterminacy of the principal investigations. A large number of nodules, approximately 15%, are classified as indeterminate despite further invasive testing including ultrasound and fine needle aspiration cytology. The recommendation in these cases is for diagnostic hemithyroidectomy to obtain final histological diagnosis. Reliance on surgery for diagnosis, which carries morbidity, is a key area for improvement. Improved accuracy for presurgical investigations can streamline care for patients and avoid unnecessary surgery. Furthermore, the increase in detection and subsequently incidence of thyroid requires better risk stratification and prognostication to guide individualized treatments.

Thyroid Ultrasound: AI-based interpretation of thyroid US images can be used to reduce the recognized subjectivity in image assessment. Buda et al. produced a deep learning model that demonstrated comparable accuracy for diagnosis on ultrasound thyroid images, when compared to 9 radiologists with an AUC of 0.87 and 0.82, respectively [34]. A more recent study used a “similarity based” MLA to accurately classify US nodule images as benign or malignant. This algorithm used its labeled training database to identify the “closest” appearing image to the new test image [35]. As the training images were labeled on pathological ground truth, this algorithm was able to provide partial “explainability” to its output, thus minimizing a key concern of “black box” AI neural networks (discussed later).

Importantly, there may be as yet unknown subtle patterns in US images that correlate with malignancy. With large enough datasets, it may be possible to deliver AI-based interpretation that diagnoses so-called indeterminate nodules as benign or malignant with superior accuracy. This may revolutionize the management of such

thyroid lesions by reducing the need for diagnostic surgery.

MRI Radiomics: Beyond US, MRI has been used to predict the aggressiveness of papillary thyroid carcinoma (PTC) preoperatively. Wang et al. imaged 96 patients prior to surgery for papillary thyroid carcinoma and using ground truth histopathological features, trained an MLA to differentiate between aggressive and non-aggressive PTC [36]. The algorithm based on the radiomic features alone demonstrated an impressive AUC of 0.92 versus an AUC of 0.52 for prediction based on clinical and patient factors alone. Wei et al. used a similarly trained MLA to predict extra-thyroidal extension on preoperative MRI scans [37].

MRI is not a standard preoperative assessment tool in thyroid cancer; however, with powerful predictive AI tools extracting reliable diagnostic patterns from this data, better preoperative planning and more individualized treatment plans for PTC may be possible.

Clinicopathological Prediction: Historically, prognostication in thyroid cancer has been based on TNM, AMES, and MACIS classifications, all devised on multivariate statistical analysis. MLAs however have proven a powerful tool in predicting survival in thyroid cancer patients. Using only seven clinicopathological variables, based on the very large national US “Surveillance, Epidemiology, and End Results” database, Mourad et al. predicted death within 5 years with an accuracy of 96% [38].

Cytopathology Diagnosis: Fine needle aspiration (FNA) cytopathological interpretation is a complex task, in part because of the large slide images with relatively isolated or sparse areas of interest. Information is too diffuse for reliable diagnosis based on whole slide images with a traditional single classification algorithm. For this reason, double MLAs have been applied to cytopathological slides, the first to identify groups of follicular cells (screening algorithm) the second to classify these groups (classifying algorithm) [39]. In a dataset of 908 FNA slide sampled the MLAs predicted malignancy with an AUC of 0.932, comparable to the cytopathologist AUC of 0.931. The near instant interpretation of

cytopathology may work to highlight “high-risk” slides earlier to the pathologist who can better direct efforts to return earlier diagnosis in patient with potential malignancy.

AI developments in thyroid cancer may not only work as an adjunct to human experts in streamlining diagnosis but later could help revolutionize the MDT through more accurate diagnosis and better risk stratification.

Parathyroid Surgery

Intraoperative Assistance: In primary hyperparathyroidism, the intraoperative evaluation of pathological glands can be difficult. A relatively new technology of near infra-red imaging to assess auto-fluorescence of parathyroid glands is a promising intraoperative adjunct. A machine learning multiclass decision tree using auto-fluorescence intensity, gland volume, and “heterogeneity index” was able to differentiate between abnormal and normal glands with an AUC of 0.98 [40]. This algorithm was not prospectively validated and was developed on a relatively small pool of 106 patients; however, it demonstrates potential in objective intraoperative assessment without need to excise the gland. Larger studies with robust validation are desirable.

A study from Germany in 2020 used intraoperative hyperspectral photography to differentiate between thyroid, parathyroid, and recurrent laryngeal nerves within less than 1.4 s of processing. A support vector machine learning algorithm based on annotated pictures was able to identify parathyroid tissue with sensitivity of 65% and specificity of 94% [41]. The dataset involved only nine patients and larger studies are warranted. In the future, more sensitive and more extensively validated algorithms, with similar efficiency, may revolutionize intraoperative surgical vision in thyroid and parathyroid surgery.

Preoperative Diagnosis: Using demographic, clinical, and laboratory measures Imbus et al. developed a random tree model of MLA to predict multi-gland disease versus single adenoma in primary hyperparathyroidism at an accuracy of 94% [42]. Interestingly, they adjusted the algorithm to maximize positive predictive value for multi-gland disease at 100%. Using prediction software

such as this we may identify where 4 gland exploration is almost certainly necessary, thus streamlining tertiary center referral and possibly avoiding the time, cost, and radiation associated with possible revision surgery and investigations such as sestamibi scanning.

Otology

You et al. published an excellent and thorough review of AI in otology in 2020 evaluating 38 studies [43]. The scope of this review is to give an overview of ENT as a whole but will touch upon some of the key otology areas. There are five broad divisions that AI research has focused on within otology: Imaging diagnostics and radiomics, auditory brainstem response analysis, sensorineural hearing loss prediction, hearing impairment technologies, and balance pathology. We provide a summary of AI research in these areas. As with other fields, a large amount of otology AI research has been undertaken in imaging modalities. A unique and extensively investigated area has been in hearing assessment and rehabilitation, driven in part by the hearing industry’s commercial interest in technological advancement.

Imaging Modalities and Radiomics

As in other fields, AI-based analysis of imaging has been applied in otology to otoscopic images, CT scans, and even optical coherence tomography.

Radiology: Accurate automated segmentation and identification of key temporal bone structures on CT scans will streamline and augment preoperative planning for otologist and lateral skull base surgeons. Fauser et al. used deep learning-based methods, on ground truth of expertly annotated images, to segment temporal bone CT scans [44]. Tested on images from 24 patients, they highlight that using this accurate, fast, and fully automated approach may facilitate planning in procedures such as cochlear implantation and vestibular schwannoma surgery.

Wang et al. developed dual DL algorithms to localize the region of interest on temporal bone CT scans and then further classify the images into chronic otitis media (COM) or normal at an AUC equivalent or superior to experts [45]. The classification algorithm also demonstrated superior

recall rates in differentiating chronic suppurative otitis media and cholesteatoma at an accuracy of 77% versus 74% in clinicians. Not only was this model more accurate but also had better diagnostic consistency when compared to experts.

Novel Modalities: The detection of endolymphatic hydrops in Meniere's disease via cochlear optical coherence tomography (OCT) has significant potential as a noninvasive and useful investigation [46]. In a mouse study and using histology as ground truth, Liu et al. trained a CNN to identify both normal and hydrops-related Reissner's membranes on OCT images [47]. On a small validation set of 37 cochlear images they demonstrated a high accuracy of 92%.

Radiomics: Within ENT, radiomic-based prediction and diagnosis is not restricted to the domains of head and neck cancer. Sensorineural hearing loss (SNHL) secondary to chemoradiotherapy for head and neck cancer was predicted through application of machine learning algorithms to CT images of the cochlea. Of the 490 identified radiomic features, 10 were associated with SNHL and were able to predict SNHL in this patient group at an impressive accuracy of 70% [48].

Oto-endoscopic Images: Misdiagnosis in medicine is not uncommon and is seen frequently on otoscopy in the community. It can result in delayed and unnecessary referrals leading to patient anxiety, avoidable cost, and even morbidity. Furthermore, even among experienced clinicians, otoscopic examination is prone to interobserver variability [49]. Objective computer vision tools may minimize this subjectivity and multiple studies have examined the use of MLAs in interpreting oto-endoscopic images. Lee et al. using a dataset of 1338 tympanic membrane images developed a CNN which was able to recognize the laterality of eardrum with 99% accuracy and identify perforation with an accuracy of 91% [50]. Similarly, Wu et al. developed a convoluted neural network on a larger dataset of 10,000 pediatric oto-endoscopic images [51]. The model was able to diagnose and differentiate between acute otitis media, otitis media with effusion, and normal tympanic membranes. While not externally validated, the model had a very high accuracy on an internal test dataset of 97%.

The development of highly accurate and broadly trained algorithms may revolutionize diagnosis in the community, especially in untrained individuals, thus speeding and streamlining the referral pathway. This has significant implications in the delivery of effective diagnostic care in the developing world where expertise in otolaryngology maybe at a premium.

Auditory Brainstem Response Interpretation

Auditory brainstem response (ABR) is considered an objective assessment for evaluating hearing thresholds as a voluntary response is not required. Nevertheless, the interpretation of the detected traces is subjective and relative to clinicians' expertise and judgment. Studies dating back at least 15 years have used artificial intelligence to classify ABRs more objectively. Most recently in 2019, a DNN was trained to classify paired auditory brainstem response waveforms into three categories, specifically "clear response," "inconclusive," or "response absent" with an accuracy of 93% [52]. Like with other complex datasets, deep learning can retrieve specific patterns within the ABR reading that may be unknown or poorly defined by clinicians. Ultimately reliable deep learning-based algorithms may diagnose in real-time and streamline ABR or other electronic signal-based screening programs.

Sensorineural Hearing Loss Prediction

Predicting audiology outcomes in patients with hearing loss is difficult given heterogeneity of disease and the presumed complex interplay between large variety of clinical, demographic, and pathological factors. This is especially the case in sudden sensorineural hearing loss (SSNHL). In 2018 a relatively large cohort of 1220 patients with SSNHL, Bing et al. investigated several MLAs to predict hearing recovery [53]. Using 149 separate clinicopathological variables they demonstrated that a deep learning-based algorithm (deep belief network) was the best predictor of audiological outcome at 78% accuracy. More recently in China, MLAs were employed to predict the likelihood of noise-induced hearing loss (NIHL) in a collection of

factory workers using several clinico-demographic factors alongside full-shift noise measurements. They were able to quantitatively predict NIHL at an accuracy of 80% [54]. Models such as this may better risk stratify a workforce, highlight susceptible individuals, and thus protect employees from occupational NIHL.

Hearing Impairment Technologies

Hearing Aids: A multitude of factors including demographic, cognitive, and audiotrical contribute to speech intelligibility. Kates et al. proposed a neural network plan to predict intelligibility of speech in hearing aid users based on clinico-demographic factors with an intention to enhance the audibility of high-frequency speech [55]. A major hurdle within hearing aid development is minimizing speech degradation. Enhancing speech sound while mitigating background noise has been successfully achieved through use of ANN. “Perceptual evaluation of speech quality” improved by 24% when a deep learning system was applied to recordings of speech sounds in a noisy office environment [56].

It is not unreasonable to expect MLAs to be developed in the near future that allow clean and enhanced audio streamed directly to device-paired hearing aids. Similarly, once processed speech is enhanced to high level intelligibility, a next possible step is near real-time and faithful translation of foreign language audio to headphones or hearing aids.

Cochlear Implants: AI has been introduced to a variety of areas within cochlear implantation and usage. Deep learning in particular will be paramount in the development of a customized cochlear implant programming.

Cochlear implant (CI) users describe limitations in the appreciation of music, especially in the perception of vocals. As recently as 2020, Tahmasebi et al. developed a source separation algorithm using a deep neural network to enhance music enjoyment in individuals with CIs [57]. This was done through effectively enhancing voice sound relative to background instruments. Most impressively, the study allowed real-time assessment of this deliberate “music remixing” in real-world environments with ambient sound.

Evoked compound action potentials (ECAPs) are useful in both postoperative and intraoperative assessment of CI and cochlear nerve function. Analysis of electrically evoked compound action potentials has been investigated using neural networks across several studies. Gartner et al. evaluated the previously developed “Automatic Neural Response Telemetry” (AutoNRT™) software, which demonstrated comparable accuracy to audiologists with a relatively fast assessment time of under 1 min per electrode contact [58]. The ECAP is clouded by interference from the implanted device itself. Extracting the neural response component of the trace has been done through support vector machines which have been shown capable of differentiating normal hearing signal and artifact [59].

An interesting study by Pile et al. developed a simulated robotic system that detected cochlear implant electrode “tip fold-over.” Through a variety of force feedback readings on a synthetic cochlear model, a support vector MLA was able to accurately predict this known intraoperative complication in real-time at 88% accuracy [60]. Rather than relying on postoperative assessment or “on table” fluoroscopy, this tool can permit immediate intraoperative rectification.

Transcription Apps: Engineered by AI natural language processing models, speech to text transcription apps have already proven their worth for patients reliant on lipreading due to the use of COVID-19 related face masks.

Balance and Vestibular Pathologies

A decision support system for balance disorders was created through use of decision tree-based algorithms trained on clinical data from just under 1000 patients with up to 350 variables. It has a reported diagnostic accuracy rate of 59.3 to 89.8% for general practitioners (GPs) and from 74.3 to 92.1% for balance experts [61]. Krafczyk et al. developed an ANN to diagnose underlying balance disorders based on posture or “body sway” [62]. They were able to identify normal balance, postural phobic vertigo, anterior lobe cerebellar atrophy, primary orthostatic tremor, and acute unilateral vestibular neuritis with high sensitivity and specificity using only

posturography measurements. In using both clinico-demographic datasets and worn device measurements AI can improve diagnostic accuracy in balance disorders for both GPs and balance specialists.

Rhinology

AI in rhinology has not been investigated to the same degree as head & neck oncology and otology. This is in part related to the sheer volume of accessible data in cancer imaging, genetics, and audiology. However, along with the common imaging and pathological interpretation, endotyping of chronic rhinosinusitis has been investigated considerably.

Imaging Diagnosis

Imaging, as mentioned previously, lends itself well to CNN analysis. Two separate studies have successfully used a CNN, Google Inception-V3, to interpret CT sinus scans for osteomeatal complex occlusion [63] and anterior ethmoidal artery identification [64]. Chowdhury et al. examined CT scans in 239 patients with chronic rhinosinusitis (CRS). Augmented to 956 images, they demonstrated algorithm accuracy of 85% and AUC of 0.87 in defining the osteomeatal complex as open or closed. Huang et al. in a larger data set of 388 patients was able accurately highlight the anterior ethmoidal artery on images with an accuracy of 82.7% and AUC of 0.86. Another study, using only CT coronal slices, achieved an 81% accuracy in their neural network model for diagnosis of concha bullosa [65].

Due to a degree of subjectivity and interobserver variability associated with interpretation of CT sinus imaging, developing objective, rapid, and highly accurate assessment of these images is desirable [66]. CNNs may eventually provide this as they demonstrate promise in interpreting and highlighting of key components on CT sinuses.

Pathological Diagnosis

A far less studied area of image-based deep learning is in digitized images of rhino-cytology and histology preparations. CNNs have been trained to differentiate between eosinophilic and non-eosinophilic nasal polypsis on histology

[67]. Their training dataset of 167 patients' slides was augmented to a robust 23,048 separate images or "patches" from slide image breakdown and externally validated with high diagnostic accuracy. Streamlining the time-intensive nasal cytological diagnostics has also been attempted with a CNN composed of three block layers, showing promising results [68]. Here, Dimauro et al. produced a very reliable model for cell identification and cell classification which was between 98 and 100% accurate on validation depending on the cell type. These developments may eventually lead to useful and rapid outpatient diagnostics.

Chronic Rhinosinusitis Endotyping

Outside of neural networks, AI has been used in assessment and clinical categorization for patients with chronic rhinosinusitis (CRS). CRS is associated with a large worldwide disease burden affecting over 100 million people [69]. Furthermore, CRS consists of multiple differing poorly understood biological subtypes or endotypes that may correspond to distinct pathophysiologies. These different groups may respond with varying efficacy to different treatments. Defining CRS as a two-group phenotype, that is, with or without nasal polyposis may be an oversimplification and suboptimal for effective individualized care. Several papers have undertaken unsupervised clustering analysis of CRS to predict endotype groups and subsequently predict surgical benefit, treatment response, and need for revision surgery.

Soler et al. used clinical data (demographics, Sino-Nasal Outcome Test-22 (SNOT-22), CT scoring, olfactory testing, and endoscopic scoring) from 690 patients who had initial failed medical management CRS. They were able to define five clusters, three of which predicted better surgical outcomes on SNOT-22. The other two clusters demonstrated no benefit to surgery over continued medical management [70].

Liao et al. used principle component analysis to define seven distinct clinicopathologic multidimensional clusters of CRS [71]. They assessed a total of 67 total variables, 28 clinical ranging demographics, symptomatology, endoscopic findings, and CT scoring alongside 39 intraoperative

molecular and cellular markers. In this way they were able to characterize difficult to treat CRS and predict differing response to treatment.

Laryngology

Assessment of the larynx, voice, and swallow has had limited dedicated AI research. Nevertheless, many of the studies undertaken have been unique, interesting, and offer significant promise.

Voice and Larynx

Most of the promising AI-based laryngology-related research has focused on diagnosis using noninvasive digitized media-based analysis. Much like image data, the large amounts of information held within video or audio recordings lend itself to interpretation by MLAs.

Anecdotally, expert voice clinicians may demonstrate an intuition in classifying voice pathology prior to endoscopic examination. Presumably, there are pathognomonic features detected by experienced humans that may not be easily expressed in words. It is also possible that subtleties within the audio recording data may code complex patterns imperceptible to the human ear that will allow highly accurate superhuman noninvasive diagnosis.

Audio-Based Prediction: Using ANNs to analyze voice recordings has been conceptualized as far back as the year 2000 [72]. In 2018, a remarkable study by Fang et al. demonstrated superior performance of deep neural network versus other AI systems in diagnosing “pathological voice” on audio samples. Trained on 462 labeled voice clips the ANN had a 99.2% accuracy when externally validated [73]. In the same year, Cesari et al. showed superior identification of “pathological voice” versus “normal” on voice recordings using a machine learning decision tree algorithm. This was best seen in the subcategories of reflux laryngitis and hyperkinetic dysphonia [74]. This program had been incorporated into a mobile phone app paving the way for highly accessible, noninvasive, AI-based diagnostics in the near future.

Video-Based Prediction: Videographic data can also be interpreted in a similar way. In a relatively small study, high-speed laryngoscopy

video (4000 images per second) has shown significant potential in differentiating T1a tumors from precancerous laryngeal lesions when analyzed by a support vector MLA [75]. The MLA was, in theory, able to identify abnormal mucosal vibration and demonstrate a specificity and sensitivity of 100%, but larger training and testing set would be needed to validate this further. In the future, high accuracy noninvasive tests may limit unnecessary diagnostic surgery in small benign laryngeal lesions.

Clinical Data-Based Prediction: Interestingly, success in voice pathology diagnosis has been demonstrated in using MLAs on simple clinical data without incorporation of digitized media. Tsui et al. applied an ANN to a combined dataset of demographic and symptomatic clinical data to predict underlying pathology for dysphonia [76]. The ANN was the most accurate of the tested MLAs, differentiating between phonotrauma, palsy, and neoplasia at an accuracy of 83%. This is especially impressive given the data set did not include video or audio; however, the model was not externally validated.

Image-Based Diagnosis: In late 2020 “AGATI” (Automated Glottic Action Tracking by Artificial Intelligence) a computer vision tool could identify unilateral vocal cord palsy by tracking true vocal fold movement on fiberoptic laryngoscopy images. Through quantitative assessment of vocal fold movement via surrogate measure of “anterior glottic angles” the program had a high diagnostic accuracy with AUC of 0.87 [77].

Swallow

Swallow evaluation through recognition of imperceptible or abstract patterns in novel noninvasive measurements may revolutionize outpatient or bedside diagnostic approaches.

Dysphagia assessment through mapping hyoid bone displacement on video fluoroscopic swallow (VFS) has been automated with an accuracy of almost 90% using deep learning [78]. This has reduced task time from over 30 min for manual annotation to less than 1 min for the algorithm. Interestingly, the same team subsequently taught an MLA to accurately predict hyoid bone movement using vibration signals from a worn neck

accelerometer, using human annotated VFS as ground truth [79]. Using similar principles, identification of upper esophageal sphincter opening via vibratory output was also possible with over 90% accuracy [80, 81]. This algorithm-based vibration assessment of swallowing has large potential as adjunctive noninvasive and zero radiation diagnostics for dysphagia.

Limitations, Challenges, and the Future

Data Access, Data Processing, and Further Research: While the charm of machine learning algorithms lies in their ability to manage large volume complex heterogeneous datasets, their successful development is dependent upon data that is clean, often annotated, appropriately specific, or broad and sizeable enough. This volume of data can both be difficult to obtain and time onerous to pre-process. Furthermore, while collaboration is improving, the data sources for the vast majority of studies are single institution – even in well-studied areas such as head and neck oncology.

Otolaryngology needs cooperative large-scale multicenter data for training and additional comprehensive external validation. Additionally, the majority of machine learning research uses single modality data inputs. Multimodal imaging-based AI is in its early stages, but has potential to further improve diagnostic and prediction capacity. Beyond using imaging alone and mimicking healthcare professionals' approach, the merger of demographics, clinicopathology, biochemistry, pathology, and imaging among other data may lead to holistic and powerful AI assessment tools.

While not obvious, ENT surgeons interested in developing real-world application tools need to incorporate unequal error costs to their models. This is central to assessment in cancer. Rather than just differentiating between malignant and benign the impact of a false negative must be recognized and factored into any algorithm. Subtly minimizing false negatives at the expense of false positive rates is instinctively what clinicians do and any ML model should be adjusted as such.

Otolaryngologists interested in artificial intelligence should familiarize themselves with

international guidance on both the interpretation of AI research and design of AI studies [82–84].

Explainability: Through the fine tuning of millions of connections (especially in deep learning), these algorithms become unfathomably complex. Machine learning algorithms are often coined as “black box” models, where data is introduced and an output produced, without an understanding of the decision process. Irrespective of their superhuman evaluation abilities, the lack of explainability and subsequent accountability when employing these tools make humans uncomfortable. Medical professionals in particular need to trust any device they use in patient care. Lack of explainability will only exaggerate any concerns clinicians have with new AI technologies.

In spite of this ethical dilemma, due to the potential to revolutionize patient care some argue that the “black box” should be overlooked in favor of adopting this technology if demonstrably effective. They highlight that clinicians frequently work on intuition and often are unable to immediately and precisely explain their reasoning nor the evidence base for some clinical decisions they make. Most AI ethicists however promote development of “explainable AI” for legal, technological, patient, and clinician-based reasons [85]. In the distant future, hyper advanced AI may be able to explain complex and multi-dimensional associations in data in a way comprehensible to humans; before this, explainable AI appears a necessary stepping stone for widespread adoption.

Privacy: The production of high-functioning and reliable algorithms is reliant on access to huge volumes of data, normally retrospective. It is impractical to seek consent for thousands or millions of patients and while much image, sound, neural signal related data can be anonymized easily, this is more difficult with clinicopathological variables. In some cases, data that is presumed to be adequately anonymized data can actually be traced back. Robust protocols to protect confidentiality should be adhered to widely.

Fragility: Deep neural networks in particular are prone to “fragility.” Due to the complex nature of these networks they have the ability to extract

subtle features from input data. Some of these patterns are imperceptible to humans and may confer a superhuman level of detection or diagnosis. However, many others may be irrelevant but given salience due to the idiosyncrasies of the training dataset. Subsequently, small and seemingly innocuous changes to the image or data can confuse the algorithm into misclassification.

One method to help overcome this fragility, which will likely be expanded in the near future, is adversarial training. Here, a second algorithm will test and train the original with examples designed to fool it thereby engineering a more robust model to safeguard against mistakes. This method in itself is imperfect and may strengthen algorithms in some areas while weakening it in others. Ultimately however, the vast and deep human experience of the world enables us to see images as a series of concepts in context and not be distracted by abstract or irrelevant minutiae. This is not something narrow AI can achieve easily.

Universalizability: If algorithms are trained on one data acquisition source, for example, a specific ultrasound machine model, they learn based on those particular set of individualized parameters and signals. As a result, they may not be well suited to interpret data from an alternative source, for example, different scanners or different recording devices. In mixed data sources, machine learning can be more difficult. In large enough studies however, researchers can hope an algorithm may see beyond this noise and develop into a more general model with good accuracy irrespective of the instrument used. Conversely, it is recognized that the use of data with widely varying acquisition parameters may cause signal alterations that are not attributable to biology and thus reduce both efficacy of model and limit the algorithm's generalizability.

Patient and Public Involvement: While a thorough understanding of any new technology is not a prerequisite for use, patient confidence in the system is a necessity. Involvement in the public at early and late stages of development will not only help with trust but will also ensure their patient-specific needs are met. Tied in with public trust is the concept of AI supporting doctors rather

than replacing them. In this sense algorithms should be narrow enough to leave the primary responsibility of care delivery with a human clinician, in the near future at least.

Bias: Bias in algorithms remains an area of concern in real-world AI application. Systematic biases within a dataset can become represented within the trained model and result in unfair, unethical, and unreliable outcomes. Due to the lack of explainability in DNNs as outlined above, these biases may be hard to recognize and thus underlines the apprehension around widespread use of such systems.

Outside of medicine, image assessment algorithms in cameras have reflected data limitation and subsequent bias through inability to recognize dark skinned faces and mislabeling of East-Asian faces as blinking. Ethnic minorities are usually underrepresented in large research studies in the developed world and outside of AI this contributes to poorer risk stratification, diagnostics, and management. Skin cancer detection algorithms prove significantly poorer at identifying malignancies in darker skin and is likely a product of the data source containing predominantly light skin images [86]. Whatever the reasons, developing and employing algorithms that have lower rates of efficacy along lines of ethnicity or any other group raises serious ethical questions.

In other ways, biases within data can result in unexpected algorithmic quirks. In two large image diagnostic studies, the likelihood of diagnosis skin cancer or pneumothorax was increased with the presence of a ruler [87] or chest drain [88], respectively. Whilst perhaps less sinister in its social equality implications, these flaws still undermine accuracy and faith in complex AI systems.

Conclusion

Advances in artificial intelligence in recent years has allowed complex examination of a broad selection of ENT datasets including radiological images, optical coherence tomography, sound recordings, neural signaling, mechanical measurements, photography, videography, and

complex clinicopathological multivariate data. We have discussed a variety of applications in ENT along the main subspecialities from head and neck cancer, thyroid and parathyroid surgery, otology, rhinology, and laryngology. While some areas are focused on prediction in diagnosis and prognosis others, especially in otology, attempt to enhance established technologies. There is little doubt AI-related research will benefit otolaryngology in the near future with appropriate direction and judicious adoption.

Increasing literacy in data science and machine learning in otolaryngologists is a necessity for the progression of the field. It will help with clinical integration of algorithms and promote early adoption of AI tools once safe and effective. It will cultivate interest in this rapidly developing field and allow better cooperation with data scientists to direct clinically relevant research. Furthermore, it will facilitate the much-needed multicenter collaboration to take ENT AI research into the future. Although there are clear and acute challenges and limitations to this technology, AI developed systems will help define ENT and health care as a whole in the coming years.

Abstract

With persistently low fertility rates at the global levels, combined with the anticipated capacitive insufficiency in specialist clinicians – in both developed and developing countries – the need for addressing the concerns of patients who intend to conceive is greater than ever. In an effort to advance the treatment of patients who experience infertility, AI is increasingly being used to optimize the clinical management options. The major areas of application continue to be in the space of analyzing semen, assessment of oocytes and embryos, and predictive analytics for the success of in vitro fertilization. Given how these automated decision systems

often operate as a “black box,” with both the technical developers and clinical users often unaware of the potential outcomes, ethical concerns around the limits of this technology remain.

Introduction

When coining the term “artificial intelligence” – by John McCarthy, Marvin Minsky, Nathaniel Rochester, and Claude Shannon at a Dartmouth conference in late summer of 1955 – it was rather inconceivable the extent of impact and the range of applications that this technology would demonstrate [1]. Now, artificial intelligence (AI) is

poised to change the delivery of healthcare as clinicians know it. The applications – and the ensuing clinical trials – that apply AI to augment the delivery of services such as pathology and radiology are clear; however, there is another area where AI is bound to play a critical role in addressing an unmet need: obstetrics and gynecology.

AI can augment clinicians by assisting with earlier diagnoses, changing the trajectory for the patient in potentially fatal conditions – such as ovarian and cervical cancers. It can sift through data much faster and more efficiently than human capacity, comparing target sample with a general sample in order to identify tumor markers, irregular genetic code, and presence of abnormal proteins. With prompt diagnosis, clinicians can not only curb case fatalities but also reduce physician burden and cost in eliminating ineffective treatments all the while reducing human suffering.

Now, with persistently low fertility rates at the global levels [2], combined with the anticipated capacitive insufficiency in specialist clinicians – in both developed and developing countries [3] – the need for addressing the concerns of patients who intend to conceive is greater than ever. In this chapter, we underscore the applicability of AI for in vitro fertilization (IVF) and bioethical issues around utilizing this technology.

AI in IVF

Evidence suggests that the quality of the embryo is often a determinant for IVF success; at the same time, technologies that will enable an accurate assessment of sperms, oocytes, as well as embryos are often not robust. In an effort to advance the treatment for patients who experience infertility, AI is increasingly being used to optimize the clinical management options. The major areas where AI is applicable in the field of obstetrics, especially in vitro fertilization, are analyzing semen, assessment of oocytes and embryos, and predictive analytics for the success of in vitro fertilization.

Analysis of semen is often the initial diagnostic tool available for infertile couples. Identifying

abnormalities with the sperm cells – especially morphology and motility – can be a significant determinant of eventual fertility. Currently, computer-aided sperm analysis (CASA) systems can assess these characteristics in sperm cells. Using AI-enabled image analysis has the potential to lead to results that are more precise and reduce variability found in the manual inspection. In 2017, researchers of the University of North Carolina at Chapel Hill applied an automated technique to categorize motility patterns of human sperm – and the model accuracy was 89.92% [4].

Another area of promise for AI in the IVF space is that of assessment of oocytes and embryos. Given that the current rate of pregnancy occurrence for every viable oocyte remains under 5% [5], the demand for automated decision systems that can address lack of options for determining success of the IVF episode by the quality of oocyte is high [6]. Often, the manual inspection of oocytes can lead to misleading results – with cells visually appearing within routine morphological characteristics – leading to chromosomal abnormalities in the fetus [7]. This constitutes one of the most compelling reasons for opportunities to employ computational intelligence for such cases. Similarly, the ability of the embryo to survive is a crucial component for increasing the rate of pregnancy and the success of IVF approach [8]. Contemporary techniques employed – including visual inspection of the embryo morphology – are plagued by specialist variability that is closely related with the training of the specialist rather than the accuracy of their methods [9–11]. These concerns around embryo viability are more serious in the IVF approach, as increased repetition of embryos being placed from in vitro to in vivo can lead to complications for the expectant mother [12].

Although IVF remains an important option for infertile couples, the high costs – and often high rates of failure – make the approach prohibitive for many [13]. Automating parts of the process – and developing an ability to predict the success of the procedure with a convincing level of confidence – presents a highly sought-after use case for implementing AI in obstetrics. Early evidence suggests that predictive analytics in estimating

embryo viability through AI-enabled technologies hold promise – with recent studies reporting differentiation capability being up to 80% [14].

Ethical Challenges

There are some clear advantages of employing AI for IVF – potential to improve assessment of gametes, reduce manual inspection, and alleviate errors. However, as is the case with numerous AI-enabled medical technologies, application of AI methods in the space of in vitro fertilization or other gynecological diseases presents severe ethical dilemmas. For instance, the moral repercussions or legal liability concerns are not clear if embryos chosen by the automated decision-making technologies are deemed to have genetic abnormalities or chromosomal aberrations, especially after implantation or during the course of the pregnancy. Given how these automated decision systems operate as a “black box,” with both the technical developers and clinical users often unaware of the potential outcomes that do not always adhere to human understanding [15], the basis of assessments for the quality of a particular sperm, oocyte, or embryo remains relatively unknown. Another severe ethical concern is that of the definition of a “normal” embryo and the potential selection bias in data that determines this status [16]. This could lead to the unscrupulousness of designating certain genes or features as desirable at the expense of other features – and we know that sociocultural norms play a significant role in such determinations [17].

Abstract

Artificial intelligence (AI) systems have been proposed for reproductive medicine since 1997. Artificial intelligence (AI) is perfectly suited to solve some of the complex problems in reproduction and pregnancy including assessment and diagnosis of infertility; oocyte and sperm analysis and selection; embryo annotation, evaluation, and selection; prediction of embryo chromosome status (ploidy); pregnancy viability; and miscarriage prediction. AI uses

multiple sources of data to reveal patterns in diagnosis, treatment, and results. AI systems are being developed to predict individual infertility patient risk, suggest treatment options in reproductive medicine, assess the chance of achieving a pregnancy and a healthy baby, anticipate complications during pregnancy, and predict “time to pregnancy.” With respect to IVF lab efficiency, manual processes and procedures currently predominate in the IVF laboratory. Automation and AI systems promise to lessen the burden of subjective, menial, or mundane aspects of the embryology laboratory, while automation can decrease inter- and intra-technician variability. The future of AI technologies promises to further address environmental stressors that can impair gamete function and embryo development.

Introduction

The applications of artificial intelligence in obstetrics and gynecology have grown significantly in the last 15 years. The health of woman during pregnancy can be effectively monitored and the provision of services improved. Disorders such as congenital heart birth defects or macrosomia, gestational diabetes, and preterm birth can be detected earlier when artificial intelligence is used. Infertility is another significant reproductive arena that AI is now significantly being developed and validated for. Millions of babies have been born through assisted reproductive technologies (ART); however, only 30% of in vitro fertilization (IVF) cycles succeed in a clinical pregnancy. Aside from increasing the success rate, there are other worthwhile goals for continued improvement across the industry, to simply get patients pregnant faster, reduce treatment dropout, or to reduce embryo wastage. Innovations in artificial intelligence (AI) will drive ART that is more reproducible, standardized, efficient, and less costly.

Artificial Intelligence in Reproductive Medicine

Opportunities and Limitations of AI in Reproductive Medicine

Predictive algorithms using AI have gained particular prominence in the field of reproduction (Table 1), maternal health, and assisted reproductive technology. The goals of automation through artificial intelligence are to improve efficacy, efficiency, and consistency of clinical decision

Table 1 Artificial intelligence and machine learning for maternal health

Preconception	Reproductive urology Genetic compatibility (HLA) Fertility management Family planning
Assisted reproductive technologies	Ovarian stimulation Gamete selection and grading Embryo grading Embryo selection Embryo ploidy Risk assessment
Prenatal care	Fetal anomalies Fetal size Fetal heart rate Ectopic pregnancy Placental function Miscarriage Pharmacological safety Gestational disease Maternal mortality
Preterm birth	Fetal mortality Fetal prognosis Contraction pattern Cervical properties Perinatal outcome prediction
Perinatal care/birth	Perinatal complication and APGAR score Date of delivery Complications
Postnatal/postpartum care	Postnatal health Postpartum depression Mortality

making during an ART treatment, such as; embryo classification and selection, sperm identification and classification, and ovarian response prediction and personalized protocols. Predictive modeling and artificial intelligence applications have evolved into a standalone subdiscipline of reproductive medicine, and the literature have been analyzed and evaluated using formal systems, such as the Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis (TRIPOD). Predictive modeling and AI's place as a support tool is growing in clinical practice, but gains in patient outcomes and improved workflows have yet to be fully realized.

The development of AI systems that are widely applicable across ART clinics and protocols, and to geographies and populations, has been

challenged by the quality, diversity, and volume of available data. AI systems need big data to achieve robustness. Accessing so-called “BIG” data for ART should be a trivial problem, as more than 2.7 million assisted reproduction cycles are performed each year. However, it is a challenge for researchers to access “Big Data” and collaboration for prospective, cohort studies. These data are highly sensitive and strictly regulated, and patient consent and ethical approval are mandatory.

Large datasets are becoming increasingly important. So-called “big” data is used for research, external quality assurance, and policy making. Over 2.7 million assisted reproductive technology (ART) cycles are performed annually, generating millions upon millions of individual data points. ART is purportedly one of the best registered procedures in medicine, with global IVF registries spanning Europe, USA, Latina America, Japan, Africa, Canada, New Zealand, and Australia [10]. The International Committee Monitoring ART (ICMART) has summarized global IVF data [14] based on existing registries from approximately 60 countries and 2,500 centers (collectively representing approximately 4.5 million IVF cycles) spanning 2008–2010. Unfortunately, many limitations exist, making these databases moderately useful. Globally, ICMART is only capable of collecting unverifiable summary data. At the national level, datasets such as the HFEA were established for regulatory, not research purposes and therefore, lack the detail necessary to answer basic clinical practice questions.

Additionally, huge data sinkholes exist. For example, the majority of IVF lab data are recorded on paper charts, many labs don’t record any image data, outcome metrics are extremely variable, and the Asia Pacific region (where an estimated 400,000 (plus) cycles are performed annually) does not (yet) report outcome data to a national registry.

Another challenge faced in AI development is the quality of the training data and how the machines learn from it. The training data – perhaps embryo, oocyte, or sperm images – still have to be evaluated and graded by human

embryologists, and the populations these training data come from may be biased (by income, race, infertility diagnosis, etc.). How well the AI learns depends on the quality and size of the dataset. The role of medical coders has not yet been fully realized for the development of AI systems for ART. Medical coders analyze individual patient charts and translate complex information about diagnoses, treatments, medications, and more into alphanumeric codes. These codes are submitted to billing systems and health insurers for payment and reimbursement and play a critical role in patient care. Billing specialists represent an untapped well of knowledge; as they are responsible for the accurate assessment of charts, they could also enrich AI systems with medical knowledge that can improve the system’s performance.

A critical step in modeling is preprocessing and the treatment of images, before feature extraction and model training. Clumsy preprocessing and federated subsets of data generated at various geographic locations (with different cropping and contrast, taken on a wide variety of cameras and microscopes) may yield an inconsistent database that leads AI models to poor accuracy. A worldwide common reproduction specific git style image and video repository (similar to genome sequence databases) and automated methods to crop, remove patient information, rotate and size images or video is a worthwhile goal, and one that will take immense international collaboration. Commercial blockchain solutions are already being built, to provide distributed frameworks to enable privacy preservation, collaborative machine learning, and guaranteed traceability and authenticity of data using a distributed ledger.

Typically, AI systems are trained with many billions or millions of data points. As of the writing of this chapter, the largest published datasets that have been used to train or validate various deep learning, machine learning, and neural network systems in the field of reproduction fall in the 1,000–10,000 range, for example, the following:

- Bormann, C. et al. [1] (742 embryo images)
Kan-Tor et al. [2] (6,200 time lapse videos); 52 Chavez-Badiola, A. [33] (1,231 embryo images)

VerMilyea M. et al. [3] (8,886 embryos)
Letterie, G. et al. [17] (2,603 total cycles (1,853 autologous and 750 donor cycles))
Tran, D. et al. [4] (8,836 embryos)
Blank, C. et al. [5] (1,052 patients)
Chen, T et al. [6] (171,239 images from 16,201 embryos)
Miyagi, Y. et al. [20] (5,691 embryo images)

AI for reproduction dataset is available for download at www.repro-ai.org.

It is likely that the majority of AI training data are generated mainly from IVF cycles in a very specific patient population – white, wealthy, etc. There is a marked, and unacceptable, difference in the outcomes after fertility treatment between minority populations. The assisted reproductive technology (ART) failure rate, defined as no live birth after treatment, is 51.9% (white), 61.8% (Asian), 62.2% (Black), and 55.9% (Hispanic), and ART stillbirths account for 16.3% (white), 18.4% (Asian), 25.0% (Black), and 17.8% (Hispanic).

These are problems that AI is uniquely suited to solve. Artificial intelligence in “precision reproductive medicine” has the potential to resolve the genetic uniqueness of individuals and the molecular mechanisms of their infertility, to match each individual to the best treatment.

Conventional IVF (despite scientific advances like genetic carrier screening, embryo biopsy with pre-implantation genetic diagnosis, ICSI, and “freeze-all” cycles) is woefully inefficient and wastes millions of gametes and embryos worldwide. Convolutional neural networks have been shown to choose genetically “normal” blastocysts from single static images or video, better than fully trained embryologists with dozens of years of experience. Advances like these, when applied clinically, have the potential to address this problem.

In the USA, there is a vast underserved infertility market that includes those seeking genetic disease prevention, LGBTQ, proactive fertility management (oocyte and sperm freezing), and those without access to fertility care (i.e., most people, as only 17 of the USA require infertility insurance, although private employers are

increasingly offering these benefits). We know beyond a shadow of a doubt this is true, by comparison with other developed countries. There are seven million women with infertility in the USA, and only 1% of those successfully deliver an in vitro fertilization baby per year. Australia, Japan, and in many parts of Europe have rates that are three times higher than the USA. IVF is an incredibly manual labor-intensive process.

There is a dearth of well-trained embryologists to perform these labor-intensive tasks, and staff training is often a “bottleneck” in the management of IVF labs. AI systems have the potential to revolutionize the market by assisting with the manual, time and labor consuming, rote, routine, intensive and subjective embryology tasks while increasing the number of patients (scale) that can be served safely.

There are significant challenges to implementing any AI system in a meaningful way into a clinical IVF laboratory, yet it is almost certain that AI is the future of reproductive medicine. Wherever electronic health records (generally), and AI systems specifically, have been proposed, there are unresolved controversies about privacy, effects on doctor/patient relationships and trust, whether individuals can opt out, who controls or can have access to data and when consent is required, how to protect data from unauthorized use or accidental loss, and use of “de-identified” data for ethically approved research.

Implementation of an AI at the actual point of care in a routine, easy, and automated fashion is also currently impossible for the majority of ART clinics that still use paper charts and doesn’t capture and store even a single digital image of their patient’s embryos or gametes, much less the videos that are needed for true big data. Additionally, data management solutions to augment patient demographics, clinical and lab key performance indicators (KPI), and other relevant data streams (ultrasound images and PGT results, competency assessments, endocrinology, microscope and incubator QC, room/environmental factors) into a single dashboard are lacking.

Research laboratories worldwide have developed AI systems to enhance diagnostic and prognostic capabilities, minimize variability and error,

and maximize precision and efficiency of IVF treatment, but they have not yet achieved robustness for safe clinical implementation, and no prospective validation trials have been published as of the writing of this chapter.

Looking to the future, research scientists and clinicians are tasked to transcend simply packaging *established* pregnancy predictors in fancy new machine learning algorithms. *Novel* variables and *hidden* relationships that allow for superior predictive capabilities will be uncovered through prospective design, big datasets, standardized outcome measures, external validation, and integration of clinical and laboratory key performance indicators, and patient demographics.

Current controversies in the field illuminate the difficulties with subjective grading, false negatives, mosaic embryos, and the near certainty that viable embryos are being discarded even using the best techniques available. Bias and black-box problems mean that AI systems that seek to diagnose, rather than rank embryos for transfer have the potential to worsen this problem.

AI for Assessment, Diagnosis, or Treatment of Infertility

Infertility is a multifactor disease, which makes diagnosis and treatment complicated. In reproductive urology, AI applications initially focused on semen parameters [15] but have advanced to automated sperm detection, semen analysis, and prediction of disease [29], for example, in the patient population most likely to need a genetic workup for azoospermia [19]. Goodson et al. [30] classified individual sperm as progressive, intermediate, hyperactivated, slow, or weakly motile using support vector machines (SVM) with 89.9% accuracy. Mirsky et al. [31] employ interferometric phase microscopy along with SVM to develop a model that assess the morphology of sperms and classify them into good or bad morphology with over 88% accuracy. Girela et al. [32] aimed to evaluate the relationship of lifestyle habits and semen quality in young healthy men, using 34 environment and lifestyle variables. They

were able to determine sperm concentration with 90% accuracy and sperm motility with 82% accuracy, while El-Shafeiy et al. [7] found that just nine lifestyle parameters could predict semen quality.

Liao et al. [34] showed that a machine learning-derived algorithm is useful to assist clinicians in making an efficient and accurate initial judgment on the condition of patients with infertility. Over 60,000 infertile couples' medical records were evaluated using a grading system that divided the condition of the patients into 5 grades from A to E. The worst E grade represented a 0.90% pregnancy rate, and the pregnancy rate in the A grade was 53.82%. The cross-validation results showed that the stability of the system was 95.94%.

Letterie et al. [17] evaluated a computer decision support system for a day-to-day management of ovarian stimulation during in vitro fertilization following key decisions made during an IVF cycle: (1) stop stimulation or continue stimulation. If the decision was to stop, then the next automated decision was to (2) trigger or cancel. If the decision was to continue stimulation, then the next key decisions were (3) number of days to follow-up and (4) whether any dose adjustment was needed. They used data derived from an electronic medical records system of a female population undergoing IVF cycles and oocyte cryopreservation to include the patient's demographics, past medical history, and infertility evaluation including diagnosis, laboratory testing for ovarian reserve, and any radiologic studies pertinent to a diagnosis of infertility. The four key decisions during the process of ovarian stimulation and IVF were compared to expert decisions across 12 providers and found to have a sensitivity of 0.98 for trigger and 0.78 for cycle cancellation. Nisal et al. show a 40% decrease in stimulation medications, as suggested by AI systems [24].

AI for Embryo Annotation, Evaluation, and Selection

It is generally acknowledged that despite advances in embryo selection based on morphology, time-

lapse photography, or embryo biopsy with preimplantation genetic testing (PGT), implantation rates in human IVF are incredibly inefficient. While morphological evaluation is widely accepted and implemented in most IVF clinics worldwide, the exact morphologic parameters used to score embryos are highly variable between clinics, and the assessment process is strikingly subjective even between embryologists at the same clinic.

The development of automatic time-lapse imaging (TLI) systems (the unification of an incubator and microscope connected to a computer for automated image capture and recording) has made it possible for embryologists to continuously monitor embryonic development without disturbing *in vitro* culture conditions. In the decade since it was introduced to the ART field, TLI has enabled embryologists and researchers to thoroughly track and annotate the specific timing and duration of morphological changes, known today as morphokinetics, as well as identify previously unobserved embryonic events. This new source of data has paved the way for an improved understanding of the clinical implications of various morphokinetic attributes, and has made it possible to conduct detailed retrospective studies on embryos with a known clinical outcomes.

TLI systems are expensive and are not readily available to most fertility centers. Therefore, assistive tools and algorithms that can work with static (2D) images acquired from traditional microscopes that are available to virtually all fertility centers are being developed. A multicenter study using large retrospective data of single blastocyst (BL) images used an artificial intelligence (AI) platform to predict FH implantation [3]. The model's predictions were compared to those made by embryologists across 11 different IVF labs and showed an overall improvement. Chavez-Badiola et al. [8] predict embryo ploidy using computer vision for feature extraction and image preprocessing on a single blastocyst image. Bormann et al. [1] examined the performance of a deep convolutional neural network (CNN), trained using embryo images from a single timepoint to detect which embryos were most likely to implant out of a group of high-quality embryos that displayed few visible differences.

AI for Prediction of Embryo Chromosome Status (Ploidy)

Embryo morphology (blastocyst grade and score) has been shown to be associated with embryo ploidy. High-quality embryos have a higher chance of being euploid. Noninvasive prediction of embryo ploidy is becoming increasingly important. Trophectoderm biopsy, performed at the blastocyst stage, is invasive and likely impairs embryo development, reducing the embryo development potential. Other downsides of trophectoderm biopsy are the cost of sequencing, the clinical management of mosaic embryos, the skill required to biopsy TE cells, and the fact that only a select number of blastocysts (BLs) can be tested. Noninvasive biopsy methods promise to provide comprehensive embryo information, prioritize embryos for trophectoderm biopsy, and successfully rank embryos for transfer.

AI in Maternal Healthcare Miscarriage Prediction

Several diseases and adverse outcomes during pregnancy (e.g., preterm birth, preeclampsia, and miscarriage) have complicated and difficult-to-understand etiology. In places like the USA, maternal mortality is increasing, unlike other places worldwide where it is decreasing. Pregnancy and maternal healthcare generate many different data types (e.g., ultrasound imaging, diagnostic screening, fetal monitoring, genetics) that can be integrated by AI to address maternal health throughout the pregnancy process: preconception, prenatal, perinatal, and postnatal period. There is a significant gap in the research on pregnant and lactating, breastfeeding women and pharmacological safety and efficacy due to their systemic exclusion from RCTs, yet up to 80% of pregnant or lactating women will need to take a pharmacological substance [16].

Ultrasound (US) images and videos are a significant source of potential data for AI analysis. Detecting or predicting miscarriage and pregnancy loss is of particular importance, particularly following infertility treatment when the patient

will already be closely monitored [18]. Among the ultrasound scan markers, fetal bradycardia is a strong marker for miscarriage prediction and could be combined with other markers such as intrauterine hematoma, crown rump length, yolk sac, and patient demographic and biochemical markers [13].

Another approach [21] explored the use of AI in combination with immunogenetic data (HLA) to predict recurrent MCs. This research implies that accurately assessing the risk of recurrent miscarriage associated with a given pair of gametes could improve gamete donor selection and therefore increase pregnancy success rates.

Paydar et al. developed a clinical decision support system to predict pregnancy outcomes among systemic lupus erythematosus (SLE)-affected pregnant women, namely, spontaneous abortion or live birth. Two ANNs were trained based on features selected by a binary logistic accurate (91%) for prediction of spontaneous abortion or live birth of SLE-affected pregnancy.

Several studies aim to predict and classify disease in early pregnancy, improve screenings, and provide clinical decision support for disease management. Chronic hypertension, chronic respiratory disease, substance-use disorders, and preexisting diabetes are common disorders that can coincide in pregnant patients. Pregnancy itself is the source of gestational diabetes mellitus (GDM), hypertension disorders, and bacteriuria (hemolysis, elevated liver enzymes, and low platelet (HELLP) syndrome). Polak and Mendyk [26] developed a GDM screening tool using ANNs to model relationships between demographic factors and the risk of GDM, while Moreira et al. [22] propose application of the radial basis function network (RBFNetwork), an ANN technique, to identify possible cases of GDM in pregnant women. Tejera et al. [27] constructed a model for classification of women with normal, hypertensive, and preeclamptic pregnancy using maternal heart rate variability indexes and ANNs. Moreira et al. [23] propose a model using ANNs and fuzzy logic to predict HELLP syndrome in high-risk pregnancies.

Boland et al. [12] developed a method that utilizes machine learning to predict the *fetal*

toxicity of pharmacologics taken during pregnancy, including first through third trimesters of the pregnancy.

Conclusion

Currently, prospective studies are necessary to validate any AI system's usefulness in the clinical setting of obstetrics and gynecology, urology, and infertility. In reproductive medicine, data is not as easily obtained due to factors like data privacy, and lack of structured EMRs among others. To overcome this problem, multicentric collaboration is one way in which some groups have managed to increase the size of their data with excellent results. Low-quality and/or small-sized databases can result in biased models, which might not be generalizable across clinics nor reproducible. Since AI relies on the quality of the information used for training, transparency about the quality of datasets becomes paramount to understanding a novel AI's clinical potential.

Abstract

Artificial Intelligence invites boundless opportunities and cutting-edge innovation in Reproductive Medicine (RM). In the future, machine learning (ML) algorithms will offer effective and efficient utility in assisted reproductive technologies (ART), as well increase the potential for individualized patient care. As the future of RM offers great advancement it is imperative to understand how this will inevitably impact people. Therefore, the purpose of this chapter is to highlight the diverse gender perspectives and issues that could derive from advanced RM. What this entails is observing

how increased technology can impact the future of gender, as ART and future enhancement technologies allow prospective parents the chance to select the gender of their future offspring. It must be examined how these technologies can contribute to existing inequalities, and whether this would worsen gender discrimination and bias. In addition, this chapter aims to employ a twenty-first-century approach to understanding gender aspects in RM. What this involves is highlighting the perspectives of often marginalized groups in RM. This includes highlighting male, transgender, and nonbinary experiences in RM. The point of this is to further enrich the discussion surrounding gender and RM, and make it as inclusive as possible for all people.

Introduction

Artificial Intelligence (AI) is “the ability of machines to learn and display intelligence which is in stark contrast to the natural intelligence demonstrated by humans and animals” [1]. Ever since the invention of Artificial Intelligence and Future Emerging Technologies (FET), pivotal technological breakthroughs have been made all throughout the twentieth and twenty-first centuries. Consequently, the invention of technology has dominated industries across all sectors. As a result, it is imperative to understand how such advances have changed the landscape of modern medicine, with a particular emphasis on reproductive medicine. Thus, the purpose of this chapter is to explore AI, and its applications in medicine, with a thorough and specialized focus on reproductive medicine (RM) and gender perspectives. What this entails is exploring the history and origins of reproductive medicine, understanding the relationship between modern-day AI and reproductive medicine, and the crucial role that gender plays in reproductive medicine. This will be done by exploring how RM has changed and how it will subsequently impact men and women.

As RM will be discussed at length in this chapter, it is essential to establish a definition.

Thus, for all intents and purposes, the definition of reproductive medicine strongly refers that...

Reproductive medicine is a subfield of medicine that specializes in the health of the reproductive organs. This includes the diagnosis, treatment and prevention of infertility in men and women, as well as issues relating to contraception, puberty, menopause and some sexual health related conditions. National Cancer Institute in partnership with the National Institute of Health [2]

As well as establishing a definition for RM, it is equally important to establish the meaning of gender. The meaning of gender in this chapter will explicitly refer to the socially constructed norms, behaviors, and assigned roles associated with masculinity and those that identify as male, and with femininity and those that identify as females [3]. This is not to be confused with biological sex that refers to the biological reproductive organ that one is born with, and assigned at birth [3]. It is also acknowledged in this chapter that there are more than two genders, and thus aims to highlight the experiences of not just biologically born men and women, but to also include the reproductive experiences of transgender and nonbinary people.

The History of Reproductive Medicine

The origins of reproduction theory and ideology can be traced back to Aristotle in ‘*De Generatione Animalium*,’ or as it is more commonly known in the West, *On Generation of Animals*. [4] In this piece of work, Aristotle proposed that human beings are made through the merger of male and female seeds [5]. It was believed that when male sperm came into contact with something with a hematogenous origin, this would cause the development of an embryo from menstrual blood that was present in the female uterus [5]. While there are understandably flaws in this hypothesis, the work of Aristotle is considered to be one of the most important pieces of work and theories in the history of reproductive medicine, and has survived for 2000 years with only slight modifications in its time [5]. In addition to Aristotle, there have been some other key figures that have contributed to the framework and body of literature surrounding reproduction. This can be evidenced by Galen’s conception theory, in which he stated that “seeds come from the fluids of the body...the seed is said to be secreted from each of the parts.” [6] This was of great importance at the time as this theory was a step closer in breaking down the theory of reproduction. Other notable work derives from William Harvey in a book entitled, *Exercitationes de Generatione Animalium* [7]. In

this book, Harvey coined the phrase “ex ovo omnia” which translates to “everything from an egg” [5].

“Ex ovo omnia” [5] was Harvey’s belief that animals are born from a “homogenous mass which has [animal] life actually or potentially” [8], and thus that is how life is formed. Harvey’s theory differed from previous theories as he rejected the hypothesis of Aristotle and Galenists [7], and instead believed that when seminal fluid comes into contact with the female momentarily, it establishes the “fecundity” of the female organism [8]. After some time, the fertilized female forms the initial embryo and then the embryo continues to grow and develop into a human being [8].

These early ideologies of reproductive medicine, while flawed or slightly inaccurate in nature, were very important in laying out the foundation for our current understanding of reproduction, and subsequently the specialist medical field of reproductive medicine.

As scientists continued to theorize about the act of reproduction and fertilization, with it came a curiosity to see if life could be made from outside an organism and with some human intervention. The earliest experiments of in vitro fertilization (IVF), an experimental procedure to see if fertilization could take place outside the body, could be traced back to the 1770s, as Lazaro Spallanzani discovered that frog oocytes developed into tadpoles after having been in contact with semen [5]. In 1827, Karl Ernst Von Baer discovered that mammals also possess oocytes and published his research [5]. Major strides continued to be made and by 1878 research conducted by, Samuel Leopold Schenk, confirmed that cell division could be made outside of the body [5] after IVF experiments were conducted on mammals, such as rabbits and guinea pigs.

All of these experiments and findings were of great importance and served as the foundations for doctors and pioneers, such as John Rock, Miriam Friedman Menkin, and Min Chueh Chang, to start conducting experiments in human beings [5]. After extensively researching fertilization outside the body in mammals, the next goal and breakthrough for the scientific community was to

see if fertilization could take place in humans outside the body. This breakthrough was achieved in 1944, when Dr. Rock and Miriam Menkin found that a human egg could be fertilized outside the womb [9]. They then published their findings in an edition of *Science Magazine* entitled “In Vitro Fertilization and Cleavage of Human Ovarian Eggs” [9]. At the time of the publication the news had become somewhat of a contentious topic and had garnered significant attention from scientific, public, and religious circles.

Noteworthy to mention is that one of the most interesting perspectives on this topic derived from couples, particularly women, who had struggled with infertility. Numerous women had written directly to Dr. Rock after the publication and had inquired about what the procedure was, what it entailed, and if it “could help them to become pregnant?” [10] A reporter, Joan Younger, who had been following the research of Rock and Menkin had written an article, “*Life begins in the test-tube*” [11], in which she had discussed an increase in infertility among healthy couples, and how this new procedure was a symbol of hope. Women at the time were happy to volunteer themselves as test subjects for Rock’s experiment [11]. This demonstrates the clear attitudes women had very early on about IVF and how for many it was seen as a renewal of hope. Although this news had encouraged hope for many infertile couples, the experimental procedure received criticism from religious circles. In many religions, the idea of creating life outside the human body was considered to be “unnatural,” and going against the Will of God [12].

In the twenty-first century, the introduction of Artificial Intelligence (AI) and future emerging technologies (FET) in medicine has raised similar concerns and sentiments that people have had in the past about IVF, and Assisted Reproductive Technologies (ART). This is because some people are skeptical about the use of AI and FET in medicine, with regard to reproductive medicine in particular. Contention on this topic derives from controversial debates surrounding ideas around genetic engineering/modification and biotechnology. With technology being a catalyst to make these procedures and innovations possible, some

people fear what this could mean for future generations. This very topic has since accumulated much literature on both sides. To adequately understand the different perspectives on AI in reproductive medicine, it is important to ask two key questions:

1. What is the relationship between AI and Reproductive Medicine?
2. What are the future objectives, issues, and challenges that derive from this?

These aforementioned questions will be discussed at length.

The Relationship Between AI and Reproductive Medicine

Over the past few years significant advancements in AI have led to the widespread implementation of AI in medicine [13]. AI applications such as ML, NLP, and robotic technology have helped to revolutionize the field of medicine by assisting doctors in the prognosis, diagnosis, and treatment of their patients, and have largely improved patient care and satisfaction. Such advancements and improvements in medicine have been possible through ML algorithms that allow computers to learn, compute, and analyze trends and patterns based upon large and complex datasets [13].

ML techniques and applications have proven to be vital in health care as sufficient evidence from science-based studies present an increase in accuracy of these applications, aiding doctors and their prognosis of patients. This phenomenon can be evidenced by a unique case study, in which a newborn baby that appeared to be healthy continued to have constant seizures, most commonly referred to as status epilepticus; despite having no signs of infections and clean CT scans [14]. The prognosis for this newborn baby appeared bleak, as numerous drugs to reduce and control the seizures had failed, and the seizures had become even more pronounced [14]. Eventually a blood sample of the infant was sent for rapid whole-genome sequencing, at Rady's Genomic Institute [14]. "The sequence encompassed 125 gigabytes of data" [14] and had searched

almost "five million locations where the infant's genome differed from the most common one" [14]. Within 20 s the NLP AI application had processed the infants digital medical record and had determined "eighty-eight phenotype features" [14] (observable traits and characteristics of an organism). The ML algorithms were utilised to filter through five million genetic variations to find the rarest gene variations that could cause the onset of these seizures [14]. Using the child's phenotypic data and cross-referencing it with all the possible genetic variations, the system was able to identify the gene ALDH7A1, as the most likely cause for the seizures [14]. The gene variant is extremely rare and "occurs in less than 0.01% of the population" [14]. After the detection of this extremely rare variant, which due to its rarity could have been overlooked by doctors, the infant was able to seek treatment and was healthy overall [14]. This case highlights firsthand how impactful and beneficial AI can be in healthcare.

In the field of RM, AI is proving to be extremely helpful in enhancing ART and can actually serve as a solution to overcome some of the biggest challenges pertaining to infertility in couples [1]. As AI and ML algorithms have the potential to analyze large and complex datasets, as previously described in the aforementioned case study, this could significantly change and impact the field of RM. With the ability to analyze large datasets in real-time, the use of AI applications could result in more personalized treatment options for fertility patients [15]. As various patient information such as different fertility issues, solutions, treatment plans, procedures, and outcomes can be analyzed and cross-referenced in databases, this can effectively assist doctors. In fact, this has huge significance as not only can diagnoses be made faster but the appropriate and individualistic treatment options can then be given to patients [15].

In a 2019 article, *Artificial Intelligence: its applications in reproductive medicine and the assisted reproductive technologies*, the collective authors discuss AI and ART, and hypothesize that the "application of AI in IVF will be significant" [15]. This is because AI can be used in the "assessment of ovarian reserve parameters and sperm selection" [15], and in the evaluation and selection

of embryos [15]. The fact that AI can be utilized to detect pivotal indicators and “developmental hallmarks” [15] for viable embryos is especially of significant importance as it allows for greater accuracy and hence, increases the risk of successful insemination [15]. The use of AI promises greater accuracy and results in embryo selection as current methods rely on the analysis of embryologists reviewing a combination of factors [15]. The issue with this methodology, however, is that there is no standardized approach in the analysis of viable embryos and analysis can thus be largely subjective [15].

This very phenomenon became apparent after a study highlighted that different embryologists had varying results in embryo grading and viability; thus, presenting how embryo selection was highly subjective [15]. Breakthroughs in AI and ML programs have allowed for computers to input the data of embryos and determine a standardized approach to grade the viability of embryos [16]. The KIDSscoreD5 system is an AI-powered system that accurately studies, analyzes, assesses, and classifies embryos [16]. Thus, this system can increase the likelihood of successful implementation and birth. A series of studies has further shown that the KIDSscoreD5 system has had a significant impact in ART and has shown great clinical promise [16]. The KIDSscoreD5 system was able to effectively analyze “more than 20,000 embryos in more than 3000 patients” [16]. Not only was the system able to compute the data of the embryos but was able to do so with effective results, thus increasing the possibility of selecting the best embryo for fertilization [16]. Moreover, the KIDSscoreD5 system is able to select the embryo with the least likely chance of having a chromosomal mutation [16]. The gains made in ART as a result of advanced AI have been immense and continues to change and innovate remedial tasks, thus, resulting in better and more favorable outcomes for patients.

Gender and Reproductive Medicine: Objectives, Issues, and Challenges

As reproductive medicine continues to accelerate and develop at a rapid pace due to the prevalence

of technology, the future of reproductive medicine is full of possibilities and challenges. The way reproductive medicine will change and develop in the future will significantly impact the population and has the potential to be a double-edged sword for modernity and freedom of choice. This is largely because reproductive medicine can often be associated with choice, and the freedom to have choices, when it comes to one’s reproductive organs and fertility. However, as technology allows us to potentially expand our choices, it must be imperative that people make safe and responsible choices when using this technology.

As AI and technology becomes increasingly more embedded within the field of RM, this will inevitably change the nature of RM. As technology becomes smarter, this opens the door to a number of possibilities in this domain. One of the areas that will greatly and fundamentally benefit will be genetic medicine. As it is desired that in the future, genes can be edited or altered via genetic engineering. “Genetic engineering (GE) is a process that involves changing, altering or manipulating an organism” [17]. GE is a broad term and also encompasses many synonyms such as genetic modification, genetic manipulation, genetic technology, biotechnology, and recombinant DNA technology [17]. There are many purposes and practical functionalities of GE [17]. This includes isolating and researching gene properties, structures, and functions [17], producing “useful proteins by novel methods” [17], diagnosing and treating patients [17], and “genome analysis by DNA sequencing.” [17] In order to do this, a gene editing technique, clustered regularly interspaced short palindromic repeat (CRISPR)-associated system (Cas) technology [18] is employed. CRISPR allows genetic engineers and doctors to precisely select, “target and study certain DNA sequences in the vast expanse of the genome.” [19] CRISPR-Cas9 also allows scientists the possibility to edit DNA [19], as through this technology, it is possible to manipulate genes and send “proteins to specific DNA targets” [19] that can switch genes on or off, or even completely “engineer entire biological circuits” [19]. The way that CRISPR-Cas9 works to make gene editing possible is through the protein Cas9. Cas9 functions as “molecular

scissors” [20] and can be programmed to cut a specific part of the DNA “as it carries with it Guide RNA (gRNA)” [20]. The gRNA will guide Cas9 exactly where to cut the DNA from [20]. After the cut has been made in the DNA, the DNA will try to rebuild itself; however, this is where scientists can manipulate and alter this process [20]. Scientists can instead introduce “template DNA that guides what bases are inserted in the gap.” [20] This then results in the genes being edited. GE using CRISPR-Cas9 thus far has mostly been successful in plants and animals [21]. In humans beings, GE has been largely experimental and is often met with contentious moral, ethical, and philosophical debates.

With the potential to edit genes, this raises some serious questions about the direction we are heading in and what it is that we want to achieve in the future with such technology. Many people believe that the ultimate goal will be the “designer baby.” [22] A designer baby is a baby that has been genetically enhanced by the pre-selection of genes prior to birth. What this connotes is that, genes that are inherently linked to more desirable superficial characteristics and traits, for example, blue eyes, brunette hair, and height, can be selected to ultimately create a genetically enhanced version of a child [22].

Some fertility clinics across the USA offer the opportunity to prospective parents to select certain attributes for their offspring through preimplantation genetic diagnosis (PGD) [23]. PGD sometimes referred to as PGT-M is a treatment option that allows embryos to be screened for genetic/chromosomal abnormalities [24]. In addition to this, PGD can also reveal other important genetic information regarding the embryo such as, the likelihood of the embryo being male or female, or even the child’s eye color. The Fertility Institutes is a fertility practice that offers the opportunity of gender selection to prospective parents [24]. The way that the procedure is done is firstly by extracting the eggs from the mother and collecting the sperm from the father [23]. The eggs are then fertilized via IVF in a laboratory [23]. The fertilized eggs are then tested and screened for genetic or chromosomal irregularities and also the desired gender [23]. A genetic test will reveal the likelihood of having a baby of a

particular gender or feature for example, eye color [25]. The selected embryo will then be implanted into the mother and gestation and birth will proceed as normal [23].

If in the future parents have permission and accessibility to utilize this technology, it leads to some wider concerns about the power and choices parents could make regarding their child. This is because this technology would give parents the freedom to choose certain attributes of their future offspring, including, even, the gender of their child. This may have some potentially adverse consequences for people that favor a particular gender over another. While the gender of a child may seem trivial at face-value, this issue is a deep-seated one that remains in the conscious bias of many cultures, globally. Particularly, many Asian cultures tend to favor males over females [26]. In Asian countries, such as China and India, patriarchal norms and ideologies are widely imbedded within society with there being an increased value placed both socially and economically on males [26]. Consequently, women and girls endure severe mistreatment both by society and familial structures [26]. Furthermore, numerous studies highlight a new and alarming trend in which baby girls in India and China are becoming victims of gendercide [26].

Gendercide is “the systemic annihilation of female fetuses solely for their sex in preference of their male counterpart.” [26] This systemic discrimination and bias has resulted in two hundred million girls less in the world, as these baby girls were “killed, aborted and abandoned” [26] solely because of their gender [26]. The ratio of girls to boys in these countries continue to decrease and this has been a constant trend since the 1990s [26]. Despite these alarming concerns, the Indian and Chinese governments have not taken measures to remedy this problem; nor has there been sufficient efforts to adequately address and or publicize the issue [26]. This apparent discrimination and declining gender issue are important to consider at present, as it must be considered what could and would happen, if parents had the freedom to select the features for their potential offspring. In countries like China and India, where gendercide is already a dangerous and concerning problem, it must be considered

what would happen if genetic editing technology was incorporated into the mix. This aspect raises many questions such as:

- Would the availability of gene editing technology be knowingly contributing to already established social problems and gender-based discrimination?
- How can it be ensured that state governments can regulate the responsible and safe use of this technology, when countries like China and India have already been unresponsive to the gendercide that has been happening in their respective countries?
- What rights should the potential offspring have? Is it violating the rights of the child to choose their gender as a novel reason; for example, financial gain, social acceptance, and carrying family names?

Reproductive Medicine and Gender: A Century-First Century Approach

Traditionally, RM was commonly associated with the experience of those born with female reproductive organs. While infertility affects both men and women, and the procedures that derived from modern medicine have benefited men and women, the issues surrounding biologically born male RM are still lacking in the literature [27]. Despite the large role that men play in reproduction, the male experience within RM is mostly absent. However it is not just biologically born men whose experiences are lacking, as transgender and nonbinary perspectives are also excluded. As our knowledge of gender in the twenty-first century evolves, it is important to include all the diverse gender perspectives. Thus, the purpose of this section will be to adequately discuss reproductive medicine from the male experience and from transgender and nonbinary perspectives, respectively.

The Male Experience and Reproductive Medicine

RM as a discipline has largely been synonymous with women and, thus, has largely excluded men

from this narrative. This is because within the field of RM, fertility is one of the leading concerns and areas of treatment. However throughout history, fertility has been mainly associated with women. This can be demonstrated through the depiction of women in religion, and throughout Greek and Egyptian mythology and folklore. The religious link between women and fertility can be presented through Eve, a figure first depicted in the Book of Genesis [28]. Eve is most commonly associated with the forbidden apple that she had taken from the Garden of Eden, against Gods wishes; resulting in God punishing Eve with agonizing childbearing and labor [28]. In the Hindu religion, fertility is associated with Parvati, the ultimate divine mother and feminine symbol [29]. The link between fertility and women is not isolated strictly to religion, as Greek and Egyptian mythology also feature goddesses of fertility. This is evident through the Egyptian Goddess, Isis and the Greek Goddess, Aphrodite. The presence of all these figures throughout history has emphasized the relationship between fertility, motherhood, and women.

As the understanding of fertility and reproduction evolves and medical procedures and studies clarify what causes fertility issues in both men and women, this greatly alters the ontological knowledge and understanding on this topic. Men equally play an important part in the study and practice of RM; yet at times their experiences do not receive as much attention as their female counterparts. The use of ART has helped to improve some of the issues involving men's reproductive health and infertility; however, a lot still remains unknown in this domain. While ART procedures such as intrauterine insemination and intracytoplasmic sperm injection have helped to overcome some of the barrier's men face when trying to conceive a child, [30] there is still a significant lack of evidence-based clinical study and knowledge [27]. The lack of knowledge is especially concerning as studies have shown a global trend in "declining sperm counts" [31] and further abnormalities in the male reproductive system [31]. It is further indicated that male infertility ensues in "40% of couples experiencing infertility" [31]. As a result, men's declining reproductive health is considered to be a "global

crisis” [31]. The reason behind this crisis is due to a lack of public awareness concerning men’s reproductive health, a lack of proficient research and funding in this area, the hesitance of men to get examined, and inadequate healthcare policies [31]. The statistics and factors regarding the decline in men’s health is of grave importance as reproductive issues in men has also been found to have a positive correlation to other health problems, including “diabetes mellitus, metabolomic disorders and cardiovascular disorder” [31].

When considering the inequality between male life expectancies in comparison to female life expectancies [31], this link is important to depict. If there were more awareness and encouragement for men to get examined and discuss their health issues, this would be a start in breaking down the crisis. Accompanying this, further research would be needed to understand the pathophysiological basis of male subfertility and infertility [27]. In a study conducted by researchers at Stanford University School of Medicine, it was deemed possible that during fetal development any harmful environmental factors could contribute to reproduction problems, as well as other health concerns [32]. However, further evidence and examination would be needed to identify the links between reproductive issues and overall health in men. The emergence of AI in RM could bring fundamental benefits to men and male health, however before technology can improve the difficulties pertaining to male health, the issues that cause this need to be further explored.

Transgender, Gender Fluid, and Nonbinary Perspectives and Reproductive Medicine

Although transgender, gender fluid, and nonbinary medicine can be considered to be its own emerging interdisciplinary area of study and medical specialty, when discussing gender perspectives and RM it would be appropriate to recall that gender conceptually encompasses more than just traditional male and female perspectives. The meaning of gender in the twenty-first century is an essentially contested topic. This is because

traditionally gender would be synonymous with cisgender men and women. Cisgender refers to a person whose “gender identity is the same as the one assigned at birth.” [33] However, the coming out of celebrities such as, Caitlyn Jenner, as transgender male to female and singer songwriter, Sam Smith, coming out as nonbinary has set a new precedent for gender and the public understanding of it over the past few years [27].

As our collective knowledge and consciousness evolves around the areas of gender and biologically assigned sex, it is important to understand that the two are not always mutually exclusive. Therefore, in order to discuss the various gender perspectives in regard to RM, it would be insightful to include perspectives from all these underrepresented groups.

Currently literature surrounding this topic is thin; however, in a 2020 article entitled “*The imperative for Transgender and Gender non-binary inclusion*” [33], the authors made a strong case that by solely referring to the experiences of cisgender women in reproductive health, this excludes and marginalizes an entire group of people that have reproductive health and medical concerns that are important and unique to share [33]. This viewpoint is an accurate depiction of the current literature as transgender and nonbinary perspectives are largely excluded from this topic.

The perspectives of transgender and nonbinary people in relation to AIM and reproductive medicine is important for three reasons that will be discussed in this section. Firstly, this gender aspect is important to include as by not doing so would be short-sighted and exclusive to entire groups of people that make up an important proponent of society. To be exclusive to these various gender aspects would also “prevent the advancement of science and clinical care for people of all genders.” [33] Secondly, it is important to include transgender and nonbinary perspectives in order to mitigate the possibility of technological bias in the future. Thirdly, it is important as with the breakthroughs that are being made in RM, as a result of AI and other emerging technologies, this can directly impact the futures for many transgender and nonbinary individuals who may use ART to have children.

As previously mentioned when discussing the lack of inclusivity of male reproductive issues, the perspectives of transgender and nonbinary people are also excluded in the mainstream literature as traditionally issues surrounding RM and infertility were often associated with cisgender women [33]. This is important as the lack of adequate research and knowledge on other genders and gender identities could prevent doctors from making more informed diagnoses in regard to health care. For example, without sufficient research and acknowledgment of these groups, it would make it more difficult to establish links between certain illnesses and diseases, thus patients may not receive the right or best care that they possibly could.

According to a report by the World Health Organization (WHO), gender plays a pivotal role in “people’s experience of and access to healthcare.” [3] This is because gender can either limit or improve one’s access to healthcare services, support, resources, and information [3]. Literature on transgender and nonbinary health care suggested that transgender and nonbinary people are less likely to request healthcare services citing discrimination, inequality, and an overall lower quality of health care in comparison to their cisgender counterparts as the reason [33]. Harmful gender bias can have a profound impact for transgender, nonbinary, and non-gender conforming groups, as the lack of empirical evidence in understanding health problems that these individuals could be susceptible to having would continually lead to misdiagnosis’ and poor access to health care. Unless more research, studies, and conversations take place to make these groups visible in all aspects of medicine, inequality will continue to persist. This underlying bias and discriminatory behavior will also hinder the progression and improvement of overall health care including RM.

Leading on from this, it is also important that these gender issues are taken into consideration as the implementation of technology can worsen existing bias. For example, as health care in general continues to advance through the innovation of AI and ML tools, it is important we do not have medical apps or programs that purposely exclude transgender and nonbinary people. The

implementation of AI and ML applications may lead to more unintended bias. This could be possible as there is evidence indicating a lack of empirical research and data in transgender and nonbinary medicine [34]. People with diverse gender identities are said to be “underrepresented in medical research” [34] due to bias, discrimination, and stigma around gender identity [34]. As previously mentioned, the discrimination that transgender and nonbinary people face leads to a harmful cycle in which patients feel uncomfortable seeking treatment, thus, less is known about certain medical issues, illnesses, and diseases that these people could face. This very issue is raising concerns that the absence of sufficient data used for “ML algorithms may contribute to socioeconomic disparities in healthcare” [35].

In order to reconcile the lack of data from those with various gender identities, researchers at Stanford University are running *The Population Research in Identities and Disparities for Equality* (PRIDE) study [34]. The PRIDE study created a digital platform for those who identify as a “sexual or gender minority” [34] with the aim to improve representation from underrepresented groups; and to collate large-scale data sets [34]. Studies such as the one conducted by PRIDE are especially helpful in breaking down barriers and stigmas surrounding gender. As health care gets increasingly more digitalized, it is crucial to make it as inclusive as possible for all people.

Furthermore, transgender and nonbinary perspectives are incredibly important and relevant in the field of RM. ART procedures have made it possible to reinvent parenthood so that LGBTQ and non-gender conforming individuals can have children. Fertility preservation of transgender people is becoming increasingly more common as procedures such as egg freezing, sperm freezing, embryo freezing, and ovarian tissue cryopreservation allow transgender people the opportunity to have biological children in the future [36]. When thinking about the future of RM and the achievements that can be made through AI, the successes will be beneficial to all people in society that would want to, and or choose to, have children. As AI has ample potential to transform RM,

it is also important to consider the issues discussed earlier within this section, regarding invisibility in health care and potential data bias. By ensuring that there are substantial discussions and data, it should be of equal importance that transgender and nonbinary people also have accessibility to ART and other reproductive procedures and technologies.

Concluding Thoughts

AI will undoubtedly play a large role in the future of RM. The technological developments that are being made have the potential to improve and remedy some of the most pressing issues in RM, especially pertaining to fertility. The use of AI and ML to aid ART procedures offers a realm of possibilities for prospective parents. Much like the early conceptualized views people had about RM, and procedures such as IVF, this brings with it a renewal of hope for patients. The implementation of AI can help to treat patients' health concerns via a more individualistic and scientific approach.

While this invites innovation, it is important to remember the full impact that AI can have on the future of RM; especially with regard to gender. It is important that these technologies are not misused to push further gender inequality through the intentional selection of gender in embryos. It should be remembered that while technology can help improve the quality of life for people and help them in their fertility journey, the aim is not to worsen existing social issues such as the current gendercide issue.

In addition, when thinking about gender and RM, it is important that the definition of gender evolves to encapsulate all genders and all people. In order to ensure RM truly advances, it is not technology alone that will achieve this endeavor but our collective thinking on the subject. What this entails is adopting a truly twenty-first-century approach to viewing gender and RM. This includes expanding and widening our definition of gender to include all diverse perspectives and understanding that fertility issues are not synonymous with just the female experience. Much like

AI, gender will also play a large role in the future of RM. Thus, it is important to ensure that gender is considered in every process of RM, including the perspectives from those that identify as a different gender than the traditional ones.

Abstract

Pediatrics is a specialty with significant promise for the application of artificial intelligence (AI) technologies, in part due to the richness of its datasets, with relatively more complete longitudinal records and often less heterogeneous patterns of disease compared to adult medicine. Despite considerable overlap with adult medicine, pediatrics presents a distinct set of clinical problems to solve. It is tempting to

assume that AI tools developed for adults will easily translate to the pediatric population, where in reality this is unlikely to be the case. The challenges involved in the development of AI tools for healthcare are unfortunately exacerbated in pediatrics, and the implementation gap between how these systems are developed and the setting in which they will be deployed is a real challenge for the next decade. Robust evaluation through high quality clinical study design and clear reporting standards will be essential. This chapter reviews recent work to develop artificial intelligence solutions in pediatrics, including developments across cardiology,

respiratory, gastroenterology, neonatology, genetics, endocrinology, ophthalmology, radiology, pediatric intensive care, and radiology specialties. We conclude that AI presents an exciting opportunity to transform aspects of pediatrics at a global scale, democratizing access to subspecialist diagnostic skills, improving quality and efficiency of care, enabling global access to healthcare through sensor-rich Internet-connected mobile devices, and enhancing imaging acquisition to reduce radiation while improving speed and quality. The ultimate challenge will be for pediatricians to find ways to deploy these novel technologies into clinical practice in a way that is safe, effective, and equitable and that ultimately improves outcomes for children.

Introduction

One of the earliest applications of artificial intelligence (AI) in pediatrics was published in 1984, and described a system called SHELP that could diagnose inborn errors of metabolism [1]. Since these early beginnings, recent advances in AI have led to considerable excitement about its potential for improving healthcare [2,3]. Pediatrics and adult medicine share many of the same subspecialties, and consequently there is considerable overlap in terms of potential applications of AI in both. However, pediatrics presents a unique set of clinical problems to solve, and development of AI systems for children involves a range of specific challenges. As a result, in order for children's health to benefit appropriately from these new technologies, a thriving field of pediatric-specific AI research and product development is required.

It is tempting to assume that AI tools developed for adults will easily translate to the pediatric population. In reality, this is unlikely to be the case. Successful applications of AI to clinical problems in pediatrics will require a deep understanding of the challenges and potential pitfalls, and careful external validation in this setting. The importance of this was demonstrated in one study where two vertebral fracture detection systems

designed for adults were applied to pediatric spine X-rays [4]. The overall sensitivity dropped significantly from 98% to 26–36%, and specificity dropped from 99% to 95–98%, rendering these adult systems useless as a screening tool for children.

While recent highest profile developments in AI for health have largely been outside of pediatrics, there have been promising signs of growth in pediatric AI research. A recent systematic review identified 363 studies where a machine learning (ML) model was assessed for the diagnosis, prediction, or management of a condition in children and adolescents [5]. Only a handful of studies used deep learning methods ($n = 15$, or 4%) that have contributed to many significant advances in medical imaging AI over the past decade. Major contributions came from subspecialties including neonatology and neurology, while most studies originated from high-income (82%) and upper middle-income (15%) countries. Only 3% came from lower middle-income countries, with just three studies (0.8%) coming from the African continent.

Pediatrics is arguably one of the most promising specialties for AI researchers to explore. In the intensive care specialties, large amounts of data are generated (estimated approximately 1 terabyte of data per neonatal intensive care bed per year [6]), including data types where AI methods have been shown to be useful, such as imaging, electronic health record (EHR), physiological time series, and genetic data. Children more commonly become unwell due to a single disease process, as compared to the polypathology and accompanying polypharmacy often found in adult populations. Past medical histories are also often naturally simpler than with adults. As a result, the pediatric patient population is generally less heterogeneous, making machine learning projects potentially more straightforward to design and execute.

Pediatric health records are also relatively more complete than those for adults. This is particularly true in the neonatal intensive care unit (NICU), where infants are usually admitted from birth or shortly thereafter, with close monitoring of physiological parameters, feeding, interaction,

test results, medication administration over their entire lives thus far. These high-fidelity datasets are unrivaled within medicine for their completeness and accuracy. Following discharge from NICU, infants are often followed up for several years, resulting in the availability of high quality longitudinal outcomes. Children are also more likely to have significant portions of their health record already digitized, given the increasingly widespread adoption of EHRs over the past decade.

In terms of impact, the benefits of improving health in children translates into some of the highest quality adjusted life years (QALYs) possible across medicine. This is because small improvements in mortality or morbidity have an effect over the rest of a child's life. Development and deployment of AI tools may democratize and expand global access to high-quality diagnostics and medical advice, particularly in low resource settings where age distributions are skewed toward younger age groups. Approximately, 50% of the population is under 18 years of age in much of Subsaharan Africa, along with countries such as Iraq, Yemen, and Afghanistan, compared with 15–25% in developed countries [7]. In combination with explosive growth in internet-enabled mobile devices, which present new ways to reach remote communities with historically poor access to healthcare, pediatric AI may offer promising solutions to a range of important global child health needs.

This chapter aims to provide an overview of recent developments in AI in pediatrics, explore the benefits, and challenges of working with pediatric data, and outline a vision for the future promise of these exciting new technologies to improve child health.

Challenges in Pediatric AI

All research in pediatrics – whether or not AI is involved – encounters the particular challenge of ensuring that the use of data derived from children, who may not be able to meaningfully consent to participate in research, adheres to legal and ethical standards. While legal guardians may

consent on behalf of children, this process has historically required additional oversight and regulation of pediatric data collection and interventional studies. As a result, access to pediatric datasets involve more complex and longer approval timelines than those obtained from adults, with very few publicly available datasets. Furthermore, disease patterns in children are closely coupled to age, meaning that only a portion of a given dataset may be useful for a particular application, further reducing the statistical power available from an already small population.

In the pharmaceutical industry, the reputational and legal ramifications of any error or negative outcome in trials involving children, alongside the additional cost and time required to run pediatric studies, has led historically to many medications only being tested and licensed for adult patients. This changed in the early twenty-first century, with the introduction of US, EU, and Canadian legislation requiring trials for novel and existing medications to consider pediatric applications. Reputational and legal risks in the development of AI parallel those of medication or diagnostics development, and legal protections as well as regulatory incentives may be necessary to ensure that children can also benefit from advances in AI.

Even if the development of AI tools in a pediatric context is more challenging, other benefits could tip the balance in favor of this work. Where disease can be prevented or effectively treated in a child, the health economic implications of this in terms of QALYs may incentivize the adoption of seemingly eye wateringly expensive interventions. This was demonstrated in 2019, with the approval of Zolgensma for the treatment of Spinal Muscular Atrophy, at a cost of \$2.1million for a single dose – the most expensive drug ever successfully brought to market. This pricing was attributed to the massive healthcare benefit of successful therapy over an entire lifetime. It is not difficult to imagine the use of similar economic incentives to justify the often high cost of AI development. Once developed, such systems are relatively cheap to scale and deploy, enabling the potential for AI to diminish global health disparities.

Despite these challenges, pediatric AI is a nascent and growing field that presents substantial potential benefits to children and their families around the world. There are positive reasons to hope that, with appropriate incentives, support, and protections, pediatrics could become a pioneering specialty at the cutting edge of AI development.

Recent Developments in Pediatric AI

Cardiology

Despite an abundance of data of the type that is particularly well-suited to AI-based applications, the status on the use and/or development of AI-based tools in pediatric cardiology was described in one 2019 review as “dormant” [8]. However, there has been much more activity in adult cardiology, including automated or enhanced classification of cardiac images, electrocardiograms, and clinical prediction models [8, 9]. In many instances, the only limitation of their application to pediatric patients is the lack of research dedicated to cardiac conditions in children.

The diagnosis, management, and palliative and corrective surgery for children with congenital heart disease (CHD) is based on a thorough understanding of the complex anatomy related to a particular condition. Up to now, clinicians have largely had to understand this anatomy by visualizing two-dimensional (2D) images into a three-dimensional (3D) space. The use of virtual reality (VR) has begun to change this. Although this technology is in its infancy, the use of VR in which clinicians could view their patient’s entire heart (and even get inside of it, virtually) in an ultra-realistic 3D space could revolutionize the field, particularly in planning surgery on pediatric patients with cardiac disease [10]. Plasencia et al. have developed a methodology based on rendered 3D images to better match cardiac size for pediatric heart transplant patients with prospective donors [11]. Currently, the clinical standard for size matching is donor-recipient body weight (DRBW) ratio, which may unnecessarily limit a

patient’s access to a transplant. For the proposed methodology, computerized tomography (CT)/magnetic resonance imaging (MRI) is used to render a 3D image of the patient’s thorax. If there are available images from the donor, a 3D image of the donor’s heart can be rendered and be virtually placed in the donor’s chest. These investigators also developed a library of 90 hearts using CT/MRI data from pediatric patients of different sizes. This library could then be used to choose a representative heart for a donor in the likely scenario in which CT/MRI data on the donor’s heart are not available.

Segmentation of the different cardiac chambers is an important step toward providing structural information that facilitates the diagnosis of anatomical and functional cardiac disorders. Manual segmentation, which is the current gold standard, is time consuming and involves both significant inter- and intra-observer variability [12]. The task is hard in pediatric CHD due to significant variation in anatomy and a higher degree of motion artifacts in infants and children. To facilitate progress in CHD, a public competition for segmentation of CHD MRI data was introduced in 2016 [13]. The competition was won by Yu et al. with “3D FractalNet” for whole heart and great vessel segmentation [14]. A range of other successful approaches have been proposed since using deep learning architectures [15, 16] and more recently generative adversarial networks [17].

A number of studies have shown promise for machine learning algorithms assisting the diagnosis of heart murmurs using machine learning [18–20], often using an open access PhysioNet Challenge database of normal and abnormal heart sounds [21]. Tools that can distinguish between innocent and pathological murmurs could assist triage and reduce time to diagnosis, while also assisting pediatricians in remote locations without access to specialist pediatric cardiologists [22].

Despite the potential clinical benefits of enabling automated diagnosis of CHD from echocardiography images, there have been only limited studies conducted to date. The acquisition of high quality standard views is a key starting point for diagnosis, and there have been a number of studies demonstrating automated standard plane

detection for fetal echocardiography [23–25]. Wang et al. proposed a framework to classify atrial septal defects and ventricular septal defects from five-view echocardiogram videos, achieving an accuracy of 95.4% for CHD vs negative classes [26]. Le et al. developed a random forest-based framework to classify CHD from normal controls in fetal echocardiography, with accuracy of 0.91 [27]. Arnaout et al. described an ensemble of neural networks for distinguishing between normal hearts and complex CHD, achieving an area under the receiver operating characteristic curve (AUC) of 0.99, sensitivity of 95%, and specificity of 96% in a dataset from 4108 retrospective fetal echocardiograms, which is comparable to human performance [28].

In terms of risk prediction, Ruiz-Fernandez and colleagues developed four algorithms to predict postsurgical mortality using a dataset of over 2400 pediatric patients who underwent cardiac surgery for a variety of conditions, using multiple AI techniques [29]. The algorithms had an accuracy of 80–99% in predicting death. Clinical prediction models such as these could help inform clinicians in the future when deciding on the proper management of children with congenital heart disease.

Respiratory

Most investigations of AI-based applications for use in diagnosing and/or managing respiratory conditions have been focused on three areas: auscultation, interpretation of pulmonary function tests, and imaging [30]. As with cardiology, much of this work has been focused on adults. However, there are some unique aspects of pediatric respiratory medicine that provide opportunities for innovation that could substantially improve the health of children.

Worldwide, pneumonia remains a leading cause of morbidity and mortality in children under 5 years old. In many of the regions where the rate of childhood pneumonia is the highest, there is a scarcity of clinicians with the skill to accurately interpret pediatric chest radiographs. Thus, the use of AI to aid in the interpretation of

chest radiographs in children is of particular interest. AI-based interpretation of chest radiographs in young children is complicated by variations in thymic size and cardiothoracic ratio. Despite this, there have been significant advances in developing algorithms for diagnosing pneumonia using AI-based interpretation of chest radiographs in young patients. In a study that included chest radiographs on 858 South African children, an AI-based algorithm was used to classify each radiograph as pneumonia, “other infiltrate” or “no-infiltrate.” The ground truth for the reading was based on a consensus of three radiologists who independently reviewed, and used World Health Organization criteria to classify each radiograph; 333 (39%) of the images were classified as pneumonia by consensus. The AI-based algorithm had an AUC for correctly classifying a radiograph as pneumonia vs no pneumonia of 0.85, with a sensitivity of 76% and specificity of 80%. The results of this study highlight the potential of this technology, but also indicate its current limitations. An additional experienced radiologist interpreted a randomized sample of the study radiographs, stratified by ground truth classification, and had a sensitivity of 90% and specificity of 94% for identifying pneumonia, thus superior to the algorithm classification [31]. Another study by Naydenova et al. used support vector machines and random forests to predict pneumonia using temperature, respiratory rate, heart rate, and oxygen saturation [32]. In a test dataset of 1093 children with 777 pneumonia and 316 healthy controls, their approach achieved 96.6% sensitivity and 96.4% specificity. The simplicity of this approach means it could be embedded in smartphone decision support tools and used by basically trained healthcare workers in resource-constrained settings.

Lung ultrasound has proved to be a useful tool for detecting areas of consolidation as evidence of pneumonia, although it is operator dependent and requires interpretation by a skilled person. Correa et al. describe an approach using neural networks to classify lung ultrasound images into pneumonia vs normal lung groups, with 90.9% sensitivity and 100% sensitivity [33]. This work presents another opportunity to improve the challenge of diagnosis

of pneumonia in developing countries where resources are scarce.

Unlike adults, there are certain pediatric conditions that are characterized by highly specific cough characteristics, e.g., the “whoop” in pertussis, and the barking cough in croup. Parker et al. used hand-crafted features to classify coughs as pertussis or non-pertussis, achieving sensitivity of over 90% [34]. Sharan et al. used an iPhone to record coughs in children seen in clinical settings in Australia and developed an algorithm to identify patients with croup based on their cough acoustics [35]. After collecting data for a training sample, the algorithm was tested in 13 children with a clinical diagnosis of croup and 102 with a cough from other respiratory conditions. In this test sample the sensitivity of the algorithm in diagnosing croup was 92.3% and the specificity was 85.3%. Although there are weaknesses in this study, such as the lack of viral testing to help confirm a diagnosis of croup and the age of the patients (the mean age of the croup patients was >5 years in the test sample), these results highlight the potential for an AI-based approach that could be used by parents to determine if the likely etiology of their child’s cough was croup.

Wheezing is a primary sign of multiple pulmonary conditions, most notably asthma. Analysis of collected breath sounds in children has been shown to accurately document wheezing in noisy outpatient settings, in pediatric intensive care units and throughout the night [36–38]. However, special equipment is needed to collect the breath sound audio and the clinical applicability of the technology is uncertain. Because asthma is among the most common chronic diseases in pediatrics, there is a need for innovative technologies that would allow for passive and longitudinal monitoring of children in their home environment. Using an under the mattress ballistocardiographic sensor, Huffaker et al. assessed heart rate and heart rate variability, calculated respiratory rate, relative stroke volume, and assessed movement during the night in children with a history of asthma. These data were used to develop algorithms to determine when a child had asthma symptoms, predict the onset of these symptoms, and predict changes in asthma control test (ACT)

results (ACT is a validated questionnaire used to assess adequacy of asthma control). The algorithm had a sensitivity of 47% and a specificity of 96% in predicting patient-reported asthma symptoms and a sensitivity of 35% in predicting the onset of symptoms one day before they occurred. Changes in several of the physiologic parameters were statistically associated with changes in ACT scores [39].

Deep learning models have also been trained to predict a child’s asthma control up to a week ahead [40]. Using data collected from a weekly asthma self-monitoring tool, the best model achieved an accuracy of 71.8% and AUC of 0.757 when predicting the level of asthma control as “uncontrolled” (vs “controlled”), derived from a modified Asthma Control Test [41]. This study potentially supports future real-time decision support and personalized early warnings of asthma control deterioration.

Cough is a common symptom in children with asthma, and it has been suggested that nocturnal cough frequency may be a valid marker of asthma control. In a Japanese study, investigators collected audio data and movement of the abdomen with an accelerometer and developed an algorithm to objectively count coughs [39, 42]. The microphone and accelerometer were placed on children hospitalized with asthma and those with coughs from other respiratory conditions during an 8-h period at night. Patients with asthma had a mean of 144 ± 125 coughs per night compared to 18.3 ± 9 for those without asthma ($P < 0.001$). Those with an asthma exacerbation characterized as severe had significantly more coughs than those with a moderate exacerbation. Interestingly, patients with asthma had a distinct pattern of coughing with most coughs occurring shortly after falling asleep and shortly before awakening in the morning, a pattern not observed in children with coughs due to other etiologies. These results suggest that tracking nighttime cough counts, timing, and probably trajectory, could be used to identify a child with asthma and monitor severity over time. The obvious need is for an inexpensive AI-based system suitable for home use that can ideally evaluate coughing in a contactless manner.

Genetics

With the relative decline of both infectious disease and birth trauma in the Western world, congenital malformations have come to represent an increasing proportion of mortality and morbidity among children, particularly infants [43, 44]. A significant subset of such congenital malformations has a genetic basis, particularly in the NICU. Recent studies suggest underlying genetic causes for around 20% of NICU admissions [45], and a similar proportion of infant deaths [46] in tertiary centers. As such, rapid and accurate genetic diagnosis is particularly relevant in children and infants. There are three broad areas of genetic diagnosis at which AI systems show promise of significant clinical impact – phenotyping, interpretation of sequencing data, and prediction of disease risk from known genetic variants.

A first stage in genetic diagnosis, where no specific disease is known to run in the child's family history, is a thorough examination of the patient, and review of their clinical history – a process known as *phenotyping*. In some cases, this process may yield a confident genetic diagnosis prior to any confirmatory testing by a sufficiently experienced clinician. Image-based AI systems have been shown to perform at or above expert level in predicting syndromic genetic conditions from photographs of facial dysmorphology [47]. Other studies have used natural language processing to identify phenotypic features from the EHR and inform genetic testing [48].

Following phenotyping, an experienced clinician will decide on the exact form of genetic testing that is indicated, depending on the differential diagnosis. Sequencing methods, in particular, are increasing in popularity as the cost falls and speed increases. Currently, an entire genome can be sequenced in less than 1 day [49], at a cost of approximately \$700 in the USA in 2020 [50], although this will vary internationally. This low cost has resulted in a relative shift away from more targeted techniques such as gene panels, microarray, and karyotyping. For example, “virtual gene panels,” whereby the entire genome is sequenced, but only genes known to be linked to the patient’s phenotypic features are interpreted,

could become cheaper than traditional custom gene panels.

Unfortunately, the time and cost of interpreting the massive volume of information produced by whole-genome sequencing has not fallen at the same pace as the sequencing itself. Next generation sequencing in particular requires alignment and statistical interpretation in order to infer the presence of genetic variations. Furthermore, interpretation of such variants requires careful synthesis of clinical phenotyping, genetic information, and published case reports, since all human genomes will contain many variants that may or may not contribute to disease. It may take many days or weeks for specialist clinicians and clinical scientists to manually review each case and report results. In this context, work has focused on both variant calling [51] and variant pathogenicity interpretation [52], and deep learning approaches have outperformed traditional methods for identifying variants [53]. Further work has demonstrated the potential applicability of end-to-end AI systems that combine phenotypic inference from EHR data with variant interpretation, resulting in preliminary automated genetic reports from WGS within 24 h of sample collection [48].

Endocrinology

Type 1 diabetes, in which the pancreas produces insufficient or no insulin, has a typical age of onset between 4–7 years, with a second peak at 10–14 years. It is important to maintain glucose levels in a target range (typically 4–7 mmol/L). Significant time spent in a hyperglycemic state increases the risk of damage to a range of end-organs including the retina, kidneys, and peripheral nerves. However, hypoglycemia presents a more immediate danger of coma or even death. Therefore, tight and accurate control of blood sugar level is critical in ensuring safety and long-term health of patients. To this end, AI systems have been developed to achieve several interrelated goals.

Continuous glucose monitoring (CGM) systems [54, 55] measure glucose levels in the interstitial fluid, a close proxy for blood sugar level, at

a regular frequency on the order of 1–10 min intervals, providing richer monitoring than intermittent self-testing, which may only be conducted a few times a day. Since the advent and widespread adoption of CGM, there has been interest in using such data to monitor and adjust treatment regimens. This is typically done by uploading the data for clinical review at regular intervals, with physicians or specialist nurses advising on adjustments to insulin dosing. AI tools have been developed, which can provide such feedback, and show good agreement with endocrinologists in adult populations with weekly adjustment schedules [56], and have been demonstrated to be non-inferior to clinician advice in pediatric populations [57].

Taking the control system one step further, the development of an “artificial pancreas” [58] links the output of a CGM system with a continuous insulin delivery system, gated by onboard logic. This typically takes the form of a “fuzzy logic” system, which has been shown to be safe and effective in improving nocturnal euglycemia in pediatric patients [59], including during time spent away from the home setting [60]. Such systems have also been shown to be superior in terms of overall glycemic control, versus traditional approaches [61], reducing periods of hyperglycemia and hypoglycemia both overnight and with 24 h usage [62, 63]. Alternate control logic have been trialed, such as including reinforcement learning [64] and artificial neural networks, which have been shown to be effective *in silico* [65].

Beyond immediate control of blood sugar, AI systems have been developed to provide an “early warning” of predicted future deviations from normoglycemia up to 1–2 h prior to occurrence, using a wide variety of techniques [61].

Neonatology

Neonatology presents arguably one of the most promising domains for machine learning researchers in medicine. Preterm infants on the NICU generate a vast quantity of data [6], including types that are already known to be suitable for

AI techniques. EHRs are typically well coordinated, while large networks that aggregate data already exist in many countries (e.g., Vermont Oxford Network [66], the UK national neonatal research database [67]). Diseases are typically more homogeneous compared to other medical disciplines, with fewer confounders from complex past medical histories. Finally, earlier detection of deterioration and disease in neonatology can make a significant difference to outcome, and automated methods to flag actionable insights are likely to transform the practice of neonatology in the future.

Neonatal Sepsis

Among neonates born at >34 weeks gestation, early onset sepsis (EOS) is a rare event, occurring at a rate of 0.2–0.7 cases/1000 live births [68–70]. However, because of the potentially devastating consequences of failing to initiate antibiotic therapy early, many newborns are treated empirically while awaiting blood culture results. Based on criteria in national guidelines, it has been estimated that 5% of all newborns in the USA and 16% in the UK might receive empiric antibiotics because of various risk factors [68, 69].

Puopolo and colleagues analyzed a large dataset and used regression modeling and other mathematical techniques to develop a more efficient scoring system for assessing risk of EOS in a newborn [71]. The initial scoring system was based on objective perinatal information such as gestation, maternal temperature, group B streptococcal (GBS) screening status, and duration of rupture of membranes to provide a numeric estimate, i.e., the risk of sepsis, in a given baby. The group expanded the scoring system to include neonatal events including APGAR scores and vital signs [72]. Clinicians can access a website for the sepsis calculator (<https://neonatalsepsiscalculator.kaiserpermanente.org/>), enter the pertinent data, and instantly receive an estimate of the estimated risk of EOS in a particular infant. The authors of the calculator have recommended threshold scores for starting antibiotics [72].

Studies have been conducted that indicate a substantial reduction in use of unnecessary antibiotics when using the sepsis calculator compared

to use of national guidelines, without apparent increase in morbidity or mortality [68, 69]. Thus, there is evidence that a web-based tool, based on standard modeling techniques, can improve care. However, there have been reports of newborns with a low calculated sepsis risk score who developed EOS, highlighting the need for an AI-based scoring system that utilizes more objective data in the maternal and neonatal EHR [73]. The unique nature of the newborn health record, including frequent vital signs, limited provider notes, screening laboratory findings, and perinatal monitoring data, may be a particularly good example of how AI-based clinical prediction models can transform care. One envisions a sepsis risk score that is part of the newborn's EHR birth and is constantly updated with each new bit of information.

Jaundice

A central focus of newborn care is identifying infants with moderate hyperbilirubinemia so that treatment can be initiated, thus preventing rise to levels associated with development of acute or chronic bilirubin encephalopathy (i.e., kernicterus). During the newborn hospitalization in the USA and other high income countries, screening newborns for hyperbilirubinemia is typically done by obtaining blood for a total serum bilirubin (TSB) level, regardless of clinical condition, or measurement of transcutaneous bilirubin (TcB) level [74].

Jaundice screening is more complicated once a newborn is discharged [75]. Use of TcB meters is limited in the outpatient setting by the costs of these devices. Thus, most screening of jaundice in a newborn following discharge from the hospital is based on visual assessment, a technique that is prone to error [76, 77]. Clinical experience suggests there are at least three factors that limit the accuracy of visual assessment of neonatal jaundice. First, there is imperfect memory of what shade of yellow corresponds to a specific TSB level. Second, assessing jaundice in newborns with a variety of skin pigmentation is complicated. Finally, and perhaps most important, the appearance of jaundice varies based on the different lighting conditions commonly encountered in

clinical settings and it is virtually impossible to standardize lighting conditions.

All of these limitations are potentially solvable by an AI-based algorithm using data from digital images of a newborn's skin or sclerae. Several groups of investigators have reported on multiple systems, most based on using a commodity smartphone to capture images and software that includes machine-learning based algorithms to convert the digital information from the image(s) into an estimated bilirubin level. To account for lighting conditions these devices typically include a color calibration card that is included in the images, or add a small piece of hardware on the phone that is placed on the newborn's skin and use an external light source, usually the smartphone flash. Outlaw et al. reported on a system that attempted to eliminate issues related to skin tone and account for different lighting conditions [78]. First, images were captured of the infant's sclera instead of skin, thus eliminating the effects of melanin. Second, images both with "flash" and non-flash were obtained and the effect of ambient light "subtracted" out.

Most of the reported studies on the accuracy of smartphone-based devices to estimate neonatal jaundice are of modest sample size and frequently lack a diverse population of neonates. Correlation with the ground truth TSB levels are typically in the 0.5–0.91 range, although most investigators report high sensitivities and moderate specificities for identifying an infant with "hyperbilirubinemia," using a threshold TSB value to define hyperbilirubinemia [78–81]. Perhaps the most thoroughly investigated system has been developed by researchers at the University of Washington. In a racially diverse sample of 530 newborns (black infants comprised 20.8% of the study population and Asian infants 21.2%), they reported a correlation with TSB of 0.91; using two different recommended screening approaches the device had a sensitivity of 85% and 100%, respectively, for identifying a newborn with hyperbilirubinemia with corresponding specificities of 75% and 76% [79].

The main issue for this technology is how to be robust across different smartphone models (most studies have utilized a single model of phone) and

account for changes in photo processing that accompany changes in the operating system used by the phone. In addition, most research to date has been done in hospital or other clinical settings. It is largely unknown how well the developed algorithms will perform in other lighting environments, most notably in an infant's home.

In high income countries the use of a smartphone-based device to estimate bilirubin levels could assuage the fears of parents and healthcare providers when estimated levels are reassuringly low, and allow for more effective and earlier triage of patients who require phototherapy. More importantly, implementation of a low-cost device to identify newborns with significant jaundice could potentially save thousands of lives annually in low-income areas where bilirubin encephalopathy remains a major source of neonatal morbidity and mortality [82].

Ophthalmology

Ophthalmology is a specialty that is naturally suited to deep learning techniques, due to the widespread use of digital imaging modalities such as fundus photography, optical coherence tomography, and slit lamp imaging. This was demonstrated by early landmark success in adult AI-enabled diabetic retinopathy screening [83], which was able to directly build upon groundbreaking advances in computer vision performance made outside of the medical domain. In pediatric ophthalmology, a key application is in the detection and grading of retinopathy of prematurity (ROP). ROP mirrors many of the machine learning challenges of adult diabetic retinopathy, with significant variability in specialist accuracy of "plus" disease diagnosis, even among world-class experts (e.g., [84, 85]), with consequent difficulty in defining robust ground truth labels for model training. Plus disease in ROP describes the most severe vascular changes of dilation and tortuosity, and is associated with visual morbidity if left untreated. The potential benefits are significant – in developed countries, there are limited numbers of

ophthalmologists who feel comfortable managing ROP, either due to lack of training or medico-legal concerns; in developing countries, there is a lack of trained ophthalmologists, compounded by variable oxygen monitoring practices that lead to a higher incidence of severe ROP. As a result, the potential for AI tools to democratize access to subspecialist diagnostic skills, while reducing human variability, makes this a compelling area for future impact.

Early work in ROP was performed by Worrall et al. in 2016 [86], although the study was limited by a variable ground truth for plus disease. Brown et al. subsequently published a deep learning system called "i-ROP DL" trained on 5511 retinal photographs, classified into normal, pre-plus, and plus disease [87]. On an independent set of 100 images, for binary detection of plus disease, the system achieved sensitivity of 93% with specificity of 94%, with equivalent performance to human experts. More recently Hu et al. demonstrated a deep learning system that detects and grades ROP severity into five stages [88]. The system achieved an AUC of 0.992 for detection of ROP, and 0.921 for classification between mild/severe forms of ROP.

Longitudinal monitoring of ROP using quantitative measures of severity using deep learning may allow better prediction of risk and enable earlier treatment. Taylor et al. demonstrated that eyes that progress to treatment have a distinct progression of disease, and presented results showing possibility of predicting eyes at high risk 1 month before treatment [89].

Other applications have included detection of neonatal retinal hemorrhage and cataract detection. Wang et al. used 48,996 digital fundus images from 3770 newborns with retinal hemorrhages of different severities alongside normal controls, obtained from a large multicenter cross-sectional study performed in China [90]. A multi-class deep learning model was trained to classify scans into hemorrhage-free, grade 1, 2, or 3, with overall accuracy of 97.4%. Deep learning has also been used to classify pediatric cataracts from slit-lamp images, with sensitivity and specificity of 97.3% and 96.8%, respectively [91].

Primary Care

A range of interesting AI applications have been developed that may assist the primary care setting. For example, combining the ubiquitous smartphone with novel algorithms has enabled a new approach to middle ear infections. Chan et al. published a technique that uses a smartphone's speaker in combination with a paper funnel to send a "soft acoustic chirp into the ear canal," and employs a logistic regression machine learning algorithm to classify the reflections and predict middle ear fluid status [92]. In a leave-one-out cross-validation study using 98 patient ears at a pediatric surgical center, the authors obtained an AUC of 0.898, which compared favorably with commercial acoustic reflectometry (requiring custom hardware) with an AUC of 0.776. The system was described as being easily operated by children's parents without formal training, potentially aiding the future diagnosis of middle ear infections.

Another smartphone app has been developed that estimates hemoglobin levels by analyzing color and metadata of fingernail bed smartphone photos [93]. While not a dedicated pediatric study, subjects' ages ranged from 1 to 62 years old. Accuracy was shown to be $\pm 2.4 \text{ g dL}^{-1}$, with a sensitivity of 97% to detect anemia at a cutoff of 12.5 g dL^{-1} when compared with laboratory hemoglobin levels ($n = 100$ subjects). With additional calibration to a specific individual, accuracy was achieved at $\pm 0.92 \text{ g dL}^{-1}$. This technology offers the potential to improve the experience of care by offering needle-free alternatives to anemia monitoring for children with chronic conditions.

Novel uses of sensors may help make diagnoses in the future. In a study by Muñoz-Organero and colleagues, a convolutional neural network was designed to classify data from two tri-axial accelerometers (one on the wrist of the dominant arm, and the other on the ankle of the dominant leg) [94]. The study was small with 11 children with ADHD, and 11 controls, but demonstrated significant group differences, with classification accuracy of 87.5% for the wrist sensor (sensitivity = 0.6, specificity = 1), and 93.8% for the ankle sensor (sensitivity = 0.8, specificity = 1).

AI models to help triage and diagnose conditions may one day improve consistency and accuracy of pediatric care. A study from the Guangzhou Women and Children's Medical Center used an automated national language processing system using deep learning techniques to analyze a large EHR comprising 1,362,559 pediatric patient visits presenting to a major referral center [95]. The AI model was accurate when diagnosing conditions including upper respiratory infections, acute asthma exacerbations, sinusitis, and bacterial meningitis. When compared to two pediatricians split into five groups based upon proficiency and years of clinical experience, the model outperformed the two most junior physician groups, but underperformed the three most senior physician groups.

Radiology

Current AI techniques are naturally suited to imaging modalities, and a range of interesting applications have been developed in pediatrics, from classification and risk prediction, to technical aspects including improved image acquisition and reconstruction. Detection of imaging abnormalities has already been demonstrated in early work including pneumonia [96, 97], developmental dysplasia of the hip [97], wrist fractures [98], elbow effusions [99], and congenital urological abnormalities [100].

Estimation of skeletal maturity has been shown in multiple studies to be possible using deep learning approaches, with accuracy similar to or exceeding that of an expert radiologist [101–105]. Skeletal bone assessment is commonly performed in pediatrics for both diagnostic and therapeutic investigations, including endocrinology conditions, growth disorders, and genetic disorders. Bone age estimations are known to have significant intra- and interobserver variability [106, 107], making this an attractive and popular clinical problem to standardize through automation. Deep learning approaches appear to provide improvements vs previous feature-extraction techniques such as those utilized by commercial systems including one called Bone eXpert

[108]. In one well-designed study, Larson and colleagues trained a model using over 14,000 clinical hand radiographs, and tested using the publicly available Digital Hand Atlas dataset, with a root mean square error of 0.73 years.

In neonatal brain MRI, a deep learning model was used to classify dysplastic cerebelli in term infants born with congenital heart disease, achieving a classification accuracy of 0.985 for subtle cerebellar dysplasia [109]. Segmentation of neonatal brains is a historically difficult task given the rapid growth of the developing brain, with atlas-based techniques requiring multiple average atlases for each period of fetal and infant brain development. Atlas-based techniques are typically fragile, and may fail in the case of poor contrast, or with significant spatial variability compared to standard atlases – both of which are common in infant brain imaging. Deep learning techniques have enhanced accuracy with this task, including achieving robust hippocampal segmentation [110] and whole brain segmentation [111–114].

In pediatrics, fast imaging is essential to achieving high quality images with successful acquisition protocol completion before children become restless or claustrophobic. MRI techniques to improve speed of acquisition (i.e., [115, 116]) have the potential for significant utility in pediatric imaging, assuming accuracy can be assured. Minimization of radiation dose is also a key focus in pediatric patients, and techniques to reduce CT radiation dose show promise [117], alongside reductions in contrast agents required to achieve high quality MR scans [117, 118].

Pediatric Intensive Care

Pediatric intensive care (PICU) is a data-rich specialty, with many potential applications for AI. Areas explored so far include detection of sepsis [119], prediction of in-hospital mortality [120], prediction of need for transfer to PICU [121], and prediction of cardiac arrest [122].

Severe sepsis is a major clinical challenge in pediatrics, where earlier diagnosis and early goal-directed therapy have been shown to reduce mortality. Diagnosis is often delayed in hospitalized patients [123], and so automated accurate

methods to flag patients at high risk for sepsis would represent a major advance. A study by Kamaleswaran et al. used a range of methods including deep learning to predict the onset of severe sepsis using physiological markers in a dataset of 493 critically ill children [119]. They found that they could predict severe sepsis up to 8 h prior to a severe sepsis screening tool. Early work like this paves the way for future bedside monitors to be integrated with more intelligent tools to help clinicians anticipate the onset of sepsis through real time monitoring.

The potential for AI in PICU has arguably been neglected so far, with most AI research efforts so far focused on adult intensive care. Predicting outcomes and quantifying risk in children on the PICU is often more challenging than in the adult intensive care setting, largely due to the substantially changing physiology from prematurity to adulthood, but also smaller available datasets due to a reduced number of PICU beds than adult ICU beds. Next steps to advance the interoperability of EHR data, and effectively aggregate multicenter research databases will be required to create the scale necessary to train robust, clinically useful AI models in this setting.

Gastroenterology

There have been limited studies investigating AI methods in pediatric gastroenterology. Mossotto et al. described a system developed to classify pediatric inflammatory bowel disease, including Crohn's disease, ulcerative colitis, and inflammatory bowel disease unclassified (IBDU). The study used endoscopic and histological data from 287 children, and used a linear support vector machine to achieve classification accuracy of 83% of patients in an independent cohort of children [124].

Future Potential for AI in Pediatrics

AI presents the opportunity to transform aspects of pediatrics at a global scale, democratizing access to subspecialist diagnostic skills, improving quality and efficiency of care, enabling global

access to healthcare through sensor-rich internet-connected mobile devices, and enhancing imaging acquisition to reduce radiation while improving speed and quality.

Despite the potential for substantial health impact globally, a wide range of addressable clinical problems, and numerous compelling properties of pediatric datasets, AI research in pediatrics lags behind other adult specialties. Ongoing efforts to curate safe research-ready datasets to attract machine learning researchers and industrial developers will be essential to advancing the field.

Patient and carer acceptability of AI solutions is also yet to be properly addressed in pediatrics. While the public have been previously found to be overwhelmingly positive about the potential for AI to improve radiology [125], engagement with pediatricians, patients, and carers is essential to inform development of AI tools.

Over the past decade, it has become clear that AI systems can be trained to perform many tasks to a comparable or better level than human specialists. However, there are very few examples of AI systems actually deployed successfully in the real world [126]. The challenges facing the rest of medicine are unfortunately exacerbated in pediatrics, and the implementation gap between how these systems are developed and the setting where they will be deployed is a real challenge for the next decade. Robust evaluation through high quality clinical study design [127] and clear reporting [128] will be essential. The ultimate challenge will be for pediatricians to find ways to deploy these novel technologies into clinical practice in a manner that is safe, effective, equitable, and ultimately improves outcomes for children.

Abstract

Infections are one of the leading causes of death in infants and detecting life-threatening events in infants is challenging. Thus, providing effective life-saving interventions in time is essential. As infants' immune and autonomic control system are under development, signs preceding potentially life-threatening events are subtle. Clinical detection is aided by analysis of biomarkers, which unfortunately requires invasive sampling and is time consuming. Infection and inflammation interfere with the autonomic control systems and consequently affect vital signs. Constantly monitoring vital signs at a high frequency enables the immediate detection of discrepancies and is thus a key, noninvasive instrument in modern intensive care units. For pediatric intensive care, several predictive monitoring systems have been developed over the last decade *that aim to* utilize vital sign monitoring to mitigate the risk of developing life-threatening events, such as sepsis. Recent advances in the field of machine learning have provided novel techniques for big data analysis. This enables an individualized risk assessment via continuous multimodal inputs and development of better clinical decision support systems. These more advanced systems are able to detect sepsis 24 hours earlier than clinical practice and enable an overall risk assessment for future sepsis, life-threatening events, and death at the time of hospitalization or during the first week of life.

This chapter summarizes the current evidence on machine learning-based monitoring systems and provides an overview on the strengths, limitations, and potential future roles of novel machine learning-based methods for the early detection of pediatric sepsis and potentially life-threatening events.

Introduction

The prediction of life-threatening events among infants remains a major challenge for health care. Infants are particularly fragile and at risk of rapidly

developing cardiorespiratory dysfunction and sepsis, and during the first week of life, they are at higher risk of life-threatening events, such as apnea, bradycardia, and oxygen desaturation [1–4]. Infants affected by such events are typically admitted to a neonatal (new-born and premature infants) or pediatric (infants typically older than 3 days) intensive care unit (NICU/PICU). This unfortunately puts infants at an increased risk of infection, leading to increased morbidity and mortality and contributing to long-term complications, such as chronic lung disease and adverse neurodevelopmental outcomes [5–7]. Numbers based on UK pediatric population report an incidence of neonatal infections of 6.1/1000 live births, compared with 48.8/1000 among NICU patients [8].

The infections, including sepsis, pneumonia, and gastrointestinal infections, are leading causes of death [9, 10] as they are hard to diagnose, especially early in life due in part to the immaturity of the innate immune system. Early, and initially subtle, signs of infections include fluctuating temperature, reduced activity, reduced appetite, and a change in behavioral patterns [11, 12]. However, in the last decade it has become evident that, sepsis- and inflammation-related changes can also be identified in vital signs, such as heart and respiratory rate patterns [13].

A clinical assessment of vital signs could become essential for the early diagnosis of life-threatening events. However, as it requires a constant monitoring of the infant, which cannot be interpreted manually, it poses a new challenge in medicine [14]. Thus, during the last decades, a realization has emerged that it is crucial to develop effective predictive monitoring (Clinical Decision Support – CDS) systems for early detection of infection and possible life-threatening events. This will enable earlier and more efficient treatment, thereby reducing morbidity and mortality [13].

The present chapter aims to review the field of predictive monitoring systems for NICU and PICU settings and evaluate pros and cons of different approaches. It is an emerging and currently expanding field. Therefore, it is important to identify both the technical and clinical aspects that must be considered when employing a predictive monitoring system in everyday healthcare.

Sepsis Definition

Based on the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score, the Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3) has established a clear definition of sepsis and septic shock for adult patients [15]. These definitions have been used for pediatric sepsis as well, but are not optimal as age-related differences in pathophysiology and clinical manifestations needs to be taken into account, especially when assessing SOFA score [16], and for neonatal sepsis they are not applicable [17]. In 2019, the Society of Critical Care Medicine (SCCM) convened the Pediatric Sepsis Definition Task Force, to develop pediatric sepsis definitions and identify risk factors. This work is currently in progress and a first systemic review is under preparation [18]. Neonatal sepsis diagnosis is most often based on the isolation of a microbe in blood or cerebrospinal fluid [12], sometimes in combination with various biomarkers [19–21]. However blood cultures are often negative for microbes despite convincing clinical signs among neonates [22] and biomarker reference intervals vary among studies [17]. Thus, culture-negative sepsis is one of the most common diagnoses in preterm infants, leading to empiric use of antibiotics [23]. Clinical signs of neonatal sepsis are often due to a systemic inflammatory response and include tachycardia, tachypnea, fever, or hypothermia [12, 24].

Infections during the first months of life may dramatically aggravate underlying cardiorespiratory dysfunction [25]. Thus, vital signs monitoring is a crucial feature when developing novel CDS systems for sepsis risk stratification. Circulatory and respiratory responses are closely connected under the control of autonomic brainstem networks and the sympathetic and parasympathetic nervous system activity [26] and regulate heart rate, vascular resistance, and blood pressure [25, 27, 28]. Infections generate an immune system response leading to the release of various cytokines and signaling molecules [29], thereby inducing the production of prostaglandin E₂ (PGE₂) [30] and ultimately affecting autonomic control systems [30–32] and neuronal

behavior [33–35]. This leads to disruptions in cardiorespiratory rhythm in neonates [3, 32, 35–38] and affects the response of the cardiorespiratory system to hypoxia, anoxia, and hypercapnia [39], apparent in the increased prevalence of apnea, bradycardia, and desaturation events in neonates and young children [3, 25, 32].

Continuous Vital Sign Assessment to Predict Life-Threatening Events

Currently, many clinical decisions are based on the observations of vital signs annotated by clinical staff, who at best may report one average value per hour [40, 41]. In contrast, monitoring systems have the potential to record vital sign data every 8 milliseconds, providing over 75 million data points per week per monitored variable. The utilization of machine learning (ML) methods is thus advantageous in clinical practice as it allows for the recognition of discrete subtle changes in the vital signs, a feat that is impossible for humans.

It is now well-established that ABD events often precede life-threatening events in the NICU and PICU [2–4, 42–45]. Therefore, high-quality detection of small subtle alterations in vital sign patterns could improve the diagnostics of infections in NICU/PICU patients (Fig. 1) [46]. Modern NICUs and PICUs are equipped with advanced monitoring systems that continuously measure vital signs, such as heart rate, respiratory rate, oxygen saturation, and sometimes also blood pressure and body temperature. However, most current alarm systems are based on threshold values, e.g., saturation below 92% elicits an alarm. Utilizing ML algorithms could allow the detection of deviations in the continuous time series and generate risk scores for patient deterioration that can be used as CDS systems.

However, while many CDS systems are currently evaluated academically [13, 43–45, 47] few have been pushed to the open market. Additionally, the available systems have limitations imposed by restricted study populations and inclusion criteria in clinical trials, and thus the clinical implementation have been limited.

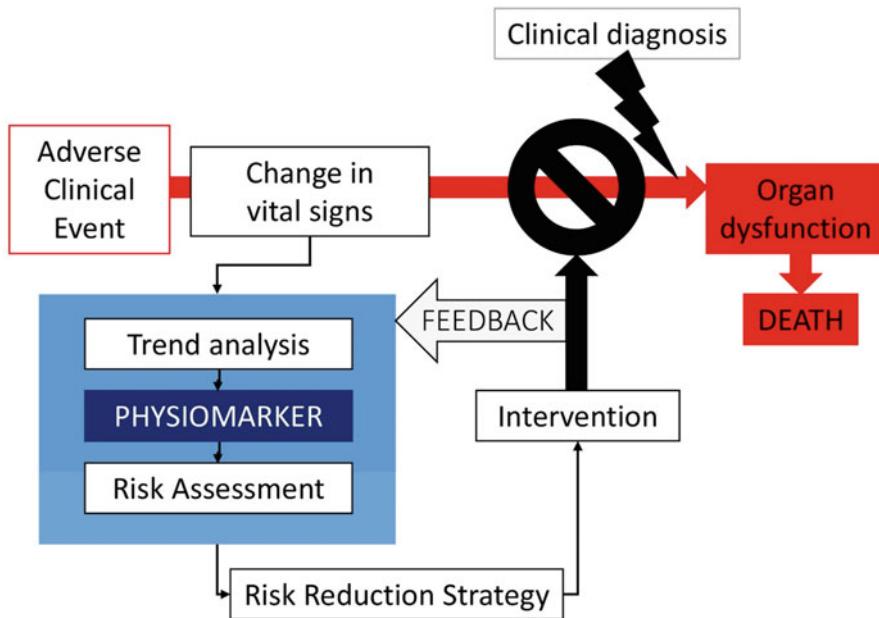

Fig. 1 Adverse events, that if untreated may lead to substantial morbidity or death, induce early, initially subtle changes in vital signs. These can be detected through a human in the loop machine learning-based trend analysis and from alterations in biomarkers for disease,

including sepsis and inflammatory-induced adverse events. A biomarker based alert can then be used for early risk reduction strategies or interventions to reduce morbidity and mortality

Moreover, data monitoring issues and high rates of false alarms may induce alarm fatigue and many clinicians hesitate to alter established routines without trust and interpretability of CDS systems. Nevertheless, hospital monitoring systems generate a huge amount of data and may detect subtle changes and trends, which would otherwise be overlooked by humans. Among the available CDS systems, the HeRO system is the most extensively evaluated and also commercially available for continuous patient evaluation and late-onset sepsis (LOS) risk assessment for neonatal patients [47].

Neonatal Sepsis and the NICU

In the NICU, heart rate characteristics (HRC) monitoring to detect sepsis has been in use for a decade. The commercial HeRO system was the first early warning system for sepsis in the NICU utilizing the continuous monitoring of electrocardiogram signals and HRC [48, 49]. It uses a time

window of input signals that is linked to an outcome of interest. By adapting a frame-by-frame approach, a score is computed using all measurements within a certain time window of a single variable. For example, the HeRO system utilizes 4096 heart beats per time window, corresponding to 20–30 min of heart beat RR intervals, and renders a score every hour, which is the risk of infection in the next 24 h [50]. The HeRO system has been implemented to predict *late-onset sepsis within 24 h* or *no late-onset sepsis within 24 h*. Used in very low birth weight infants, HeRO monitoring is effective in detecting sepsis [42, 49, 51] and lowers mortality [50]. A combination of HRC index and pulse oximetry during the first week of life can identify patients with a higher risk of developing sepsis or death sometime during their NICU stay [51]. Notably, patient demographics alone, including birth weight, gestational age, sex, antenatal steroids, and Apgar score provided an equivalent risk assessment [51].

In a comparison of 22 separate vital sign features for neonatal sepsis detection, the usefulness

of heart rate variability-based features, such as HRC, was confirmed [45]. Notably, features based on respiration and respiratory instability consistently outperformed features based on respiratory cessations, including cessations constituting clinical apneas and sometimes outperformed various features of HRC [45]. However, the authors emphasized the issue with impedance-based measurements of respiration using ECG electrodes. Additionally, each feature was compared separately while combining features did not improve the classifier-performance, as measured by AUROC, in the 49 patients included in their analysis, even though no data is shown. Combining features, e.g., HRC, respiration, oxygen saturation, and patient demographics have previously been shown to improve performance effectively [43, 44, 51].

A manually designed decision tree model has been developed to predict late-onset sepsis and necrotizing enterocolitis in $n < 32$ week preterm babies – the RALIS algorithm [43]. This algorithm utilizes multiple vital signs; heart rate,

respiratory rate, and temperature from monitoring devices and manually recorded desaturation and bradycardia events along with patient characteristics, including weight, sex, and gestational age [43]. This algorithm showed promising results, especially in a high negative predictive value (95%) but requires 72 hours of individual patient learning as well as combining vital signs with manually entered electronic health record data [52]. Such effectiveness could potentially allow the system to assist in decisions in antibiotic treatment to avoid unnecessary administration. A high NPV is important since a lot of infants receive antibiotics, possibly saving lives but also disturbing the microbiota. Antibiotics and deranged microbiota double the risk of NEC in preterm infants.

As several more continuous vital parameter assessments exists and seem to improve the prediction of life-threatening events, most systems currently under development use more parameters and include base characteristics of infants in the algorithms (Fig. 2). Human-in-the-loop is the

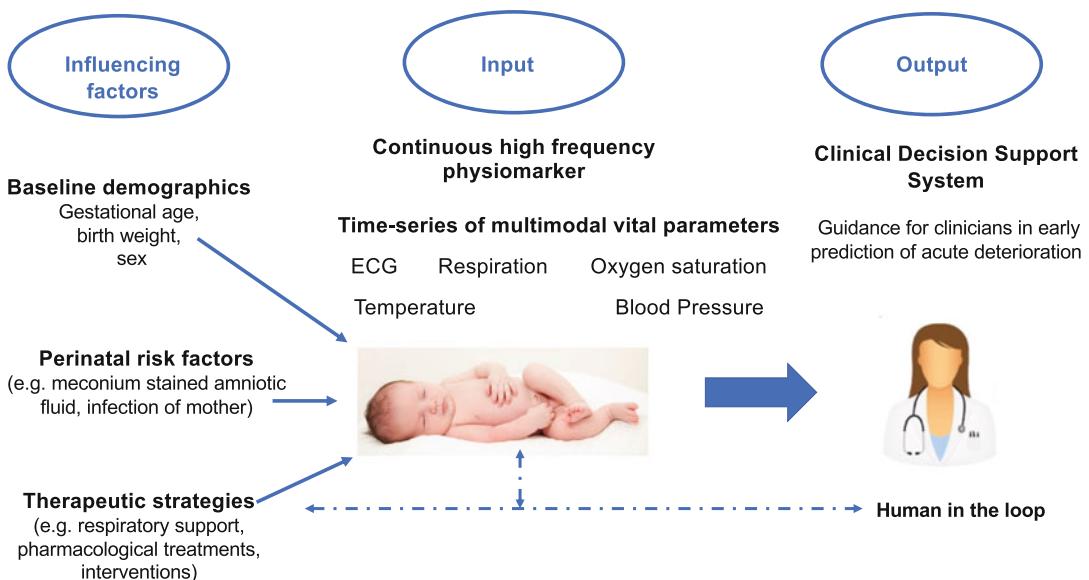

Fig. 2 Clinical Decision Support system - machine learning and human interaction Machine learning analysis of continuous multimodal complex and entangled physiological time series data –“Physiomarkers” is the basis for early detection of subtle alteration that help to predict adverse life-threatening events. The predictability

is improved by additional information. Both basic demographic data e.g. age, weight, sex and ongoing therapeutic interventions. Human in the loop machine learning-based trend analysis also involve tuning the model to improve its accuracy and guide adequate therapeutic strategies

process of leveraging the power of the machine and human intelligence to create ML-based AI models. Thus, humans annotate or label data then give to the ML algorithm to learn from such and take decisions from such predictions. And then humans also involve in tuning the model to improve its accuracy.

Pediatric Sepsis and Early Detection

Slightly older children are commonly monitored manually using bedside PEWS (Pediatric Early Warning Score), which relies on manually entered data by nurses at the patient bedside. This has been linked to a reduction in life-threatening events, but not deaths among hospitalized infants [40]. PEWS is widespread over the world but is labor-intensive and renders slight but limited benefits. Similar to the NICU, efforts of automatizing patient monitoring and developing biomarkers for sepsis have been made. Using logistic regression analysis, random forests, and convolutional neural network models with data on heart rate and blood pressure, patients with severe sepsis can be detected 8 h prior to fulfilling sepsis criteria [53]. Another random forest model was able to differentiate between sepsis and noninfectious systemic inflammatory response syndrome in PICU patients [54]. However, the model was based upon biomarkers in combination with other registered clinical events and thus did not utilize continuous automatic vital signs monitoring.

In children arriving at the pediatric emergency room (ER) with a diverting temperature (fever or hypothermia), ML models had a higher sensitivity in discriminating sepsis based upon vital signs compared to a routine physician judgment of the patient [55]. The ML models had however a lower specificity. An elastic net regularization model based upon patient demographic features in combination with blood pressure and body temperature measurements has also provided high negative predictive values for detecting septic shock in pediatric ER patients with a clinical suspicion of sepsis [56]. This model was not designed to screen all ER patients, but instead confirm suspicion of sepsis. Interestingly, vital

signs, such as heart rate, respiratory rate, and oxygen saturation, were evaluated but not included in the final model as they did not contribute to septic shock prediction. However, there is evidence that CDS systems developed for older children may be beneficial in ruling out sepsis [54–56], similar to the NICU systems.

Although not sepsis-specific, the Pediatric Risk of Mortality Prediction Tool (PROMPT) has been developed to estimate the mortality risk for PICU patients using vital sign monitoring. In a convolutional neural networks model, blood pressure, heart rate, respiratory rate, body temperature, and oxygen saturation were included as features. The prediction of death, independent of cause, was high as early as 60 h before the event.

Challenges and Future Perspectives of Automated Vital Signs Pattern Analysis

Although the automated vital sign pattern analyses for life-threatening event detection have shown great promise for clinical implementation, several challenges remain.

Important obstacles are the lack of consensus in outcome definition, heterogeneity in patient characteristics, and interpretability of data [57]. Can we trust in and interpret a deep learning-based ML-CDS? For the use of ML in the design of efficient and trusted CDS systems, it is important to develop an explainable ML (EML) for robust, reliable, and comprehensible data analysis. Explanations could help examine whether an ML method has employed true evidence instead of biases that widely exist in training data. This development of a new paradigm in EML, with focus on deep systems analysis of time series data, could be achieved by combining model-driven systems and data-driven learning methods. Models will help to design necessary constraints for analysis, in turn explainability. We hypothesize that data-driven optimization of proposed deep systems composed of many model-driven components will offer high quality performance along with explainability. Please see Yonina Eldar et al. chapter regarding mathematical foundations and explainable deep learning.

The majority of available pediatric CDS systems currently available that use continuous assessment of vital parameters are developed for the NICU and close to all based on preterm infants [13]. However, this is a heterogeneous population due to varying gestational ages at birth and birth weight, particularly when it comes to autonomic control [13, 25, 45, 58, 59].

The cardiorespiratory pattern changes over time and is dependent on gestational age, postnatal age, and postconceptual age [45, 58] and continue to develop during childhood. Most studies are conducted among neonates up to 1 week old, thus limiting its generalizability to older infants.

Sensors monitoring preterm infants' vital signs are often subject to movements. This creates an artifact on the signal, which may result in misleading or irrelevant features [60] attempted to clean the vital signs signal by recording movement around a patient. This enables discarding portions of vital signs disturbed by movements and may produce less noisy and more relevant signals. However and notably, infant movements might be used as a feature for detecting illness, as lethargy is a warning sign for sepsis [45, 61], and therefore discarding information may introduce a bias and result in suboptimal systems.

Including several parameters may improve early detection of life-threatening events [62]. In addition, more recently, there has been advances in video and audio processing, which provides the possibility of adding such features to algorithms [60, 63]. However, this requires additional hardware at the ICUs, potentially limiting system implementation. Using multiple features, and potentially a combination of features, may be the best way forward. Further research is required to identify the key ones. Pros and cons of different vital signs, and on which features these could be based have been discussed recently [13, 45].

Conclusions

Multiple attempts have been made to generate a functional CDS system for sepsis detection in young children. Although several of them have promising results, especially in the possibility of

excluding sepsis and other life-threatening events, very few have reached commercial availability. CDS systems generally allow detection of sepsis up to 24 h prior to current clinical praxis. Most systems are based on the analysis of heart rate variability and heart rate characteristics, but combining multiple features improves system performance. The use of CDS systems in study settings have been shown to allow earlier interventions and improve patient outcome. Currently, many systems are limited in that they are developed for narrow and specific patient subgroups, such as very low birth weight infants.

Every new system should be systematically evaluated in comparison to current systems already in use. International collaborations and data sharing would be fundamental in improving neonatal and pediatric care on a global scale, especially among intensive care unit patients. How to best approach ML model design, feature inclusion, and practical implementation are still issues that needs to be resolved. Research utilizing continuous real-time high-frequency vital sign monitor data to develop automated early warnings is crucial. Prospective evaluation using real-time data and decision-making in clinical trials and also testing in different healthcare settings is required, but a reduction in mortality from sepsis by only a small percentage would represent several tens of thousands of lives saved annually worldwide [64]. Therefore, further improving real-time algorithm-assisted clinical decision support systems to better guide treatments and improve outcomes, reduce morbidity and mortality of hospitalized infants is a crucial and exciting endeavor for the coming years.

Abstract

Artificial intelligence (AI) implies the use of a machine with limited human interference to model intelligent actions. It covers a broad range of research studies from machine intelligence for computer vision, robotics, and natural language processing to more theoretical machine learning algorithm design and, recently, “deep learning” development. The application of AI in medical fields is booming, including the use of AI in data collection, analysis, mechanistic prediction, to clinical disease diagnosis and drug development. In this chapter, we focus on the challenges in the studies of aging and the age-predisposed Alzheimer’s disease (AD) and summarize on how to use AI to help addressing these questions. We finally provide future perspectives on the use of AI in aging research and AD.

Introduction

Artificial intelligence (AI) is a generic concept that implies the use of a machine with limited human interference to model intelligent actions. It covers a broad range of research studies from machine intelligence for computer vision, robotics, and natural language processing to more theoretical machine learning algorithm design and, recently, “deep learning” development. In general, AI is recognized as having begun with the invention of robotics in the 1920s. There have been several waves of success and stagnancy over the years, most recently exemplified in the recent breakthrough powered by the development of more powerful graphics processing units (GPUs) and the outbreak of big data. Funding for both AI-based research studies and industrial innovation projects has further propelled progress and accelerated development.

In medicine, artificial intelligence (AI) research is growing rapidly with broad applications (Fig. 1). In 2016, healthcare AI projects attracted more investment in comparison with AI projects from other sectors of the global economy. In addition to conventional mathematical and statistical methods, AI techniques, in particular machine learning and deep learning approaches, draw significant attention to the analysis of medical data as medicine is becoming an increasingly data-centric discipline. The nature of evidence-based medicine is to guide therapeutic decision-making through learning from past data. Statistical approaches have historically addressed this challenge by characterizing correlations inside data through statistical equations, such as linear regression, indicating a “line of best fit.” Through machine learning or deep learning, AI can reveal nuanced relationships, which cannot simply be deduced by an equation. AI can extract valuable details from the electronic footprint of a patient. This will initially save time and increase performance but can also explicitly guide patient management after appropriate research. Specialist diagnostic skills can now also be carried into primary care by AI-based technologies. Broadly speaking, there are three types of algorithms for machine learning including (1) unsupervised learning (capable of identifying patterns directly from data, e.g., activity recognition using smartphone sensors, clinical outcome prediction from the electronic health records, anomaly detection, and knowledge discovery), (2) (semi-)supervised learning (classification and inferencing based on previous examples, e.g., chemoinformatics and drug discovery, multifactorial omics analysis and biomarker identification, imaging, and data enhancement), and (3) reinforcement learning (synergy of reward and punishment sequences to form an operating strategy in a given problem space, e.g., therapy optimization, treatment management, and surgical robotics).

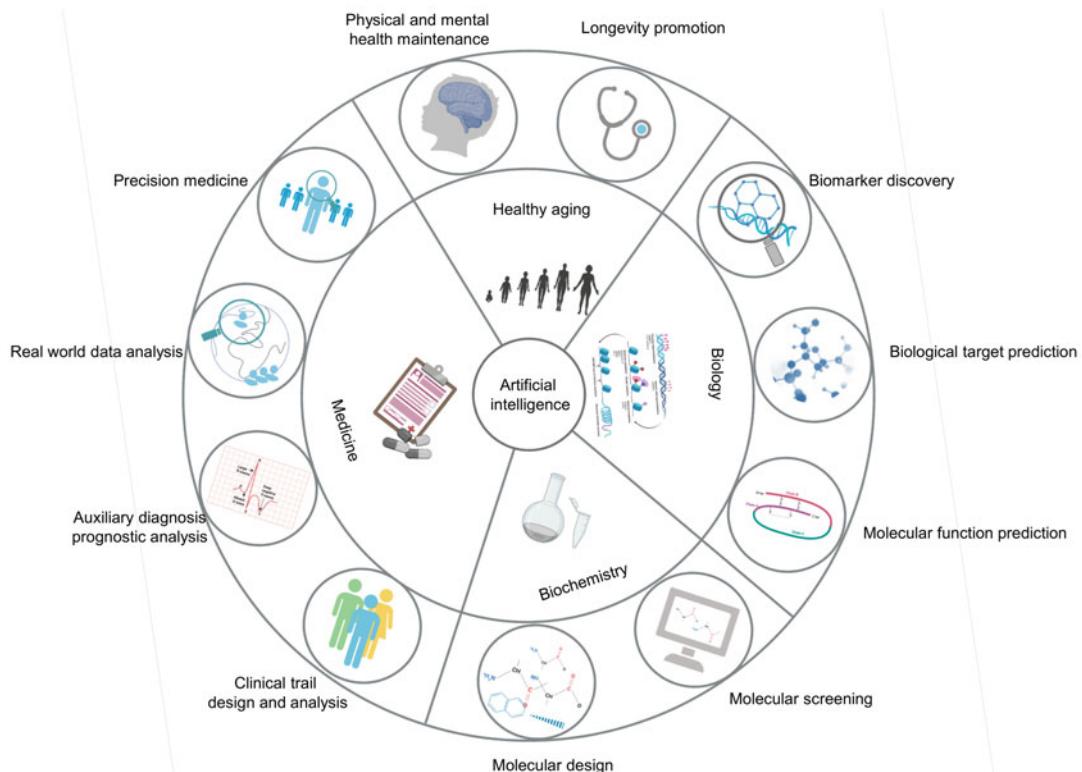

Fig. 1 The use of artificial intelligence (AI) in healthcare. The broad application of AI in healthcare consists of overlapping fields like biology, biochemistry, medicine, and healthy aging. For details see the text

In general, AI techniques have returned significant dividends by achieving outstanding performance in various applications especially for AI in medicine. There are a few key problems that need to be solved. For example, most current AI-based algorithms are typical black boxes. The end users can easily access high-performance AI, but the interpretability of the derived features and prediction is not clear. Therefore, explainable AI will be a major area for future research. Moreover, although current studies rely on a human operator's manual labelling, the ultimate goal will be "Taking the Human Out of the Loop." This encompasses future research directions including self-supervised learning, semi-supervised learning, and more advanced non-supervised learning methods. The first sections of this chapter will detail the historical development of AI in healthcare and in particular AI in biology, biochemistry, medicine, and healthy aging. The

rest of the chapter will focus on the application of AI in clinical work for Alzheimer's disease including diagnosis, treatment planning, drug development, and prognosis. We will also shed a light on future perspectives.

AI in Healthcare

Historical Overview

Among the broad range of research studies covered by machine intelligence, medicine has been identified as one of the most important areas for AI applications. Since the advent of AI, applications of AI in medicine have been explosive and make it possible for more precise and personalized medicine. The progressive growth and development of the application of AI in medicine can be organized by specific periods.

From the 1950s to the 2000s

In the first 20 years of this stage, researchers in this field primarily focused on the development of decision-making systems that had the ability to make inferences or decisions that could be applied in the clinical setting. In this period, some clinical informatics databases and medical record systems were firstly built, which had established the foundation for future applications of AI in medicine [1]. The last 30 years of this period was referred to as the AI winter. During this time, research funding and interest in AI in general were significantly reduced, and accordingly there was slow progress in the field. Generally, two major historical limitations had led to this famous “winter” which was also reflected in its application in medicine. The first was the extensive cost of building and maintaining the expert-labelled databases and obtaining the necessary calculating power. The second was the perceived limitations of AI such as the efficiency of the algorithm. Although there was a lack of funding and interest from academia during this period, collaboration among pioneers in the field of AI and medicine continued. In 1973, the Stanford University Medical Experimental Computer-Artificial Intelligence in Medicine (SUMEX-AIM) project was founded to enhance the connectivity between computer scientists and biomedical researchers from several institutions [1]. In 1975, the NIH sponsored an AI in medicine workshop which was held in Rutgers University [2]. Those initial collaborations among the pioneers in the field facilitated AI’s application to medicine at this stage.

In later years of this period (after the 1970s), research turned toward comparing the performance of computer-aided diagnostic systems with that of human physicians [3]. Some systems had also been shown to have the ability to interpret ECGs, diagnose diseases, choose appropriate treatments, provide interpretations of clinical reasoning, and assist physicians in generating diagnostic hypotheses in complex patient cases [4–6]. Scientists also put some research effort into the use of a computer to improve the detection and classification of the lesions in the vascular and integumentary systems using image analysis.

After the 2000s

As the development of computer hardware accelerated, the application of AI in medicine started to grow fast. Although the development of neural networks had begun in 1950, by the 1980s, it had progressed to such a point that it was now possible to create deep learning models (a phrase first coined by Rina Dechter in 1986) [7]. The development of deep learning (DL) marked important progress. Although deep neural networks had technically first been studied in the 1950s, their application to medicine had been limited by two problems for many years: first, insufficient computing capacity and second, the lack of available training data [8]. These limitations were overcome in the 2000s with increases in the availability of large data sources and significantly improved computing power. The large data sources included large-scale studies (e.g., UK Biobank), data-collection platforms (e.g., Broad Bioimage Benchmark Collection and the Image Data Resource), and electronic medical record (EMR) data [9, 10]. To highlight this increase, a national survey conducted in 2008 noted that only 13% of physicians reported having a basic EMR system, but by the end of 2012, 72% of physicians had adopted some type of EMR system [11, 12]. Since that time, the application of AI in medicine has been on the “fast track.” With the advances came substantial progress in image classification tasks and innovations in the application of AI to other fields such as drug development.

AI for Drug Discovery

The discovery of molecular structures with specifically required properties has been one of the most impactful scientific and industrial challenges. Normally, to develop a novel drug, the mean pre-tax expenditure is nearly \$2.55 billion over 10–15 years [13]. In recent years as more and more big chemical datasets have become available, deep learning has been applied to those data to accelerate the process of drug discovery and reduce costs in the process. AI technology can be applied during several steps of the drug design process, including virtual screening, activity

scoring, quantitative structure-activity relationship (QSAR) analysis, de novo drug design, and in silico evaluation of absorption, distribution, metabolism, excretion, and toxicity (ADME/T) properties [14].

Virtual Screening

Virtual screening (VS) is defined as the use of algorithms to find bioactive molecules from known molecular libraries for a drug target, typically an enzyme or a protein receptor. It has proved to be a very effective approach to filtering out those compounds with unfavorable properties [15, 16]. Based on traditional computer-aided drug discovery (CADD), virtual screening usually uses 2D and 3D structural information from ligands and target proteins. Similarity searching of small molecules, pharmacophore-matching, and molecular docking are commonly used techniques in traditional virtual screening. All the abovementioned techniques depend on the knowledge of chemistry, physics, and biology. While the technology used to run these CADD methods for virtual screening is affordable and easy to learn, it is hard to master them to successfully find the bioactive molecule for a given target. Recently, deep learning has been applied to virtual screening [17]. As opposed to traditional knowledge-based methods, deep learning VS directly extrapolates the rules through examination of its training data. Using molecular features, it tries to predict the classes of bioactivity through the examination of many abstract and high-level features that are sometimes not immediately obvious to the human eye. Due to the high feature extraction ability and low generalization error of deep learning, it is especially well adapted for use in ligand-based virtual screening which does not rely on the 2D/3D structural information of proteins [18–21]. For example, traditionally, the sparse distribution of active compounds in the general database wasted a lot of time during the process of virtual screening [22]. DL methods have been used to address this issue through use of the long short-term memory (LSTM) network model. The model was based on the similarity between natural language and simplified molecular-input line-entry system (SMILES) which is a specification in the form of a line notation for describing the

structure of chemical species using short ASCII strings [23]. Using AI for virtual screening may increase the chance of identifying new targets and make the process more rational. Another implementation of AI virtual screening is the use of abundant data from high-throughput experiments with gene expression profiles. For example, researchers tried to find potential drugs through measurement of the functional similarity of small molecules based on gene expression data [24].

Bioactivity Scoring

Activity scoring is one of the core components of molecular docking, a process that evaluates the potential binding affinities of drug-like molecules toward an interested target [25]. The DL-based methods perform well in this field due to their high nonlinear mapping ability and the fact that they could extract features efficiently from genomic, chemical, and physical force data [26]. For instance, some studies using convolutional neural networks (CNNs) to extract the features from protein-ligand interaction images were able to predict protein-ligand affinity [27]. A study using a 3D CNN model demonstrated prediction of binding affinities that was well matched with the experimental data [27]. Additionally, some studies used DLs to extract features from basic and primitive features. DeepVS was built with a CNN model and was designed to discern abstract features from basic chemical features (e.g., the atom context). DeepVS outperformed the traditional docking programs on area under the curve (AUC) and enrichment factor [28].

ADME/T Properties Prediction

It is vital to identify the molecules with poor chemical properties in the drug discovery pipeline. Early identification of ADME/T properties can reduce the risk of failure and save a large amount of time and money during development. Many DL-based methods were developed to address this issue [29]. One study utilized a CNN-ANN that extracted data from the molecular graph, and another study used the tensor-based convolutional embedding of attributed molecular graphs method to predict the solubility of molecules [30, 31]. The two models both showed good predictive performance

in their testing data. Some studies that focused on predicting drug absorption, the process by which drugs entered the blood from the site of administration, also applied DL-based methods. For example, a study with 1,014 molecules used the MLR model to predict bioavailability with structural fingerprints and molecular properties [32]. The model had a good predictive performance (correlation coefficient 0.71, MSE 0.24). The DL-based methods have also improved predictive performance in modelling drug distribution, metabolism, excretion, and toxicity. Recently, some multitask DL models for ADME/T prediction were also developed and showed good performance compared with other models targeted on predicting single property [33].

De Novo Drug Design

The de novo molecule generation problem involves generating novel or modified molecular structures with desirable properties. Thus, generative AI models are usually coupled with the abovementioned predictive neural networks to generate new compound structures under the constraints of interesting molecular properties. For example, Mariya et al. proposed ReLeASE which combined a molecular property predicting neural network with a molecular generative neural network to design chemical compounds with desired physical, chemical, and/or bioactivity properties [34]. However, Mariya et al. did not combine their generative AI model with bioactive experiments in their research. In silico medicine built the generative AI model GENTRL to auto-design novel inhibitors for kinase DDR1; their generated chemical compounds were identified as bioactive by their wet labs [35]. Additionally, because of the high generative ability of DL models, a study used data from the NCI-60 cell line assay to train an adversarial autoencoder model. This model could be used to generate the molecular fingerprints that were helpful in the search for potential anticancer agents.

AI in Biology

DL can be applied in the field of biology to answer some fundamental questions because it is suitable

for dealing with high-dimension data from omics, such as genomics and proteomics.

Genetics

Currently, a massive amount of genomics data is produced using next-generation sequencing technology, and AI is applied in analyzing those data. There are an increasing number of studies using DL to examine the genome and functional genomics. For example, DL has been applied in: (1) predicting the sequence specificity of DNA- and RNA-binding proteins, (2) methylation status, (3) gene expression, and (4) control of splicing [36]. Additionally, DL has been successfully applied in regulatory genomics. In this field, some architectures from computer vision or natural language processing were well suited after some genomic-specific modifications [36].

DL can also answer the question “how much RNA is produced from a DNA template in a particular cell” by building a model to predict gene expression from genotype data. It can be used for studying splicing-code models as well as for the identification of long noncoding RNAs. DL has been used for the interpretation of regulatory control in single cells [37], for example, the detection of DNA methylation in single cells, and for the identification of subgroups of cells through improvement of the representation of single-cell RNA-seq data. Additionally, predicting phenotypes is also one of the major interests of DL in genomics [36].

Proteomics

Proteomics aims to study the proteins’ structure and function in biological systems and is gradually becoming a data-rich discipline. Accordingly, DL is warranted to interpret the huge amount of data, giving biological insights. In the field of proteomics, DL performed well in predicting protein structure, posttranslational modification, and MHC-binding peptide [38].

The function of a protein largely depends on its structure, and predicting the spatial structure from an amino acid sequence plays a vital role in protein design and drug screening [39]. Currently, nearly 170,000 protein structures have been measured through a multicenter effort; however, it is a very

time-consuming and high-cost process to directly measure the structure. Using DL to predict the structure may reduce the cost and accelerate the related research [38]. Recently, the performance protein structural predictive models was significantly improved through the application of AI, especially in those predictions without previously known homologous structures. After 11 rounds of Critical Assessment of protein Structure Prediction (CASP), the performance of DL in predicting protein structures increased quickly, especially in terms of development of residue-residue contact predictions [40]. In the most recent CASP14, the performance of AlphaFold2 achieved remarkably high improvement, and its success rate received considerable interest from both academia and the general public. Although the structure of AlphaFold2 has not been published yet, we know that its precursor AlphaFold has a highly complex, dilated residual neural network (ResNet) with 220 blocks to predict the C β distances of residue pairs given the amino acid sequence and many MSA-derived features [41].

AI in Medicine

Diagnosis

Image-based diagnosis has been regarded as the most successful application of AI in medicine. Its application scenarios in the hospital are widely used in radiology, ophthalmology, dermatology, and pathology to assist with image-based diagnoses [42].

In the department of radiology, the earliest application of computer-assisted diagnosis may date back to the 1970s [43]. Currently, with the development of methodology, AI was applied in the detection of lung nodules and the diagnosis of pulmonary tuberculosis and other common lung diseases using images from chest radiography [44, 45]. Additionally, breast-mass identification using mammography scans reached expert-level diagnostic accuracies [46, 47]. Currently, many clinical diagnostic AIs are seeking legal approval for clinical applications. For example, an AI system for cardiovascular disease diagnosis with MRI image was registered by the FDA in 2018.

In dermatology, physicians use AI to diagnose various skin lesions and further differentiate disease. A recent study suggested that in diagnosing skin malignancy, convolutional neural networks achieved dermatologist-level accuracy [48]. The DL model performed better than the dermatologist in a comparison of algorithm predictions to the assessments of 21 dermatologists given a set of photographic and dermoscopic images. Although the training phase of the deep learning model can be expensive and time-consuming, the final model can easily be used on mobile devices which is very convenient and fast for disease screening [48].

Fundus photography is a noninvasive procedure that uses retinal cameras to capture images of the retina, optic disc, and macula [49]. Images acquired by fundus photography can be used as another source of data for the AI-assisted diagnosis. Recently, a research team of computer scientists and clinicians trained convolutional neural network models to identify referable diabetic retinopathy and diabetic macular edema with 128,175 retinal images. In this study, the DL model had a good performance in two independent datasets (areas under the receiver operating characteristic curve > 0.99) [50]. Additionally, its performance was comparable to the performance of expert-level ophthalmologists. This study also demonstrated that DL could identify the underlying associations between the images and age, gender, systolic blood pressure, smoking status, or cardiovascular events, which indicated the ability of DL to elicit new knowledge from raw data [51]. Another study showed that the performance of a convolutional neural network exceeded in pre-specified sensitivity (85%) and specificity (82.5%); it was authorized by the FDA for use by healthcare providers to detect diabetic macular edema and moderate-to-severe diabetic retinopathy [52].

In the Department of Pathology, images from histopathological assessment are used with AI algorithms to assist diagnosis. AI can be applied in the detection of various cancers and their metastases using biopsy specimens. For instance, DL models used in conjunction with normal clinical assessments can facilitate risk stratification of prostate and breast cancer patients [53]. In the USA, it is estimated that there will be a deficit of

more than 5,700 pathologists in the next 10 years [54]. DL detection system may be able to mitigate this gap and provide a fast and accurate assessment from histopathological slides or other biopsy specimens, further improving the quality of care for cancer patients.

Overall, successful applications of AI in radiology, dermatology, ophthalmology, and pathology have been followed by the availability of large labelled datasets, improved computational power, and the development of deep learning methods. Currently, those applications are changing medical practice dependably.

Prognosis

As more and more longitudinal data and EHRs become available, the DL model can learn from the trajectories of a large number of patients and further predict their prognosis. For instance, whether the patient could go back to work in a short period or how long they may have before the disease progress could be predicted. Several large integrated health systems included a DL model to evaluate the risk of transferring to the intensive care unit for in-hospital patients [55]. Additionally, some studies built DL models to predict mortality, readmission, and length of hospital stay using data from EHRs, classifying the cancer patients with different responses to chemotherapy. At the large population level, the same type of forecasting could perform risk stratification and identify those patients who have a higher risk of readmission or may need more healthcare services. Such information could lead to a better healthcare resource allocation and provide evidence-based healthcare [56].

One limitation for such models is the integration of the health data. Building prognosis systems needs longitudinal data to provide a comprehensive view of the patients' disease course. The integrated data need to include outcomes such as mortality, readmission, and medical cost; however, those data are held by a variety of bodies such as hospitals, the local public health bodies, medical insurance departments, and public security bureau. To integrate those data from different sources, a better solution could be to put those data in the hands of patients through ID

cards or other personal terminals. Additionally, standardization of the collected data is a vital issue for building such models [56].

Aging Biomarker Development

Aging is a gradual, multi-organ process that leads to multiple age-related diseases. Currently, some new experimental techniques have produced a huge amount of aging-related high-dimensional data. These data can evaluate the aging process precisely. AI technologies are suitable for the identification of the biomarkers of aging through patterns within these high-dimensional datasets [35].

Some DL-based aging clocks have already been created using data from genomics, biochemistry, proteomics, and clinical imaging. Biological age is a more precise measure of aging compared to chronological age. Generally, changes in biological age can provide a more comprehensive and objective evaluation of general health status [57, 58]. Data from MRI has been used for the determination of biological age, which can serve as a biomarker of aging. A study using a deep neural network (DNN)-based DL method on T1-weighted MRI images was shown to outperform random forest- or ANN-based age prediction models, with the predicted age named the brain age gap (BAG) [59]. The results demonstrated that age could be accurately predicted using unimodal imaging in a young population using engineered features instead of raw images. Notably, the discrepancy between the BAG and chronological age could be regarded as a marker of aging speed, and BAG could be used as a biomarker for neurodevelopment and disease detection that could be easily interpreted. Additionally, the biological age also can be built with transcriptomic data using deep learning. Some studies built deep learning models using transcriptomic data were presented. In one study using data from 545 transcriptomic samples from 12 datasets of human skeletal muscle, a deep feature selection (DFS) model was built and compared with several regression models. Linear regression was used as a baseline, and its performance was compared with other DL approaches. Although all models achieved a strong correlation

between predicted and chronological age, SVM and DFS models clearly outperformed the other methods in age prediction (R^2 0.83/0.83, mean absolute error 7.20/6.24 years). Some studies also used clinical EMR data to estimate biological age using DL. One study used DNNs to predict human chronological age using 41 biomarkers extracted from thousands of blood biochemistry samples from patients undergoing routine physical examinations. The DNN model with the best performance had an R^2 of 0.80 with an MAE of 6.07 years. In the analysis of feature importance, albumin, glucose, alkaline phosphatase, erythrocytes, and urea were identified as the five most important variables. These five biomarkers could also be identified from within thousands of biomarkers by DL [35].

Application of Machine Learning in Clinical Work for Alzheimer's Disease

Etiology

Alzheimer's disease (AD) is a neurodegenerative disease. Patients experience a steady progression of dementia, finally losing the ability to respond appropriately to their environment.

Currently, the pathogenesis of AD is still unclear although it is thought to be caused by an interaction between genetic and environmental factors [60, 61], with genetic factors contributing approximately 70% [62–65]. One of the prevalent theories of AD pathogenesis is the amyloid hypothesis which holds that different factors cause an imbalance between β -amyloid production and clearance which leads to β -amyloid accumulation in the brain. In turn, this accumulation leads to the formation of neurofibrillary tangles and neuroinflammation. As a result, the neurons may eventually become dysfunctional and die. Recently, the mitophagy pathway has also been found to contribute to AD [66], but the detailed pathology is still unclear [62].

Etiological studies are aiming to discover the environmental and genetic factors causing disease, and these can be clues for researching both

the prevention and treatment of AD. Recently, the development of AI technology has made it possible to achieve this goal using big data and ultra-complex models that exceed human brain processing capabilities [67–69]. AI provides a new way to model neuronal biological components using pathophysiological functional modules that can be embedded to model the complex dynamics influencing neuropsychiatric disorder phenomenology [70]. Because genetic factors contribute to approximately 70% of AD cases, they have been the main focus of AD pathogenesis research. In recent years, wide use of microarray and next-generation sequencing technologies has allowed research using genetic data to grow explosively. AI technology is becoming urgently required. Currently, genetic research on AD with AI is continuously growing.

In the population, individual genetic variations include (1) aneuploidy or polyploidy; (2) chromosome rearrangements including duplication, deletion, and inversion as well as translocations; (3) large segment deletions and duplications; (4) small insertions and deletions; (5) tandem repeat variations; and (6) single nucleotide variations (SNVs) [71]. There are approximately 3.2×10^9 base pairs (bp) in the genome of human beings, but 99% of those form noncoding regions. These regions have important cellular regulatory functions and are associated with regulatory elements, such as promoters, enhancers, silencers, and insulators. This region can produce microRNAs, ribosomal RNAs, and transfer RNAs and form structural elements of the chromosome, such as telomeres, and satellite DNA [72–74]. Now, four strategies have been applied in the AD field to discover genetic variations in the human genome including genetic linkage analyses, candidate gene/pathway association studies, genome-wide association studies (GWAS), and next-generation sequencing (NGS)-based association studies [75].

For example, three mutations in genes, presenilin 2 (PSEN1), presenilin 2 (PSEN 2), and amyloid precursor protein (APP), were suggested to be causative in early-onset familial AD using genetic linkage analyses. Besides, the apolipoprotein E gene (APOE) alleles were identified as risk factors for late-onset AD by candidate gene/

pathway approaches [76]. The International Alzheimer's Disease Project (IGAP) has collected many patients' samples to conduct large GWAS samples of LOADs [77, 78]. This strategy has also confirmed that APOE 4 is the most important genetic risk for AD [64, 75, 79]. To discover the extremely rare variants in AD, NGS was used to complement GWAS which requires large samples. Susceptibility loci, such as *ZNF655*, *ZBTB4*, *TTC3*, *TM2D3*, *PLD3*, *NOS1AP*, *NCSTN*, *IGHG3*, *GRN*, *FSIP2*, *CSF1R*, *CHMP2B*, and *ARSA*, were missed by GWAS but have been found to be related to AD development by NGS in very small population [80–83].

In order to better understand AD etiology, it might be necessary to consider additive or multiplicative effects, as well as the interaction of genes with the environment. However, more information is still needed, such as how genetic variations and environmental risk factors interact and mitochondrial genetic variation.

Diagnosis

Mental capacity and cognition preservation play an important role in the maintenance of autonomy in elderly people. Early detection of pathological cognitive impairment facilitates early, more effective treatment interventions focused on restoration and prevention. However, early detection of cognitive decline is a challenge due to the insidious symptoms, which are usually initially diagnosed as normal age-related cognitive decline [84, 85]. Requiring a longitudinal follow-up using multiple diagnostic criteria, mild cognitive impairment is often misdiagnosed as various different forms of dementia [86].

While magnetic resonance imaging (MRI) and genetic tests are the most common methods used in the clinic for the diagnosis of AD, there is currently no method available to detect early AD. Later-stage diagnostics are usually time- and money-consuming, and most importantly, they are not especially suitable for early detection and screening of large populations in a short time. As a result, an ideal diagnostic tool, sensitive enough to detect early disease, with a high

specificity is needed. AI, being noninvasive and practical, could be an appropriate candidate.

AI can detect prognostic signals from data that can be easily collected such as MRI data, and electronic health records (EHRs). These signals enable the screening of aging populations prospectively. Currently, test results analyzed and interpreted by trained people may lead to delay in diagnosis. However, these delays can be reduced by using the AI approach. There remains much room for improvement, but applying AI to diagnose AD is already growing at an amazing speed [87–89]. For example, one study applied an artificial neural network (ANN) model to the diagnosis of AD within a cohort of 2482 community-dwelling people aged 60+ over 3 years. The study aimed to establish an early warning ANN model with high accuracy and diagnostic efficiency and to find a biomarker which was sensitive to early exploration. This model could be used as a low-cost, practical tool for the early detection and diagnosis of AD [90].

Physicians currently rely on subjective self-reported clinical measurements to diagnose and detect response to therapeutic intervention due to a lack of appropriate biomarkers [91]. Machine learning models can be used to identify the biomarkers of response to treatment from clinical trials. In fact, large publicly funded databases, namely, the ADNI, have set biomarker identification as one of their major objectives. We summarize **possible applications of AI in AD diagnosis and drug development** (Fig. 2).

Therapy

There are no effective treatments for AD; however, the large pharmaceutical companies have slowed their work in this field because of the high failure rate of clinical trials [92–95]. For example, from 2002 to 2012, more than 400 clinical trials for treating AD were performed, but only 1 drug was approved [96]. This highlights the complexity of developing personal drug strategies and provides the opportunity to use new approaches to design and discover new drugs.

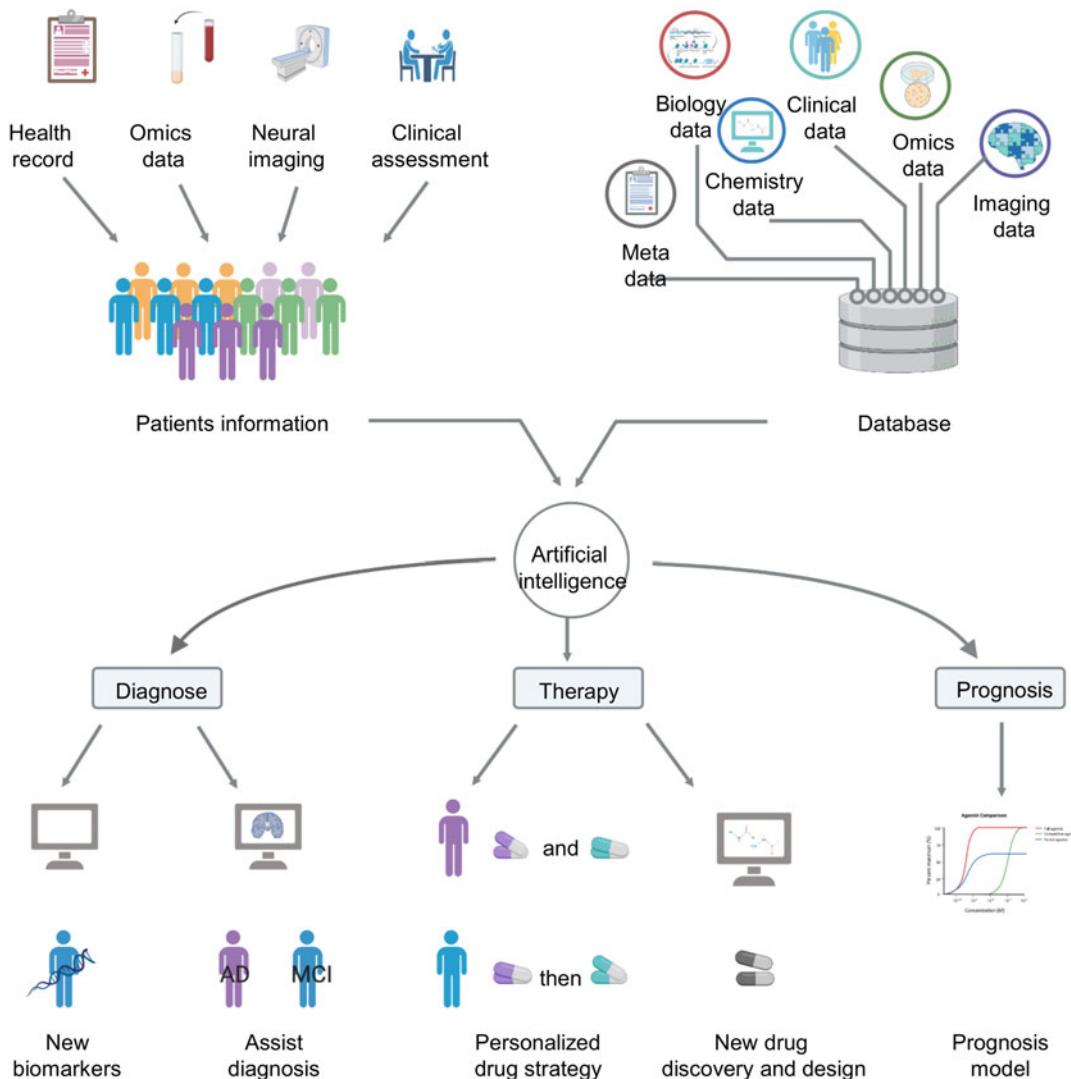

Fig. 2 Possible applications of AI in AD diagnosis and drug development. Through the use of patients' information and big databases, AI could improve diagnosis,

treatment, and prediction of prognosis. For details see section “[Application of Machine Learning in Clinical Work for Alzheimer's Disease](#)”

The use of machine learning techniques for developing personal drug strategies is becoming more and more popular because the whole data of an individual including clinical history, transcriptomic, and neuroimaging as well as biomarker data can be fed into an algorithm of neurodegeneration disease [97]. Using deep learning by unsupervised models may be one approach to stratifying patients to reduce dimensionality in high-dimensional labelled data and to classify patients' outcome. Patients with different

endotypes or subtypes of AD which are not obvious using traditional diagnostic methods may be identified [98]. These subtypes provide evidence for further development of personal drug strategies. For example, using this evidence, physicians may prescribe single drug or combination drugs to an individual patient to improve treatment effects.

AI could also be a new way to design and discover new drugs for AD. As mentioned before, AD pathology involves a vast array of mechanisms. How to explore the data related to these

pathways in an efficient, holistic, and thorough manner is key to understanding AD. However, this can be a challenge for individual researchers. AI can help make sense of or even predict or design new drugs. Knowledge graphs, which link genes, diseases, and drugs, are built from the integration of different data types including ChEMBL, Ensembl, OmniPath, KEGG, and PubMed [99, 100]. This approach can highlight the less-obvious links between drug targets and AD. However, the downside is lack of granularity in biological relationships, which leads to reductions in specific predictions [101]. Several relational inference methods have been published for AD. In contrast to knowledge graphs, machine learning enables a more detailed biological specification. By extracting gene expression data from healthy control and individual patients' gene expression data, molecular networks can visualize biological processes that change in different disease stages. For instance, a combination of Bayesian inference, clustering, and co-regulation was used to analyze transcriptomic data collected from the brain tissue of individuals with late-onset AD and non-AD controls [102]. A group of microglial-specific genes coding the TYROP protein and immune-related genes were found to be highly expressed in late-onset AD patients. After further verifying the function of TYROP in the AD mouse model, researchers found a deficiency of this protein, showing a neuroprotective function [103, 104].

Prognosis

Prognosis is as important as diagnosis because it quantifies the potential disease progression, and therefore how to predict when MCI converts to AD is also a hot research topic. Among the studies, some have focused on the roles of different imaging modalities in the prediction of MCI conversion [105]. Compared to this kind of early study, an atypical approach using multiple modalities was able to concatenate features into a combined feature set that was further used to build up a classifier. Because of the high dimensionality of the combined feature set, researchers built a

logistic regression model with 71.6% accuracy in classifying MCT conversion rate over 4 years [106]. Another line of research which encapsulated each modality feature could better keep intramodal integrity and reveal intramodal differences. One common approach was multiple kernel learning (MKL), which achieved classification with 76.4% accuracy, 81.8% sensitivity, and 66% specificity [107]. Besides using baseline multimodal imaging data alone, some researchers tried to use longitudinal multimodal image data. For example, imaging and Neuropsychological Status Exam Score (NPSEs) data, both at baseline and development stages, were used for AI-based prediction; in this way, the accuracy, sensitivity, and specificity reached 81.40%, 79.69%, and 83.08%, respectively [108]. Finally to increase the accuracy, researchers used florbetapir-PET, together with MRI, FDG-PET, and ADAS-cog scores, which increased accuracy to 86.05% with 81.25% sensitivity and 90.77% specificity [109].

Future Perspectives and Concluding Remarks

As the quality of life and clinical technologies improve in the twenty-first century, a dramatic increase of lifespan, and correspondingly an increased aging population on Earth, is expected. Since the elderly population is more susceptible to disease, infection (e.g., COVID-19), and neurodegenerative diseases (AD), we foresee pressure on society and the healthcare system [110–112]. Thus, it is timely and necessary to apply AI for clinical use. In recent years, AI applications have been widely used in precision medicine, including AI diagnosis, prognosis, and drug development. AI-aided medical applications have not only supported the doctors, researchers, and scientists to increase inefficiency and provide decision-making support but have also accelerated the development of the medical and healthcare industry. With more and more breakthroughs such as DeepMind's AlphaFold 2, we can foresee that AI will be able to revolutionize the drug development and disease diagnosis industry in the near future.

Abstract

The reductionist approach has dominated scientific research for several centuries and has been widely applied in the biomedical field. However, as we move into the realm of complex diseases, this approach fails to provide the insight needed to explain disease pathogenesis. Network medicine is a new paradigm that applies network science, artificial intelligence (in particular, machine learning and graph mining), and systems biology approaches to study a disease as a consequence of physical interactions within a cell. Pieces of evidence in this field show that if a gene or

molecule is involved in a disease, its direct interactors might also be suspected to play some role in the same pathological process. This evidence has lead to formulating the so-called “disease module hypothesis”: genes involved in the same disease show a high propensity to interact with each other. However, the number and structure of disease modules are largely unexplored. The purpose of this study is to systematically analyze the relationship between structural proximity of disease modules and categorical similarity of diseases, by aligning human-curated disease taxonomies with disease taxonomies automatically induced from proximity relations of disease modules within the human-gene interaction network (*interactome*). We propose a large-scale analysis of a vast collection of diseases leveraging a novel network and taxonomy perspective. Our aim is to support clinical studies by obtaining relevant insights to improve our understanding of disease mechanisms at the molecular level.

Network Medicine: A New Paradigm for the Study of Diseases

The purpose of this section is to introduce the main objectives and challenges of a new emerging and interdisciplinary approach to the study of diseases, network medicine (section “[An Introduction to Network Medicine](#)”), and to provide a summary of state-of-the-art network medicine methods based on machine learning and artificial intelligence (section “[Machine Learning Challenges in Network Medicine](#)”). Finally, we present the motivations and objectives of this study (section “[A Network-Based Analysis of Disease Modules Using a Taxonomic Perspective](#)”), whose aim is to gain more insight on categorical relationships between diseases, through the alignment of human-curated disease ontologies with taxonomic structures automatically induced from proximity relations of disease-related genes in the human interactome network.

An Introduction to Network Medicine

In the last decades, academic research and technological developments have supported the evolution of medical knowledge, on the one hand,

providing a continuously growing set of biomedical data and on the other hand, revealing a complexity only perceived until now. In this context, biological networks have become a central hub of multidisciplinary research, to address essential challenges on both diagnostic and therapeutic aspects such as drug development and disease classification [1, 2]. The reductionist approach to scientific discovery has dominated modern Western thought, and has been successful in the quest to understand observable phenomena. This fundamental principle of scientific investigation has also dominated biomedical research, and has led to the identification of causative mechanisms and effective therapeutic approaches for many diseases. Yet, as we move into the realm of increasingly complex, chronic diseases, this straightforward approach fails to provide the insight needed to explain disease pathogenesis. In addition, drug discovery, tied as it is to the purely reductionist principle of single drug target identification and validation, has been waning despite great advances in the fields of structural biology and bioinformatics. Owing to these limitations, alternative approaches have emerged to better understand diseases and therapeutics. Network medicine is one of such approaches. In medicine, the standard reductionist approach tries to identify a single disease by decoupling the complex biological or medical phenomenons into multiple components. Network medicine surpasses the standard reductionist approach, exploiting the network topology and the network dynamics (e.g., the information flow across the network) of biological networks to understand the pathogenic mechanism underlying the complex molecular interconnections. Network medicine is a new research field that applies network science, artificial intelligence, and machine learning to “-omics” (genomic, proteomic, and transcriptomic) data with the aim of studying, preventing, and treating diseases.

The central finding of network medicine is the following: “given the functional interdependencies between molecular components in a human cell, a disease is rarely the consequence of an abnormality in a single gene, but reflects the perturbations (due by mutations, deletions, copy number variations, or expression changes) of the

complex network of intra-cellular interactions” [4]. Network perturbations such as gain and deletion of disease nodes or edges can result in a similar disease phenotype altering the activity of the disease module [3]. Network medicine, therefore, offers a new perspective of the disease with respect to the complex system of molecular interactions within our organism. This new way of approaching the disease has led to a fundamental “holistic” observation and hypothesis of the disease mechanisms, the *disease module hypothesis*. According to Barabási et al. [4]: “A disease module represents a group of network components that together contribute to a cellular function whose disruption results in a particular disease phenotype.” From the network science perspective, molecular components (e.g., proteins) associated with the same disease are not scattered in the human interactome, but tend to interact with each other forming a network local structure or neighborhood, the disease module [2–4]. From a medical and biological perspective, the disease becomes a reflection of the alteration of one or more biological processes that interact in the human interactome [2].

Despite the potential relevance of this hypothesis, due to the high estimated incompleteness of disease-gene associations modeled in the human interactome [5], disease modules are not yet molecularly well defined and devoid of a clear, dense network structure in literature [2].

In addition to the formulation of this “local” network hypothesis of the molecular components associated to a disease, network medicine studies have shown a “global” network tendency for pathobiologically similar diseases to have their respective modules located in adjacent or overlapping areas of the interactome [2, 3, 6]. According to Loscalzo et al. [3] and Menche et al. [2], “proximity and degree of overlap of two disease modules (in the human interactome) has been found to be highly predictive of the pathobiological similarity of the corresponding diseases” and “network-based location of each disease module determines its pathobiological relationship to other diseases.” Indeed, different disease modules can overlap (see Fig. 1), so that perturbations caused by one disease can affect other disease modules that could leading to

comorbidity and pathogenesis mechanisms [4]. A further objective of network medicine is to construct a complete overview of the disease at the molecular level. To accomplish that, recent studies have analyzed the relationships between disease modules and drugs, extending the human interactome with drug data, such as drug-target associations and drug-drug interactions. Similarly to the disease module relationships, recent studies in network medicine proposed and tested a novel network proximity principle regarding the relationships between disease and drug in the human interactome. According to Cheng et al. [1], “a drug with multiple targets to be on-target effective for a disease or to cause off-target adverse effects, its target proteins should be within or in the immediate vicinity of the corresponding disease module in the human interactome.” Furthermore, Cheng et al. [7] expanded the drug-disease network proximity principle to polypharmacy, identifying network topological rules on the adverse or therapeutic impact of drug combinations in treating complex diseases such as hypertension and cancer. Moreover, they propose a drug or drug-target modules perspective, characterized by a well-defined network-based footprint but smaller in size compared to disease modules, moving beyond the “one-drug, one-target” paradigm. In network medicine most of the efforts are focused on using these findings to discover pathobiological relationships underlying molecular networks, such as disease drivers, comorbidity, and pathogenesis mechanisms, to refine the classification of diseases and support drug repurposing and discovery.

Machine Learning Challenges in Network Medicine

Traditional ways to address network medicine tasks are time consuming, labor intensive, and extremely expensive techniques. For example, the assessment of disease-gene associations is performed by statistical studies based on sequencing the DNA of a large number of patients affected by a given disease, known as genome-wide association studies (GWAS) (<https://www.genome.gov/27541954/dna-sequencing-costs-data/>).

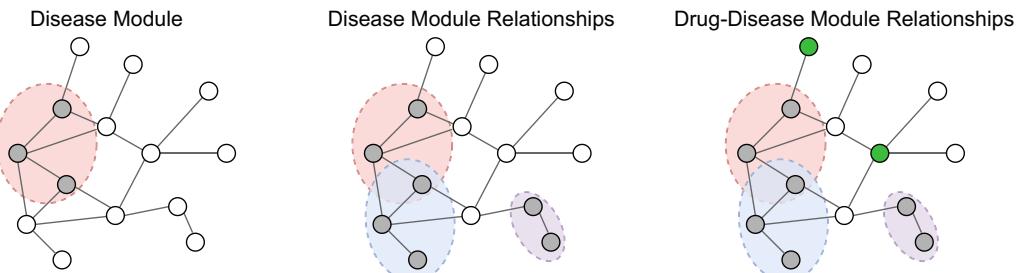

Fig. 1 Disease module properties and observations

Network methods and machine learning have a high potential to boost progress in this field. Recent advancements in machine learning, especially in graph deep learning, led to powerful methods to interpret the complex and interconnected patterns hidden in biological networks, reducing the search space for wet lab experiments, or providing biological insights.

In this section, we summarize some major machine learning challenges in network medicine, and their related issues. As summarized in the previous section, challenges in network medicine ranges from the analysis of the molecular components of a disease to the discovery of therapies based on combinations of drugs. The identification of all disease-associated or causing gene products (i.e., disease genes) is a crucial step to shed light on the nature of the disease modules and their molecular mechanisms. The traditional ways to assess disease-gene associations imply time-consuming and labor-intensive wet lab experiments such as linkage analysis or genome-wide association studies. In recent years, the literature has explored several machine learning strategies to identify disease-gene associations [8]. ProDiGe [9] and CATAPULT [10] use SVM in a positive-unlabeled (PU) learning scheme to rank candidate genes. Other scholars in the field propose deep graph representation methods. In [11], authors predict disease-gene associations by combining node2vec embeddings and features based on network motifs [12]. RW^2 [13] extends node2vec to jointly integrate high-order network structure and disease relationships. Furthermore, the authors of [14] propose to analyze diseases through a deep learning method combining

relation network (RN) and graph convolution neural network (graph CNN) to classify cancer types of patients.

Another relevant field of research is drug repurposing, the identification of new therapeutic effects for a drug [15]. Drug repurposing or repositioning tools are high demanding since the development of a new drug (i.e., drug discovery) is a time-consuming, laborious, expensive, and high-risk process. According to [16], the discovery and development of a new molecular entity (NME) takes 13 years and billions of dollars. Despite these issues, the trend of the number of drugs approved by the Food and Drug Administration (FDA) every year is decreasing [1]. In network medicine, drug repurposing is usually achieved by discovering a new candidate drug for a disease by exploiting network connections between the corresponding drug targets (i.e., proteins) and the disease module. In recent years, literature has explored several machine learning strategies to identify drug-target interactions [17, 18]. In drug-target interaction prediction, DBSI and TBSI [19] are drug or target similarity-based models based on DeepWalk [20]. DTINet [21] infer drug interactions by ranking and learning low-dimensional vector representations of drugs and proteins by combining a network diffusion algorithm and a dimensionality reduction scheme. Other challenging drug-related problems have been recently addressed. For example, [22] assesses new therapeutic combinations of drugs (polypharmacy) using graph convolutional neural networks. In [23], the authors employ the graph convolutional networks to find candidate therapies for the Sars-Cov-2.

Despite the great interest of these approaches, several issues complicate the application of machine learning methods to “-omics” data.

1. Incompleteness: It is estimated that only 20–30% of the existing protein-protein interactions (PPIs) in the human interactome have been discovered [5].
2. Reliability: Protein-protein interaction as well as disease-gene association datasets available in literature are noisy and rely on different evidence scores, based on the reliability of the sources [3, 24].
3. Absence of negative knowledge: When a biological association is not present between two biological entities, we are not sure if it actually does not exist or if it is still unknown [18, 25, 26].

On the other hand, the interest of scientists in network medicine remains high, since a growing interdisciplinary effort gives hope for an acceleration of results in this field.

A Network-Based Analysis of Disease Modules Using a Taxonomic Perspective

Human-curated disease ontologies are widely used for diagnostic evaluation, treatment, and data comparisons over time and clinical decision support. The classification principles underlying these ontologies are historically guided by the analysis of observable, often anatomical, pathological similarities between disorders. Although, thanks to recent advances in molecular biology, disease ontologies are slowly changing to integrate the etiological and genetic origins of diseases, nosology (the science of building medical taxonomies) still reflects a reductionist perspective.

Proximity relationships of disease modules (hereafter DM) in the human interactome network are also increasingly used in diagnostics, to identify pathobiologically similar diseases and support drug repurposing and discovery. Similarity relations induced from structural proximity have also several limitations, although of a different nature w.r.t. those encountered in human-curated ontologies. These

limitations (incompleteness, reliability, and absence of explicit negative knowledge) have been already discussed in previous section “[Machine Learning Challenges in Network Medicine](#).”

The purpose of the study described in this chapter is to shed more light on disease similarities by analyzing the relationship between categorical proximity of diseases in human-curated ontologies and structural proximity of the related DM in the interactome. Our clinical research question is the following: Can we detect meaningful correspondences and discrepancies between distance-based hierarchies automatically generated from disease genes in the interactome network and etiological, human-curated disease taxonomies? The analysis of commonalities and differences among structural and categorical disease relationships could shed more light on the molecular interactions underlying the disease mechanisms, and help refine the human disease classification and better identify limitations and perspectives of current module-based computational approaches to the study of diseases.

Figure 2 shows the workflow of the proposed approach, described in detail in the next sections.

1. **Taxonomy induction:** First, we automatically induce a hierarchical structure of diseases based on proximity relations of DMs in the human interactome. This taxonomic structure is hereafter referred to as the interactome taxonomy (I-T).
2. **Taxonomy alignment and labeling:** Next, we label the intermediate nodes of the I-T using taxonomy alignment and labeling algorithms. The algorithm finds the best map between categorical nodes in a human-curated *reference ontology* (hereafter R-T) and the unlabeled inner nodes of the I-T.
3. **Taxonomy analytics:** The alignment between I-T and R-T supports a large-scale analysis of a vast collection of diseases jointly from an ontological and molecular perspective. We provide insights to refine state-of-the-art nosology and knowledge on disease interactions, by using our framework to investigate the efficacy of the anatomical disease classification principle at the molecular level, identify nomenclature

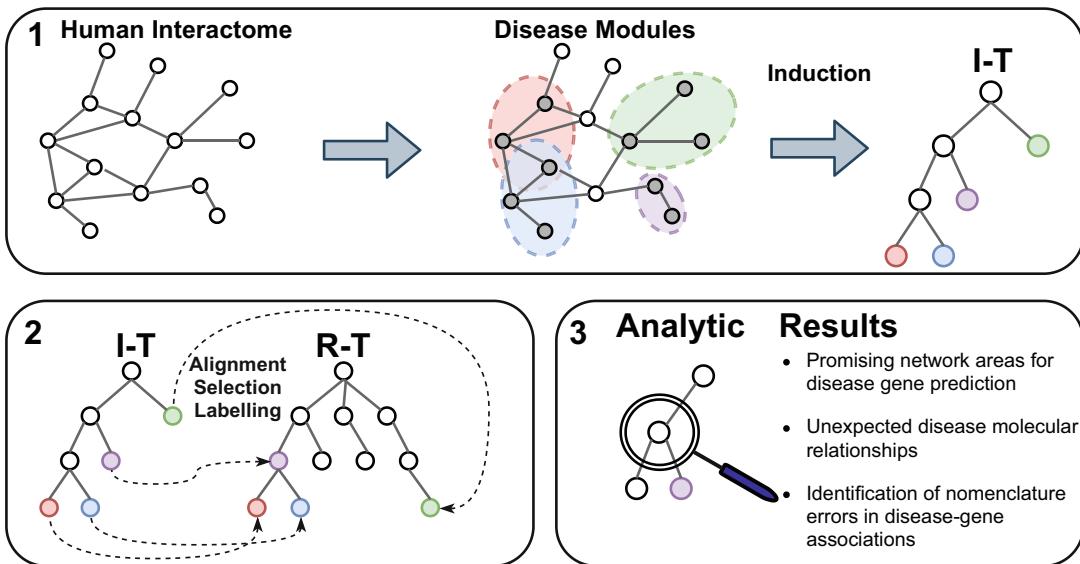

Fig. 2 The work flow of our study. Box 1 shows the taxonomy induction phase, Box 2 represents the phase of taxonomy alignment and labeling, and Box 3 summarizes the results of the analytic phase

error in disease-gene associations, and discover unexpected hidden molecular mechanisms among diseases.

literature to represent disease modules [2, 11]. Given the human interactome network $G = (V, E)$ and a disease d in a set of diseases D_{it} :

- 1. Induced module:** The induced module $I_d = (V_d, E_d)$ is a subgraph of G , where $V_d \subseteq V$ is the set of genes nodes associated with d and E_d is the set of gene-gene interactions $E_d = \{(u, v) | (u, v) \in E \text{ and } u, v \in V_d\}$ [2]. This definition includes in a DM all the disease proteins but, due to the incompleteness of the network, it is usually a graph with many connected components and devoid of a strong local structure [11].
- 2. Largest connected component (LCC) module:** The LCC_d module is the largest connected component of I_d [2, 11]. Unlike the induced module I_d , LCC_d usually has a denser local structure but may not include all the disease-related nodes d .

Given the human interactome G , a set of diseases D_{it} , and their disease modules DM_{it} in G , hierarchical clustering is performed using a distance matrix of disease modules (defined as previously explained), based on the following network-based distance measure (Eq.(1)) [1–3]:

Construction of the Interactome Taxonomy (I-T)

We induce a disease taxonomy (named interactome taxonomy, I-T) by applying hierarchical agglomerative clustering to the human interactome network, exploiting proximity relations of disease modules. Hierarchical agglomerative clustering (HAC) is a set of greedy approaches that create a hierarchy of clusters from unlabeled input data. Given a distance matrix of seed clusters, the HAC algorithm iteratively merges two clusters based on a selected intercluster distance measure. Common methods to merge clusters are average and complete linkage.

In our context, clusters are DM in the human interactome network. However, due to the high incompleteness of the disease-gene associations modeled in the human interactome [27–29], disease modules are not molecularly well defined and devoid of a clear, dense network structure in literature [2]. To cope with this problem, we use two alternative definitions of modules in network science, commonly used in network medicine

$$\text{dist}(A, B) = \frac{\sum_{a \in A} \min_{b \in B} SP(a, b) + \sum_{b \in B} \min_{a \in A} SP(a, b)}{|A| + |B|} \quad (1)$$

where A, B are respectively the set of nodes in modules DM_A and DM_B associated to diseases $d_A, d_B \in D_{it}$, and SP is the shortest path length between two given nodes in G .

In our experiments, we used two DM definitions (induced module and LCC) and two cluster-merge methods (average and complete), and we select the best solution among the resulting four I-Ts, using the methodology described in section “Comparing Alternative Induced Taxonomies.”

Taxonomy Alignment and Labeling

The result of the hierarchical clustering algorithm is a binary tree taxonomy, hereafter referred to as interactome taxonomy (I-T). I-T is a connected directed acyclic graph $T(V_T, E_T)$ in which nodes V_T represent disease concepts and edges represent “is-a” semantic relationships (Edge (v, u) with $u, v \in V_T$ means that v is a kind of u). In our context, leaf nodes (i.e., nodes with out-degree equal to zero) are “specific” diseases D_{it} , physically represented by the corresponding modules DM_{it} , and the inner nodes (i.e., nonleaf nodes) are disease categories DC_{it} (Note that the most generic concept of “disease” is the root node, a node with in-degree equal to zero.). Note that inner nodes $c \in DC_{it}$ are unlabeled, and extensionally defined by the set of their subsumed disease nodes D_{it}^c , also denoted as the C_c clusters.

Similarly, given a “reference” human-crafted taxonomy, denoted as R-T, let $T(V_R, E_R)$ be the set of its nodes and edges, DC_{rt} its disease categories, and $C_{c'}$ the clusters associated with category nodes $c' \in DC_{rt}$.

Taxonomy Alignment

Whatever the choice of the R-T, the R-T and the I-T are expected to be structurally diverse and defined on different sets of diseases nomenclatures, D_{rt} and D_{it} . For example, R-T has usually a polyhierarchical structure, while I-T is a binary tree.

To compare I-T and R-T we first need to create a mapping M from D_{it} to D_{rt} nomenclatures (details on the mapping are given in the experimental section). In Fig. 3, mappings among nodes of the two taxonomies are highlighted using the same colors. As shown, M is not one to one and there are four cases:

1. Case 1: Some D_{it} nodes may map onto inner nodes in the R-T.
2. Case 2: Some D_{it} nodes may map onto multiple nodes in the R-T.
3. Case 3: Some D_{it} nodes may map onto the same node in the R-T.
4. Case 4: Some D_{it} may have no mappings in the R-T and vice versa. These nodes without mappings are the white leaf nodes in both taxonomies.

Our taxonomy alignment procedure consists of three methods: *merge*, *split*, and *pruning*. We apply *merge* and *split* to the R-T to solve cases 1, 2, and 3; instead, *pruning* is applied to the R-T and the I-Ts to solve the case 4. The pseudocode of these algorithms can be found in the online Appendix (http://iim.di.uniroma1.it/pdfs/AIM_in_Genomics_Appendix_Springer_Nature.pdf).

The *merge* algorithm turns in leaves all the R-T colored inner nodes. If the node has noncolored descendants, these are simply removed. Else, the node and its colored descendants are aggregated

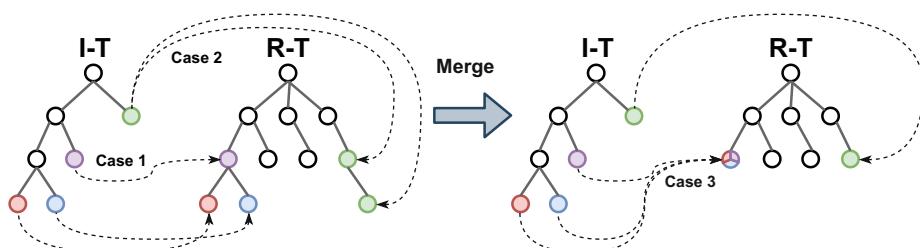

Fig. 3 Visual example of the *merge* algorithm

into a single multicolored node, as shown in Fig. 3 (right).

After the merge, the *split* algorithm splits all the nodes with multiple colors (see Fig. 4). As a result, all colored R-T nodes are all leaf nodes, and every I-T node points to its correspondent R-T node. Note that these new nodes inherit the ancestors of the splitted multicolored node. Furthermore, polyhierarchy in the R-T is preserved, as shown in Fig. 5.

Finally, the *pruning* algorithm (see Fig. 6) prunes both the R-T and the I-Ts by recursively removing survived “white” leaf nodes, those not linked by any mapping relation in M . As a final result, the R-T and the I-T have as leaf nodes the same set of diseases, denoted as D_{\cap} .

Comparing Alternative Induced Taxonomies

As remarked in section “[Construction of the Interactome Taxonomy \(I-T\)](#),” the I-T is built using different definitions of disease modules and different intercluster similarity functions during agglomerative clustering. In this section, we present a method to select the best I-T, among four I-Ts, based on its structural and semantic

closeness with the R-T (Four aligned I-Ts resulting by the combination of the induced and LCC disease module definitions with the average and complete clustering methods.). To this end, we use the Lin semantic similarity [30]:

$$S_T(a, b) := \frac{2 * IC_T(LCS_T(a, b))}{IC_T(a) + IC_T(b)} \quad (2)$$

where IC is:

$$IC_T(x) := -\log \left(\frac{|\text{leaves}_T(x)| + 1}{\text{MaxLeaves}_T + 1} \right) \quad (3)$$

where a, b are two leaf nodes in a taxonomy T , and $LCS_T(a, b)$ is the least common subsumer of a and b in T ; $\text{leaves}_T(x)$ is the set of leaves descendant of x and MaxLeaves_T is the number of leaves in T .

The Lin similarity increases when two nodes are structurally close and decreases otherwise. Furthermore, by construction, the distance between two nodes is normalized with respect of the maximum distance, a property that favors the comparison of taxonomies with different depths. This is a desirable property since the I-T is a binary tree and has a much higher depth than the R-T.

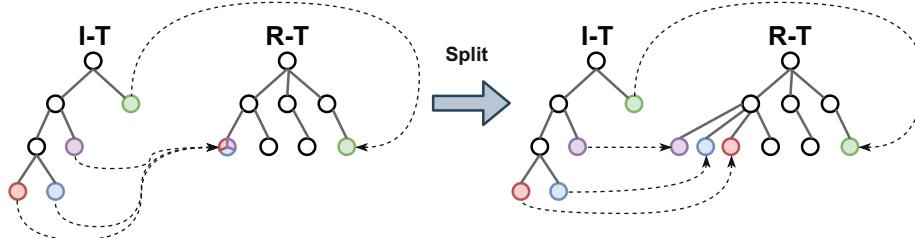

Fig. 4 Visual example of the *split* algorithm

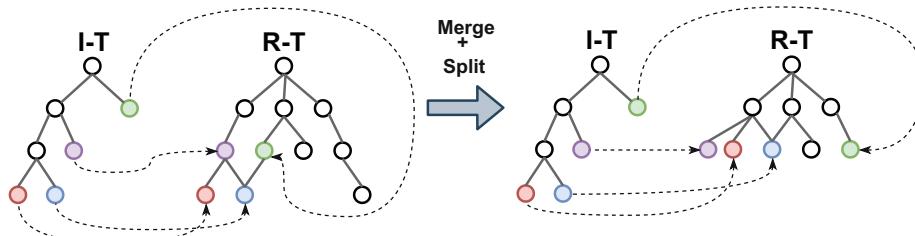

Fig. 5 Visual example of the *merge* and *split* algorithms for a polyhierarchical case

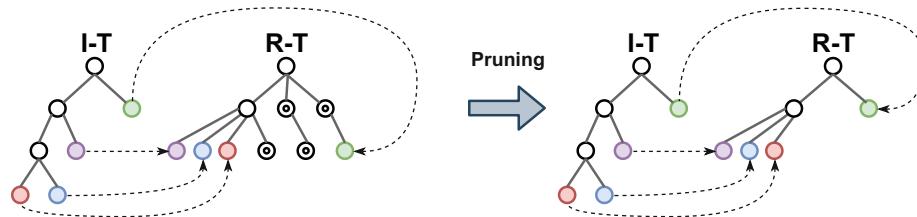

Fig. 6 Visual example of the *pruning* algorithm

To compare I-T and R-T, first, we calculate the pairwise Lin similarity $S_T(d_1, d_2)$ in D_{\cap} for each taxonomy, where $\{(d_1, d_2) | d_1, d_2 \in D_{\cap} \text{ and } d_1 \neq d_2\}$. Next, for each taxonomy, we construct a vector of $S_T(d_1, d_2)$ pairs, and calculate the cosine similarity of R-T and I-T vectors. The idea is that if the two taxonomies are similar, disease pairs that are “close” in one taxonomy should be “close” also in the other taxonomy, and those who are far apart in one taxonomy should be far apart also in the other.

The experimental application of this methodology is described in section “[Discussion](#).”

Interactome Hierarchy (I-T) Labeling

As previously noted, the inner nodes of the aligned I-T have no semantic labels. To facilitate comparison, we defined an algorithm to label each inner node in the I-T with the most similar category label in the R-T. In order to find the most similar R-T category node, we define the *cluster* C_c associated with a category node c in a taxonomy as the set of all its descendant disease nodes that are also in D_{\cap} .

Then, the *labeling* algorithm (see online Appendix for details (http://iim.di.uniroma1.it/pdfs/AIM_in_Genomics_Appendix_Springer_Nature.pdf)) labels every I-T disease category c with the name of the R-T category c' with highest similarity score $sim(C_c, C_{c'})$ between the clusters of c and c' . To compute the similarity between two clusters, we use the Jaccard similarity. Note that the labeling method uses the full set of R-T categories to obtain more fine-grained labels, but the node clusters C_c are defined on the common disease set D_{\cap} of the aligned taxonomies (The

alignment method ends up removing several inner nodes in R-T for the purpose of alignment.).

Experimental Set-up

In this chapter, we considered the human protein-protein interaction network from a recent work of Barabasi et al. [7], which is an extension of a highly cited and popular interactome used by Menche et al. [2] to conduct disease module analysis. The network has $|V| = 16,677$ proteins and $|E| = 243,603$ physical undirected protein interactions.

To construct disease modules, we collected disease-gene associations from DisGeNET [31] with a GDA (GDA is a “reliability” score, for details see www.disgenet.org/dbinfo#section43) score greater or equal of 0.3. Finally, we selected as disease modules the 948 diseases with a set of disease genes of size at least 10.

We selected the disease ontology (DO) as reference taxonomy (R-T) [32]. An alternative widely used reference ontology is ICD-9 (used, for example, in a work by Zhou et al. [33]). However, ICD-9 has been designed to promote international comparability in the classification and presentation of epidemiology and mortality statistics. Its hierarchical structure is not based on etiology, but on anatomical and disciplinary principles. Hence, ICD-9 does not represent a good categorical framework for integrating network-based disease properties. Instead, the disease ontology has been created for describing the classification of human diseases exploiting etiological agents. Its purpose is to identify commonalities of diseases located in a common molecular area (i.e., close to each other in the interactome), originating

Table 1 Comparison of Lin-similarity vectors of the aligned R-T (extracted from the disease ontology) and I-T taxonomies obtained with different methods. The value in

	Induced	LCC
Measure	Complete (RD)	Complete (RD)
Cos. Sim. (%)	43.59 (28.55)	46.33 (29.84)
	39.94 (28.58)	43.7 (29.71)

from a particular cell type or resulting from a common genetic mechanism. Therefore, even though the “localist” view of diseases is still a guiding principle, the DO also exploits the molecular insights of disease phenotypes.

By parsing the DO “obo” file (<http://www.obofoundry.org/ontology/doid.html>), we generated a directed acyclic network hierarchy of 10,012 diseases and disease categories, 10,061 edges and 12 levels. To create a mapping M between the two different nomenclatures, we used partial mappings directly provided in DisGeNET and in the DO, which we further extended with the support of clinicians.

First, we applied the comparison method of section “[Interactome Hierarchy \(I-T\) Labeling](#)” to select the best method to induce the I-T taxonomy, i.e., the one producing a taxonomy with the highest similarity with the selected R-T (namely, the disease ontology). Table 1 shows the result of this comparison. Note that similarity values are compared against those obtained by a random shuffling the disease nodes. Based on the results of Table 1, we select the I-T taxonomy obtained using induced modules to represent DMs, and the average linkage method to merge clusters during hierarchical clustering. This induced taxonomic structure shows a significant similarity with the disease ontology and therefore represents a good basis for our study.

Discussion

Our research hypothesis in this work is that jointly analyzing the structural proximity of disease modules in the human interactome and the semantic proximity of corresponding diseases in human-cured taxonomies could help both refine the classification of human diseases and identify the limitations and perspectives of current module-based computational approaches to the study of

the round brackets represents the average of values generated by ten random distributions of leaf nodes

diseases. In this section, we summarize the major outcomes of a clinical analysis supported by the methodology presented in previous sections. Our analysis is based both on the study of matching and unmatching pairs of R-T and I-T categories.

Finding Disease Categories with a Corresponding Dense Neighborhood in the Interactome

First, we conducted an analysis to reveal in the human interactome large neighborhoods of disease modules associated with disease categories in R-T. Dense neighborhoods of diseases are useful to identify promising disease categories for disease-gene prediction, drug repurposing, and comorbidities detection. To find these large neighborhoods, we verified the existence of topmost disease categories of the R-T with a high overlapping with some internal nodes in the I-T. An R-T disease category c' that is “well-represented” by an I-T category c implies a strong molecular proximity relationship among the diseases in cluster C_c . Symmetrically, this implies that there exists a molecular mechanism that strengthens the classification principle of the R-T category.

We considered the nine disease categories in the first level of the R-T as the most general disease categories. To evaluate the degree of similarity between these R-T categories and their most similar correspondents in the I-T, we used the Jaccard similarity, i.e., the “label score” computed by the labeling algorithm of section “[Interactome Hierarchy \(I-T\) Labeling](#).”

We also calculated the statistical significance of our results by computing the p-value over a random distribution. Table 2 provides an overview of the topmost R-T disease categories and their relationships with I-T categories induced from DM molecular network proximity. In

Table 2 Correspondence among topmost DO categories and the induced taxonomy

R-T (Disease ontology)	Induced I-T
Disease category name (size)	Best label score (P-value)
Disease of cellular proliferation (255)	54.77% ($3.14 \cdot 10^{-20}$)
Disease of anatomical entity (434)	50.05% (0.08)
Genetic disease (12)	41.66% ($6.14 \cdot 10^{-10}$)
Disease by infectious agent (10)	30% ($1.92 \cdot 10^{-7}$)
Physical disorder (21)	26.09% ($1.51 \cdot 10^{-9}$)
Disease of mental health (76)	21.51% ($1.06 \cdot 10^{-13}$)
Syndrome (42)	21.27% ($8.69 \cdot 10^{-11}$)
Disease of metabolism (55)	16.36% ($4.66 \cdot 10^{-11}$)

particular, we found that the R-T disease categories that show a higher localization in a network neighborhood are “disease of cellular proliferation” and “genetic disease.” This means that tumors and genetic diseases are highly localized in two neighborhoods of the human interactome. From a biological network perspective, close DMs of “disease of cellular proliferation” are motivated by the fact that cancer diseases have similar genetic causes in proliferation control genes such as the well-known *P53* [4, 34, 35].

The second best matching category is “disease of anatomical entity,” i.e., disease grouped by human experts according to an anatomical localization principle. However, as shown in the table, the similarity value is high but not statistically significant. This is motivated by the fact that diseases belonging to this topmost category are grouped in diverse subcategories scattered over the network rather than in a large “anatomical” neighborhood. To confirm this hypothesis, we performed a systematic pair-wise comparison among subcategories of “disease of anatomical entity.” We found that very rarely category pairs belonging to different anatomical subsystems have overlapping clusters in the I-T, with some obvious and well-documented relations like nervous and respiratory systems, gastrointestinal and integumentary systems, and musculoskeletal and cardiovascular systems [36–38]. In other terms, the validity of the anatomical classification principle is not disproved by the DM localization hypothesis.

One limitation of the above analysis is that, as remarked in section “Machine Learning Challenges in Network Medicine,” a well-known problem of the human interactome network is its

incompleteness [5]. It follows that, while positive results (disease categories corresponding to highly overlapping disease modules) are useful pieces of evidence to identify interesting areas of the interactome to discover new disease-gene associations, the absence of such evidence could be either motivated by the nonexistence of a similarity relation, or by a lack of knowledge on gene interactions in specific areas of the interactome.

Finding Unexpected Structural Relations Between Disease Categories

A more interesting result would be to identify “unexpected” neighborhoods in the I-T, e.g., disease categories that are not connected in human-curated taxonomies but whose strong molecular similarities suggest that one such connection should be exploited to enrich the ontology.

To help finding these relations we developed a visual tool to explore the labeled I-T in a more systematic way. Clinical experts have identified, among the others, the following interesting results: There exist strong unexpected molecular relationships between glaucoma and pulmonary arterial hypertension (see Fig. 7), cholestasis and chronic obstructive pulmonary disease (COPD), peroxisomal diseases, and ciliopathy-related syndromes. For these relationships, we were able to find confirmations in very recent clinical studies. For example, Gupta et al. [39] and Lewczuk et al. [40] confirm our finding by shedding light on common molecular mechanisms and manifestations between pulmonary hypertension and glaucoma through multiple case reports. Instead,

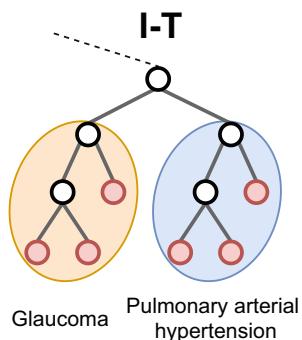

Fig. 7 A branch of the selected I-T groups together glaucoma-related diseases and pulmonary arterial hypertension-related diseases

Tsechkovski et al. [41] observed that cholestasis and COPD pathomechanisms are mediated by common molecular components like the alpha-1 antitrypsin protein. It is interesting to note that there is an emerging hypothesis connecting gut, liver, and lung as playing a key role in the pathogenesis of COPD [42]. Finally, Miyamoto et al. [43] and Zaki et al. [44] found biological mechanisms between peroxisomal diseases and ciliopathy-related syndromes (e.g., Joubert syndrome, Bardet-Biedl syndrome, and Jeune syndrome). These relationships should be used to extend the DO.

Other identified unexpected relationships lack at the moment support from published studies, however the results reported above demonstrate the relevance and potentials of our proposed methodology (Clinical confirmation of our findings is clearly outside the scope of this research, although it represents a study hypothesis for further research by clinicians in the field.).

Detection of Nomenclature Errors in Disease-Gene Associations

Finally, we tried to identify “unconvincing” strong matches between R-T and I-T categories. An in-depth analysis by clinicians has led to the detection of a number of nomenclature errors in DisGeNET.

Disease modules in the interactome have been identified, as discussed in section “[Experimental](#)

[Set-up](#),” using disease-gene associations in DisGeNET, one of the most widely used association databases. Publicly available disease-gene associations databases are manually or computationally curated and some of them integrate other disease-gene collections. However, especially for ambiguous diseases with similar names, all these mechanisms are prone to errors resulting in wrong disease-gene associations. Although in our work we selected only associations with a high GDA score, nomenclature errors might still survive.

The identification of wrong disease-gene associations is of primary importance both for disease-gene discovery and clinical diagnoses. Indeed, on the one hand, disease-gene discovery tools, using wrong disease-gene associations, would make wrong predictions. On the other hand, clinicians usually make and justify diagnoses using the disease-gene associations contained in public databases (as we said, DisGeNET is one among the most widely used resources) leading to wrong diagnoses or therapies for a patient. Here, we demonstrate that our framework may facilitate the detection of wrong disease-gene associations.

To this end, supported by clinicians, we identified a number of R-T disease categories with an unconvincingly high overlapping with I-T inner nodes. Specifically, a clinical expert analyzed all R-T/I-T categories pairs with a Jaccard similarity score greater or equal than 90%. Then, we manually verified the DisGeNET pieces of evidence supporting the related disease-gene associations. We found a number of nomenclature errors, for example: “obstructive lung disease” and “bone remodeling disease” have several wrong disease associations. More in detail, in “obstructive lung disease” the pulmonary emphysema, focal emphysema, panacinar emphysema, and centrilobular emphysema diseases have the same 12 disease-gene associations almost all supported by the same published study, but related only to the pulmonary emphysema or the generic category of emphysema. The same happens in “bone remodeling disease” for the following diseases: osteoporosis, age-related osteoporosis, post-traumatic osteoporosis, and senile osteoporosis.

Conclusions

We believe that the biomedical understanding of diseases is on the edge of a radical change. The disease module hypothesis, with its relevant applications to disease-gene discovery and drug repurposing, is leading the revolution of biomedical research of the future. For these reasons, we deem it fundamental to discover the degree of relationships between the disease module hypothesis and human-curated disease taxonomies. Given the complexity underlying the disease mechanisms, we developed a machine learning methodology to analyze diseases by leveraging, in a novel way, both taxonomic and molecular aspects. We used our methodology to give an useful global view over the human-curated “general” disease categories and their relationships with molecular network proximity. We used our framework to identify large disease network neighborhoods representing promising areas to discover new disease-gene associations, to find “unexpected” disease associations between disease categories that can be used to enrich human-curated ontologies, and finally to detect a number of wrong disease-gene associations in public databases, whose presence could negatively impact on diagnoses and network-based methods. In conclusion, we presented a novel disease module analytic strategy leveraging both the molecular and the taxonomy perspectives, providing new insights into the molecular mechanisms of diseases and a way to refine the human-curated taxonomy.

Abstract

Genomic medicine, which can be used for the appropriate diagnosis, treatment, and prevention of a disease based on information obtained from genome analysis, is now being used in clinical practice to realize precision medicine. It involves the interpretation of genomic variants to clarify their effect on molecular processes, link them to phenotypes, and search for clinical and biological evidence for their relationship with disease. These tasks require an enormous amount of time and effort, which is

why artificial intelligence (AI) is expected to be used. Moreover, it is important to determine which drugs are effective for which genotypes to make treatment decisions. However, it is not realistic to experimentally verify the effectiveness of drugs for various genotypes. Therefore, AI is also being applied to the search for effective drugs for each genotype, which is an important issue in genomic medicine. In this chapter, we introduce the applications of AI to address these important issues in genomic medicine.

Introduction

The Human Genome Project, which started in 1990, revealed that the human genome consists of approximately 3 billion bases, and the reference

okuno.yasushi.4c@kyoto-u.ac.jp

sequence of the human genome was determined in 2003. The determination of the reference sequence made it possible to compare the genomes of individuals and discuss differences. In general, approximately 0.1% of the total genome, or 3 million bases, differs between individuals. It is becoming clear that these differences are involved in disease onset, chronicity, and drug efficacy.

Especially in cancer, the response rate to drug treatment differs depending on the genetic differences between cancer cells. For example, although the response rate to standard treatment with drugs is 27.5% [1] in Japanese patients with advanced non-small-cell lung cancer, the response rate increases dramatically to 76.4% [2] in patients with epidermal growth factor receptor variants. Additionally, many molecular-targeted drugs that target overexpressed proteins or those with driver mutations have been developed. It is expected that the optimal drug for patients with cancer can be selected using the presence or absence of somatic variants as an indicator. It has also been reported that the risk of developing various diseases, such as lifestyle-related diseases, Alzheimer's disease, intractable diseases, and cancer, differs depending on the genotype. Thus, "genomic medicine," which can be used for the optimal diagnosis and treatment of a disease based on the patient's genomic information, has begun to be implemented in clinical settings to realize precision medicine.

In genomic medicine, genomic variations detected by DNA sequencers are clinically interpreted based on the patient's background and the vast amount of existing knowledge; then, diagnosis and treatment decisions are made. This interpretation process is referred to as "curation," which requires the aggregation and comprehensive understanding of an enormous amount of information. Although the cost of genome analysis itself is now less than 1000 dollars, that of curation is nearly 100 times more expensive, which is one of the reasons why the use of artificial intelligence (AI) is required. In this chapter, we will introduce the application of AI to genomic medicine, focusing on the following four topics:

1. Classification of genomic variation
2. Interpretation of variants using natural language processing (NLP)
3. Diagnosis (phenotyping)
4. Proposal for optimal drug treatment

Classification of Genomic Variation

A genomic variant is different from a reference sequence at a chromosomal position. Experimental functional validation is required to determine how a variant affects molecular processes. However, with the vast number of variants detected, it is difficult to identify the effects of all of them. Therefore, we can make predictions for de novo genomic variants using AI and the life science/medical knowledge available.

Variants in the Coding Region

Proteins are produced, through transcription and translation, based on the genetic information stored in DNA. After transcription, the region of mRNA that is the target of translation is called "the coding region." For the process of translation, each amino acid that constitutes a protein is designated by three bases (a codon); multiple codons can produce the same amino acid. The amino acid designated by the codon may change because of a change in one of the bases, called a non-synonymous substitution (missense variant). Many computational methods have been developed to predict the relationship between the molecular function of a missense variant and disease.

Various features have been utilized to predict the impact of variants on molecular function. In particular, sequence conservation in homologous sequences and the physicochemical property of protein structure are often used. These features can be used as descriptors in machine learning for more accurate prediction, such as PolyPhen2 [3] using naive Bayes classifiers, MutationTaster [4], and MetaSVM [5] using support vector machine (SVM) [6].

Furthermore, the ensemble (meta-prediction) method, which integrates the scores of each method to make predictions, has shown good accuracy. The first proposed ensemble method, CONDEL [7], uses linear classification to make predictions based on the weighted average scores from five different methods. Following this, many ensemble methods have been developed. REVEL [8] and ClinPred [9] are two examples of successful prediction tools with high accuracy that use random forests. REVEL is also recommended in guidelines for hearing loss [10]. Combined annotation-dependent depletion (CADD) has been claimed to be useful for the diagnostic classification of rare diseases [11]. CADD is an ensemble method that uses logistic regression (version 1.0, SVM-based) and predicts the impacts of variants based on approximately 60 prediction results, including those based on conservation, epigenetic modification, functional prediction, and genetic context [12]. DANN is an extension of this model using deep learning [13].

It is difficult to determine whether molecular functions are genuinely unaffected by a missense variant. Therefore, PrimateAI [14], published in 2018, sequenced six nonhuman primate species and constructed a dataset that shows that most commonly retained missense variants are clinically benign in humans. A deep neural network model trained on this dataset predicted variants associated with rare diseases with high accuracy and detected novel variants associated with intellectual disability. This primate dataset holds great promise for the interpretation of variants of uncertain significance.

Many of the prediction scores of these tools have been published in the dbNFSP database [15].

Epistasis refers to the interactions between different gene loci that affect a single phenotype. Several prediction models based on epistasis have been developed. For example, EVmutation [16] quantifies the effect of multiple mutations on multiple sequence alignments (MSAs) by evaluating the interdependence of amino acid residues between positions using a stochastic model. The validation tests showed that this method can predict the effect more accurately than the method that evaluates variants individually.

EVmutation can evaluate the cooperativity between mutant pairs. It has been extended to a deep generative model called DeepSequence to evaluate higher-order dependencies [17]. In DeepSequence, a variational autoencoder (VAE) is constructed as a generative model with evolutionary statistics obtained from MSA as latent variables. It can predict the effect of variants better than the pairwise model. Various prediction methods using protein sequence generation models have been proposed, including methods using VAE [18–20] and generative adversarial networks [21, 22].

Variants in the Non-coding Region

Non-synonymous variants predict functional consequences at the protein level. Regions that are translated into proteins account for less than 2% of the human genome, and most of the human genome (98%) is composed of non-coding regions that are not translated into proteins. The non-coding regions play a significant role in gene regulation, and some variants in these regions have been reported to be associated with disease [23–26].

The non-coding regions include intronic and exonic splicing enhancers, silencers, insulators, and DNA interactions that influence gene splicing. Thus, it is not easy to identify the effect of a variant on the non-coding region because of its complexity.

Among non-coding variants, many variants in the regions involved in splicing have been detected. Splicing is the process of combining the exon regions of the mRNA precursors transcribed from DNA, excluding the regions that are not involved in determining the amino acid sequence of the protein, called “introns.” One-third of the alleles responsible for hereditary diseases are believed to alter the splicing process [27].

Various methods have been proposed to predict the effects of splice variants. SpliceAI [28] employs a deep neural network architecture consisting of 32 dilated convolutional layers. It utilizes a long window size (10 kbp) and can

predict the effect of a splice variant directly from exon-intron junction sequence data.

Deep learning-based sequence analyzer (DeepSEA) [29] is a multitask hierarchically structured convolutional neural network (CNN) trained on large-scale functional genomic data. It directly learns a regulatory sequence code from large-scale chromatin-profiling data, including data on transcription factor binding, DNase I sensitivity, and histone-mark profiles, and is able to predict the effects of a non-coding variant on these regulatory elements. Utilizing the DeepSEA framework, some non-coding variants have been identified as candidates related to autism spectrum disorder onset [30]. The ExPecto algorithm [31], an extension of DeepSEA, can predict the tissue-specific transcriptional effects of variants from a genomic sequence.

Interpretation of Variants Using NLP

The American College of Medical Genetics (ACMG) guideline for the clinical interpretation of variants has been referred to worldwide for monogenic and other genetic diseases [32]. This guideline was jointly published in 2015 by the ACMG, Association of Molecular Pathology, and College of American Pathologists.

It evaluates multiple pieces of information related to a variant's pathogenicity according to the strength of the evidence and synthesizes the obtained evaluations to determine the final pathogenicity. This guideline allows for a more objective and accurate evaluation.

Some of the information used in the guideline, such as allele frequencies in a population or predictive scores from the tools described above, can be easily obtained from databases and other sources. However, other information, such as functional analysis, case reports, and household information, which is strong evidence of pathogenicity, is often only basically described in the literature and electronic health records (EHRs). Therefore, it is necessary to survey the literature to obtain these evidences.

This evidence search requires considerable time and effort. To search medical papers, a

string-searching algorithm, using relevant keywords as the input, can be used. Currently, the relevant papers must be identified among a vast number of candidate papers that match the keywords. Then, the portion of text that contains the desired information must be located. As more than 200,000 cancer-related papers are published annually, this is a difficult and time-consuming task.

There are high expectations for AI to conduct an efficient evidence search. In an AI-based evidence search, NLP techniques are used to extract genes, drugs, and diseases using entity recognition, targeting the abstracts or full texts of articles. The next step is to extract the relationships between the tagged entities. At this time, a vast number of specific dictionaries and corpora are required to handle technical terms. For this reason, curation is often conducted by corporations and large groups.

The Clinical Interpretations of Variants in Cancer (CIViC) database provides information on all types of variants in cancer and their biological and clinical interpretations (<https://civicdb.org/>). CIViC is unique because it is an expert-crowdsourced knowledge base with researcher (user) participation [33].

More recently, the CIViCmine project has been implemented to improve the efficiency of the curation process. In this project, an information extraction method was developed to obtain evidence on cancer biomarkers that had not yet been aggregated in the knowledge base [34]. Cancer type, gene, drug, and specific evidence type (diagnostic, predictive, predisposing, or prognostic) were extracted from the PubMed Central Open Access subset. As a result, 87,412 gene-cancer associations with clinical relevance were identified. The curators evaluated the obtained biomarkers based on accuracy, usefulness, and necessity, and 73% of the biomarkers were evaluated as useful.

Bidirectional Encoder Representations from Transformers (BERT) [35] is a pre-training language representation method that excels in an array of NLP tasks. Domain-specific BERT models have been released, such as SciBERT [36] for scientific text, BioBERT [37] for

biomedical text, and PubMedBERT for biomedical NLP [38]. As the validation of PubMedBERT has shown that domain-specific models are useful for biomedical NLP tasks, it will be possible to use them for highly accurate information extraction in the future.

Diagnosis (Phenotyping)

The purpose of genomic medicine in clinical practice is to diagnose and predict disease risk. For a long time, it has been believed that facial features and expressions show signs of various genetic diseases, and they are expected to be utilized as diagnostic tools in the medical field. However, because of the wide variety of genetic disorders, it has not been easy to accurately link a disorder with a human facial feature or expression.

DeepGestalt [39] is a CNN-based model that can detect genetic diseases from face pictures with high accuracy. DeepGestalt is trained with approximately 17,000 face pictures of patients with more than 200 genetic diseases and predicts candidate genetic diseases that they may have. The evaluation results showed that accuracy for correct disease was present among 10 predicted candidates in 90.6% of cases (top 10 score), among 5 candidates in 85.4% of cases (top 5 score), and among 1 candidate in 61.3% of cases (top 1 score). In several experiments comparing these answers with those of medical specialists, the diagnostic accuracy of DeepGestalt exceeded that of the human.

PEDIA [40] is an SVM-based phenotype prediction model that combines CADD scores for exome variants and scores for symptoms as features in addition to the DeepGestalt scores described above. This strategy achieved higher accuracy than DeepGestalt alone (86–89% top 1 score) in 679 individuals with 105 different monogenic disorders.

To predict genetic diseases based on phenotypes obtained from EHR data and other sources, Bastarache et al. [41] defined phenotype risk scores, named PheRS, by mapping the clinical features of monogenic diseases to phenotypic information obtained from EHRs. Although this

score is simple, it can discriminate monogenic diseases using phenotypic information with high accuracy. Furthermore, by applying this method to large-scale genomic data, they successfully identified rare variants associated with hereditary diseases that have not been previously recognized.

These reports indicate that genetic features in phenotypic information can be identified using AI. Thus, there is a growing interest in using AI to diagnose genetic diseases based on phenotypic information.

Currently, the use of AI to extract useful information for diagnosis from the results of genome analysis is being investigated on a large scale in many countries. Additionally, for hereditary diseases, such as Mendelian genetic diseases, research on the use of AI to predict pathogenicity and disease risk [42] is being conducted.

For common complex diseases, the polygenic risk scores (PRS) have been widely studied for risk prediction (stratification). The PRS reflects the genetic risk of developing a disease by combining the genotype information of many single nucleotide polymorphisms (SNPs) and has the potential to screen (stratify) people at high risk for a specific disease. The PRS has generally been derived using only summary statistics from genome-wide association studies (GWAS).

Recently, it was reported that breast cancer risk is better predicted from the large-scale data of the UK Biobank using the penalized regression model than using conventional methods [43]. A study predicted the risk of diseases, such as heart attack and diabetes, from the same biobank data using Lasso [44]. This study reported that a higher area under the curve can be achieved by considering more data, such as sex and age, and adding SNP data. In this context, a computational framework for PRS calculation has been developed [45].

However, all of these studies were based on linear regression models and limited to association analyses. To elucidate the complex pathogenesis of multifactorial diseases, it is necessary to consider the combination of multiple variants and the patient's background, such as lifestyle. In the future, the discovery of potential mechanisms from complex interactions is expected using AI

to consider a large number of genetic factors, environmental conditions, and disease phenotype data that are being accumulated.

Proposal for Optimal Drug Treatment

Genomic medicine aims to stratify patients for optimal treatment based on their genetic background. Various deep learning approaches have been developed for optimal drug treatment, especially for cancer.

Several large-scale anticancer drug screenings have been conducted, and the results have been published in public repositories. In particular, projects such as Genomics of Drug Sensitivity in Cancer (GDSC) [46] and Cancer Cell Line Encyclopedia (CCLE) [47] are often used to predict drug sensitivity in cancer. CCLE and GDSC provide genomic data, including somatic variant, copy number variation, and mRNA expression data, to characterize cancer cell lines.

DeepDSC [48] uses a stacked deep AE for feature extraction from gene expression data. Then, precomputed Morgan fingerprints for the compounds are combined with the gene expression features. These are finally used as inputs for the fully connected network model, and the model predicts drug sensitivity (half-maximal inhibitory concentration [IC_{50}]).

MOLI [49], a multi-omics late integration method based on deep neural networks, uses gene expression, copy number, and somatic mutation data as inputs. For each data type, a distinct encoding subnetwork is constructed, and the features are extracted. The obtained features are integrated and input into the final subnetwork to predict drug sensitivity. Validation has shown that MOLI is useful for the use of multiple omics data, and a more accurate prediction can be achieved by integrating different data types after representation learning.

DeepDR [50], by Chiu et al., enables transfer learning by reusing parts of a network trained on other datasets. They prepared encoders that were trained on the Cancer Genome Atlas tumor data ($n = 9059$) in the Genomic Data Commons Portal [51] and performed feature encoding for gene

expression and somatic mutation data from GDSC and CCLE. The two subnetworks were combined with a five-layer feed-forward neural network to predict the IC_{50} . Although it does not utilize compound information such as fingerprints, using pre-trained AEs, it achieves more accurate predictions than linear regression models or SVM.

The above models were combined into a single network for prediction. However, it has been reported that the combination of several independent machine learning models can slightly improve the accuracy of drug response prediction [52].

CDRScan [53] separately constructs five CNN models (each called a base model) and uses them as an ensemble to achieve highly accurate and robust predictions. Four of the five base models have a two-step convolutional architecture, in which each mutation and compound datum is separately convoluted. These two convoluted features are merged (called “virtual docking”), and convolution is applied again. The final model predicts the IC_{50} values. The validation results confirm the usefulness of the proposed architecture, and that the two-step convolutional model is superior to the ensemble approach. However, in terms of robustness and generality, the ensemble approach may be more useful.

In the treatment of cancer, acquired resistance mutations often result in decreased efficacy. For this reason, it is common to administer two or more drugs in combination. Several computational methods have been developed to predict drug synergy.

DeepSynergy [54] is the first to use deep learning to predict the effects of drug combinations. DeepSynergy uses the chemical descriptors for drugs and genomic information of the cell line (gene expression profile for the untreated cell) as inputs to predict drug synergy. To train the model, the developers utilized large-scale oncology screening data produced by Merck & Co. [55] and omics data from GDSC. The Merck & Co. dataset comprises 23,062 samples; each sample consists of 2 compounds and a cell line. It covers 583 distinct combinations, and each was tested against 39 human cancer cell lines derived

from 7 different tissue types. DeepSynergy performed well on validation data. However, the authors pointed out that, as with other methods, it is difficult to predict the interaction of cell lines and compounds that are not included in the training dataset.

Xia et al. [56] utilized more diverse omics data and constructed individual encoding subnetworks, such as the drug sensitivity model described above, to predict combination effects. The model was trained on the large National Cancer Institute-A Large Matrix of Anti-Neoplastic Agent Combinations (NCI-ALMANAC) [57]. The NCI-ALMANAC consists of the therapeutic activity of over 5000 pairs of Food and Drug Administration-approved cancer drugs against a panel of 60 well-characterized human tumor cell lines (NCI-60). The model's input data types are drug descriptors, gene expression, microRNA, and proteomics data. Encoding subnetworks for each input data are learned, and the final prediction subnetwork estimates the growth inhibition value for each drug combination and cell line. Their model showed high performance in the fivefold cross-validation of the dataset. However, as discussed with DeepSynergy, the prediction performance of unknown datasets has not been shown.

Although they did not use genomic profiles, Jiang et al. [58] utilized graph convolutional networks (GCNs) to predict the effects of combinations on each cell line. They constructed a multimodal graph for each cell line using a drug-drug synergy network, drug-target interaction network, and protein-protein interaction network. The constructed multimodal graph was used as the input for the GCN, and the GCN model predicted cell line-specific drug combination synergy.

Here, we have introduced AI approaches to cancer genomics as an optimal drug selection method based on genomic profiles. Moreover, in terms of genomic drug discovery (the development of optimal drugs based on the genome), various major pharmaceutical companies have commenced collaborative research and development on AI. For example, GlaxoSmithKline has invested in the consumer genetics company

23andMe, utilizing the datasets they hold to develop drug targets with AI.

Summary and Future Implications

This chapter has introduced the applications of AI in genomic medicine by addressing the classification of variants, efficiency of curation, and drug selection based on genomic background. The mechanisms of genomic aberrations in many diseases are still unclear, and research is advancing at an ever-increasing pace. In this section, we will discuss the challenges of using AI in genomic medicine.

The first is the amount of data and bias involved. It is necessary to consider genetic divergence in the datasets used for AI training. Most of the genomic information accumulated so far is biased toward the Western population. For example, DeepGestalt has shown low accuracy in the identification of Down syndrome in individuals of African descent compared with those with European ancestry [59]. It has also been reported that PRS prediction in GWAS analysis is prone to uneven performance owing to ethnic group bias in the training data [60].

Additionally, there is limited clinical information on most of the shared variant data. For accurate clinical interpretation (discrimination), it is necessary to use detailed clinical and patient background data as training data. Currently, large-scale biobank cohorts, such as the UK Biobank [61] and the All of Us Research Program [62], are being promoted globally. By utilizing these data, learning data can be made more enrich and reliable. AI is expected to be more accurate and useful in clinical practice in the future.

The second issue is related to ethical issues. As mentioned above, sharing detailed data is essential for the development of a more beneficial AI. However, the amount of detailed genomic and clinical information that can be shared is limited because of restrictions on personal information sharing. The ethical, legal, and social implications of data sharing have been discussed in many countries. The Global Alliance for Genomics and Health, an international community

established to promote the sharing of genomic and clinical data internationally, discusses technical and ethical issues in data sharing. In terms of data utilization in AI algorithm development, the authors proposed data visiting [63], in which researchers apply their algorithms to large-scale studies and clinical cohorts instead of downloading shared data. To this end, discussions on standardization for interoperable and federated genomic and clinical data are underway.

The final topic we will discuss is AI interpretation. The use of AI on vast amounts of data is expected to reveal the latent mechanisms of disease. For clinical application, the interpretability of results is essential because of the high risk of applying predictive results. AI is often described as a black box because the process of making predictions is not visible. It is necessary to clarify the learning process to interpret the prediction results. In deep learning, techniques for visualizing the learning process have been developed. Practical approaches have been proposed to overcome image discrimination problems [64]. However, complex interdependencies exist between the genome and disease; thus, accurate AI output interpretation becomes very difficult [65].

However, currently, techniques are being developed to extract the factors involved in the differences between populations by utilizing Bayesian networks that estimate causal relationships. This technique makes it possible to visualize the crucial factors and is expected to be useful in interpreting interactions [66].

Many methods described in this chapter are still in the research stage, and only a few methods have been put to practical use. Additionally, AI predictions can only be used as a reference for clinical applications. Some AI settings, such as thresholds in prediction, require the judgment of researchers with domain knowledge. Moreover, it is also essential to understand each algorithm's habits and methods to correctly interpret the results. A strong collaboration between AI development engineers and clinical healthcare professionals will become even more critical in the future to apply AI in medicine.

Abstract

Stem cell therapy displays various applications in biomedical fields in transplantation and treatment of neurodegenerative, cardiovascular, and cancerous diseases. The current understanding of the development of artificial intelligence (AI) contraption such as machine learning and deep learning is useful in many of the healthcare challenges like limited accuracy, detection, and identifying the nature of biological molecules. This review article focuses on the insights of applications of AI in the nature of stem cells and regenerative medicine, recognition of stem cell earlier to differentiation, characterization of stem cells employing

mathematical models, and estimation of toxicity related to stem cell transplantation. The reduction in complexity and costs by use of AI techniques for enhancement of clinical trials for stem cell and gene therapies by treating patients with detailed planning, forecasting clinical results, and maintaining the patients, applying to new outcomes from input data. The application and modern approach through digitalization by use of AI system for stem cell therapy and regenerative medicine play as an essential tool in highlighting the potential for improvement in fields of medicines in the future.

Introduction

Artificial intelligence (AI) is the capability of a system to interpret data, acquire the learnings from data, and use the well-read data to complete the specific goals using flexible adaptation [1]. It is a permutation of deep learning (DL) and neural networks (NN) wherein the computational power mimics the functioning of the human brain by simplifying complex tasks. DL and computer vision, also known as Fourth Industrial Revolution Technologies, are key elements for the upcoming modern world [2]. Some of the convolutional neural networks (CNN) in medical and healthcare for diagnosis and treatment were studied for comparing human and AI performances and suggested “man with machine” approach [3]. AI shows a wide range of applications in health care and medicines like hematology, neurology, cell biology, oncology, cell therapy, and ophthalmology. AI tools also

reported improvement and development in hematopoietic cell transplantation (HCT) for pre-transplantation, post-transplantation, and grafting. Similarly, creating algorithms via AI to predict the risks involved in developing adverse events and assist clinicians in making healthier decisions leading to improved patient’s quality of life [1, 4]. AI displays ability to collect large data from healthcare systems, known as “big data” with help of different data bases like National Health and Nutrition Examination Survey Database, Genome Wide Association Studies, United Network for Organ Sharing, etc. AI provides risk assessment, general prognosis, correlating risk parameters with the disease condition, as well as clinical intervention strategies [5]. The application of AI for analysis of pluripotent stem cell (PSC)-derived colonies for overcoming the challenges like a time-consuming process, errors, and training-dependent that occur while manual identification leads to enhanced potential with greater accuracy and minimum errors in biomedical field. Stem cells (SC) show the ability of self-renewal division and produce two daughter cells wherein one cell undergoes final differentiation and the other one acquires the self-renewal process. The main types of stem cells are embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs), and adult stem cells (ASCs) where ESCs display the ability to differentiate into ectoderm, endoderm, and mesoderm germ cell layers like hematopoietic stem cells (HSCs), mesenchymal stem cells (MSCs), and neural stem cells (NSCs) [6]. The current technologies using AI serve immunohistochemistry and cytogenetics by phenotypically and genotypically characterizing plasma cells. Further, microfluid-assisted single-cell technology helped in the innovation of cancer stem cell subclonal evolution by developing the spatial distribution of quantitative subclonal measurement of multiple myeloma via AI-Med algorithms. Therefore, artificial intelligence-based integration of genome, epigenome, and pathological measurements are used for targeted therapy in the treatment of cancers (Fig. 1) [7]. Also, the molecular and cellular level tissue dynamics are easily obtained by using a three-dimensional computer model for developing and analyzing the

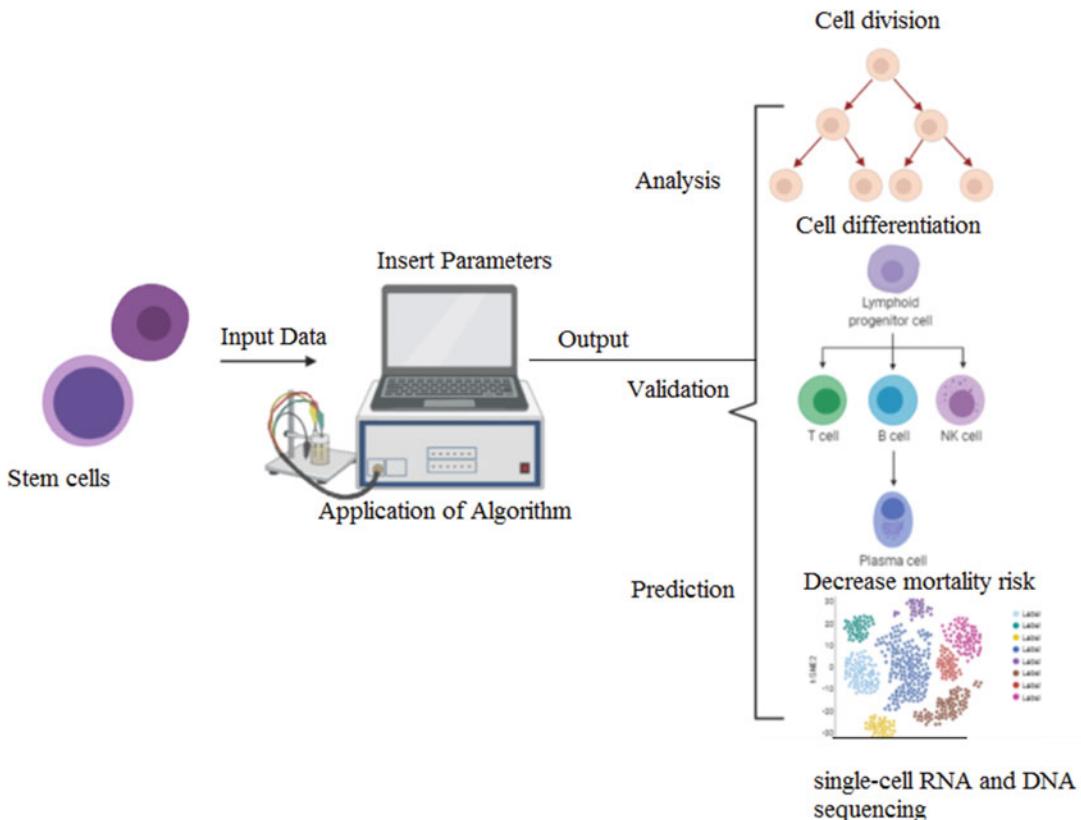

Fig. 1 AI approaches used in prediction, validation, and analysis of stem cells

hypothesis on mutations in the cells, identifying competitor stem cell and signaling pathways while activating intestinal tumor genesis. The multi-scale in silico computational model (Notch and Wnt signaling) serves as a tool for optimizing study designs used in tissue regeneration and tissue dynamics in the gut [8]. Similarly, the mismatching of the donor and acceptor specimen in transplantation leads to high level of acceptor rejection. The replacement of bronchoscopy with AI-driven techniques on chronic lung allograft dysfunction (CLAD) helps in forecasting immune-mediated allograft damage and optimizing reproducible better outcomes after lung transplantation by pulmonary diagnosis serving as next-generation tool for converting paradigm from “Detect” to “Detect, Quantify, and Predict” [9]. Stem cells display wide range of applications in treatment of various conditions such as diabetes, vision impairment, infertility, HIV,

Parkinsonism, osteoarthritis, etc. Currently stem cell therapy also showed potential in treatment of SARS-CoV-2-related diseases like pneumonia and other lung injuries due to virus leading to significant impact to save life of patient [10, 11]. Also, certain mesenchymal cells are used in organ transplantation for auto-immune disorders. The umbilical cord mesenchymal cells in combination with disease-modifying antirheumatic drugs (DMARDs) showed effective treatment in patients suffering with rheumatoid joint inflammation [12]. Further, the regulation of cultured stem cells by mechanical signals and bioactive agents displays liposomal-based stem cell therapy for multimodal cancer treatment [13]. The multidisciplinary computational immunobiology-based predictive models disclose mechanisms and pathways for organ transplantation through proteomics, genomics, protein modification, analysis of gene expression,

development of statistical models, identification of gene networks, host-pathogen interactions, and bioinformatics. The applications of such high-end multi-scale models in facilitating immune response and other cell-related discrete events like molecular interactions and Van der Waal forces in the proteins provide a next-generation tool for antibody editing, tissue regeneration, and peripheral immune regulation [10, 14]. Bioinformatics analyses and functional validation, a type of AI neural network, defined the transcriptomes of progenitors present at various stages of embryo such as erythroid-, megakaryocyte-, and leukocyte-committed progenitors, as well progenitor markers and membrane markers like CD44, CD326, ICAM2/CD9, and CD18. Also, single-cell RNA sequencing with protein expression analysis and CITE sequencing helped in identifying transcriptional factors and molecular pathways of in vitro-generated HSC-like cells from the fetal liver and comparing in vitro-generated progenitors with in vivo-produced cells, exploring improvement in the production of SC in the future [15].

Implementation of AI in Stem Cell Progression

Machine Learning

Machine learning is a branch of AI where the algorithms are automatically learned by the models on basis of examples and predict the response to a treatment constructed on different parameters related to the patients, drug, biological cells, etc., overtaking regression methods and attaining accuracies with enhanced and easy interpretation of obtained results [16]. The combination of AI and ML aids in problem-solving, indulging different languages, distinguishing various images, voices, and additional “smart” tasks. The flexibility of machine learning is better than the typical statistical method and is better suited for predictive problems providing advantageous technology for healthcare systems [13, 14]. The different algorithms of machine learning are applied in the determination of cell morphology, graft transplant, and molecular imaging cardiac

tissue contractility. Moreover, ML shows a wide range of applications in the systemic analysis of the method, optimization, and diagnosis of disease conditions with higher accuracy and precision leading to better medical decision-making [11, 12]. The three types of machine learning model mainly used are 1) supervised learning where the predictions are revealed by labeled data set, 2) unsupervised learning wherein the patterns and clusters are identified by the algorithm, and 3) reinforcement learning where the sequences are detected on basis of trial error longitudinal from data. These models are applied for prediction of survival of allogeneic stem cell transplantation, gene expression profiles, and administration of vasopressor for critically ill patients [17]. New screening techniques were developed by utilizing machine learning for the improvement of recapitulation of human cardiac functioning and responses to drug using human pluripotent stem cells. Further, the comprehensive analysis of 17 parameters and contractility on human pluripotent stem cells-cardiac tissue strips exposed to drugs like norepinephrine, ramipril, flecainide, and lisinopril was measured by automated drug classification for predicting the mechanism of anonymous cardioactive drugs [18]. The machine learning-based analysis of stem cell donor availability associated with age, gender, and other characteristics was established for predicting the potential donors employing the receiver-donor curve to reduce the time for transplantation. The National Bone Marrow dataset was separated into two: training accuracy set and testing accuracy set using domain-specific knowledge [19]. A high risk in prediction mortality associated with hematopoietic stem cell transplantation is observed, and the use of the ML in silico computational method helped in identifying the HCT-comorbidity index. The optimized ML model was developed with a type of algorithm, data sets, and number of variables that resulted in 6 ML algorithm models including 24 variables filtered down to minimum variables and compared accordingly to the AUCs. The prediction of morbidity via ML technology showed more efficient results as it overcomes the limitations like lengthy methodology, medical procedures,

and cost [20]. Also, the mortality rate of 55% in patients was due to sepsis during hematopoietic stem cell transplantation. Therefore, the prediction of sepsis was achieved 41.5 h beforehand on 313 patients using ML survival random forest model to prevent the patient suffering at the time of engraftment admission for autologous and allogeneic HCT. The different variables like patient's blood calcium, ferritin, creatinine level, glucose, lymphocyte percentage, WBC count, heart rate, platelet, body temperature, blood pressure, and respiratory rate were observed, and differentiating patterns between septic and the non-septic patient were determined to prevent organ damage due to sepsis [21]. Another ML model is known as one-class logistic regression to remove the transcriptomic and epigenetic specific set from PSC and predict biological mechanisms from oncogenic cells in the tumor microenvironment. Novel targeted therapies developed from the stemness prediction by revealing data molecular heterogeneity. The results showed DNA demethylation stemness index, correlation of mRNAs and mDNAs, and cancerous undifferentiated cells further helping in mutations in genes representing oncogenicity and analyzing the stem cell-based immunogenic therapy for the safety of the patient [22]. A supervised ML system based on SimFSC software in combination with voltage-sensitive dyes for classifying the chronotropic drug (propranolol and isoproterenol) effects on cardiomyocyte by using algorithm, resulted in predicting the membrane polarization occurring due to drugs on the cardiomyocyte [23]. Single-cell molecular-based technologies established a method to provide HSC profile model wherein the single-cell transcriptomes were detected from the murine bone marrow by gene expressions. The highly variable genes through protein-coding were divided into positive and negative significant correlation data sets known as "Molo" and "Nomo," respectively. This data represented the functionality and transcriptional changes and genetic perturbations and provided new insights into disrupted hematopoietic situations [24]. The unsupervised type of ML technique known as K-means++ was used in cell-based therapy for quantification of magnetic

particle imaging. The application of canonical algorithm to in vitro (VivoTrax-labeled islets), in vivo (labeled islets under the kidney capsule), and ex vivo (excised kidney grafts) data using islets and mouse models for segmenting the regions of interest in formed images and quantifying iron (0.5–7.5 µg). The 3D phantom imaging and optimization of the algorithm with intra-class correlation coefficient and inter-rater reliability validation followed by statistical analysis (ANOVA) showed higher accuracy in low time. Further, this methodology is also applied to iPSC or chimeric antigen receptor T cells for analysis, magnetic imaging, quantifying uptake of nanoparticle monitoring post-transplant graft loss, fluctuation of transplant cells, etc. and serving potential in clinically transplantation therapies for type 1 diabetes [25].

Computational Methods

The interconnected molecular network in the cells is known as "systems biology." The assessment of high throughput of biological complexes, molecular-level interactions, DNA variants, gene-level modification, and recognizing the role of biomolecules is feasible via computational modeling and simulation models (Fig. 2). The combination of computation modeling-based AI in cancer, diabetes, cardiology, and neurology helps in better treatment of disease and understanding of health care [26]. A computational cell kinetics model for understanding the intercellular signaling networks and alteration of lineage specification in early progenitor cell culture population also known as HSC lineage engineering was used in a study on the femur and tibia bone marrow of the female C57BL/6 mice, wherein STELLA and Berkeley Madonna computational models were used to determine the high-impact parameters useful in cell expansion and transplantation. The cell kinetics were observed on four types of cell-secreted biomolecules such as differentiation stimulators and proliferation stimulators and inhibitors for identifying cell differentiation rates and plan experimental designs [27]. Similarly, a study demonstrated a full automatic computer-aided

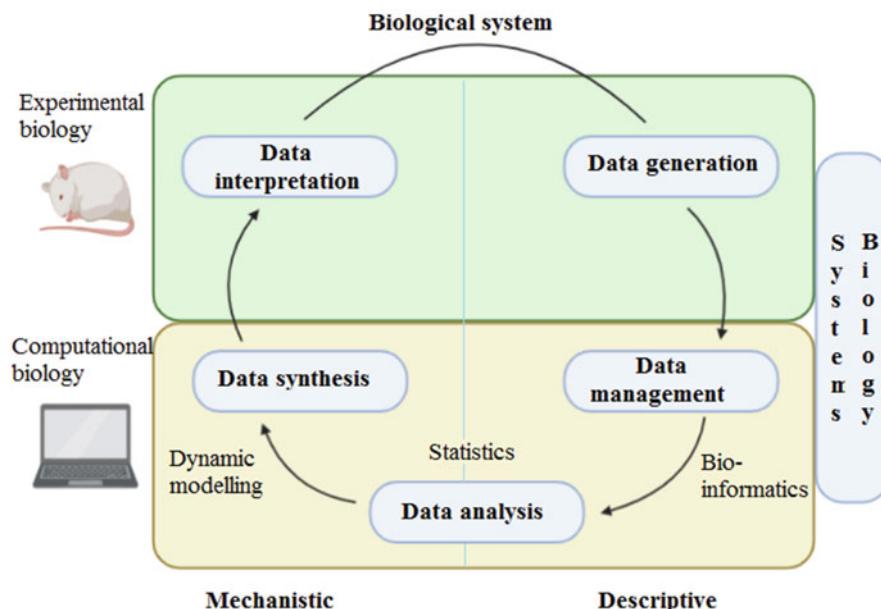

Fig. 2 Computational approaches in the biological system

clustering system for finding relations between cell differentiation and morphological and structural changes in phenotype. A computer model, known as a multi-stage Content-based Microscopic Image Analysis (CBMIA), was applied for segmentation of images, extraction, selection, and fusion techniques. The original microscopical image of multiple stem cells was introduced to Improved Supervised Normalized Cuts (ISNC) segmentation algorithm leading to higher similarity (92.4%), enhanced specificity (96.0%), and greater accuracy (107.8%). The three algorithms known as normalized cuts, supervised normalized cuts, and improved supervised normalized cuts were functionalized, and Hu and Zernike moments (most robust characteristics) are selected and applied to the k-means clustering method revealing the enhancement in the cell description on phenotypic level of the stem cells [28]. Another study displayed the use of the computational method and mathematical modeling approaches to defining underlying processes and the fate of ESC in mouse cells. The three transcriptional factors, namely, Oct4, Sox2, and homeobox protein NANOG were used to measure the gene expression in human and mouse ESC. The identification of network components and topology by

descriptive, dynamic modeling, and explorative statistics for the analysis of gene expression was carried out by using Boolean network approaches and Bayesian network model. Different algorithms like gene regulatory network, K-means clustering (clustering algorithm), multi-scale model (mathematical framework), ordinary differential equations (mathematical equation), principle component analysis (statistical method), support vector machine, stochastic differential equations, etc. are applied for identification of topology, several genes, changes occurring in genes and cells, and behavior variability and interactions [29]. According to a study, the migration of hematopoietic stem cells inside the bone marrow is proposed by the use of a mathematical model where in vitro HSCs were simulated with a finite element tool Gascoigne resulting in improvement of the solution of an accurate chemotaxis model with nonlinear boundary situations. The HSCs formed in the bone marrow migrate to the blood periphery and differentiate; therefore the analysis and study of transplantation would be helpful for issues such as forecasting the consequences of various treatments for specific blood-related disorders and limiting the time where the patient is missing their effective

immune system [30]. A multi-parameter immunophenotyping model identified differentiation of HSC in healthy donors ($n = 10$) and determined plausible hierarchies by quantitative model selection to confirm robustness of model selection at varying levels of noise. HSC differentiation is initiated by progenitor compartments of reducing plasticity and enhancing maturity in a hierarchical order. Seven cell-type compartments were determined via computational modeling wherein there was 90% differentiation of multipotent lymphoid progenitor into granulocyte-monocyte progenitors that were plausible. The established data of ten HSC donors were analyzed by in vitro fluorescence-activated cell sorting (FACS) process followed by Bayesian information criterion selection [31]. Stem cell therapy also showed effective treatment in HIV infections wherein, the mathematical equation-based system known as 4th-order Runge-Kutta (RK4) was applied to obtain numerical solutions graphically and transfer model to provide an enhancement in the detection and identification of CD4⁺T cells. The relationship between the SC for production of T cells and population of CD4⁺T was determined by symmetric and asymmetric self-renewal cells and differentiated cells with probability factor eventually providing global stability at the prevalent point [32]. Further, the computer-aided classification from stem cell fate analysis by quantified 2D and 3D images and improvement of accuracy and recognition via optimizing the confocal laser scanning microscope was carried out by classification protocol known as Volocity® cytoplasmic cell marker. The validated and analyzed images of hNSC progeny showed quicker (twofold) and higher strength than human-based image analysis. The parameters like object size, the intensity of color, and z-step interval are applied for quantification of different human cell lineages in combination with microscope image capture systems [33]. The determination of HSC biology in transcose-6-phosphate dehydrogenase heterozygous cats was demonstrated by using computational-simulated gene therapy through analysis of autologous transplantation studies where, the Splus statistical programming language approach with

parameters like the intensity of replication, apoptosis, and differentiation was used wherein the marked clones controlled the hematopoiesis process. Therefore, the simulated computer model showed applications in hematopoietic cell-related disorders such as sickle cell anemia, thalassemia, and myeloproliferative disorders like myelogenous leukemia, etc. with a 10% survival advantage [34]. A hydrodynamic environment in a bioreactor was described by developing a computational fluid dynamic (CFD) model wherein the determination of ESC size was correlated with eddy size. The hydrodynamics of suspension bioreactors affects cell viability, proliferation, differentiation, and pluripotency. The cell showed 95% gene expression of SSEA-1, Sox-2, and NANOG without changing the distribution pattern in various bioreactor parameters. Moreover, decrease in eddy size enhances the potential cell damage with a higher volume shear rate (40 times) thereby affecting the morphological, structural, phenotypic, and functional abilities of the stem cells. Therefore, CFD is applied in the production of large-scale stem cell culture processes [35]. A similar study conducted by using CFD on seven different scale-up parameters was used to analyze the agitation rate of the bioreactor. The model identified a constant maximum shear stress/dissipation rate required to attain the murine ESC cultured in aggregate sizes and therefore effective stem cell growth scale-up was achieved without high agitation rate by CFD [36]. A study demonstrated live camera-based stem cell tracking system for identification of variables in donor HSC (human umbilical cord mesenchymal stem cells). The improvement in cellular activity was achieved by applying automated high-throughput time-lapsed microscopic imaging, with custom-built live automated cell imager and microscope attached to modern digital camera. Further, an environmental control system with robotic microscope stage provides parameters to be measured via time-lapsed images like cell morphology, proliferation, velocity, and fluorescence leading to analysis of bone morphogenic protein for assessing osteogenic potential by measuring the level of alkaline phosphatase in populations [37]. The analysis of motility of spermatozoa in

the testis of genetically sterile mice after spermatogonial stem cell transplantation from testicular cells of fertile donor mice by computer-assisted validation helped in determination of the sperm motility analysis technology, quality of sperm flagella motion, and three velocities such as curvilinear path, straight path, and average path. Thus, the cause for reduction of fertilization rate post-IVF was established by using computer and AI models wherein the decreased number of motile spermatozoa and the earlier reduction of the individual sperm movement characters led to increase in fertilization [38]. The HSC transplantation from the bone marrow to peripheral blood is also used for the treatment of chronic myeloid leukemia. There exists already available IT applications for the donor search process such as the German Marrow Donor Information System (GERMIS), Donor-Center's Communication Workbench (DoCCom), Search Coordinator's Communication Workbench (SeCCom), etc. used for donor management, patient administration, transplant request management, and handling communication (telematics) online [38].

Deep Learning

Deep learning is a type of machine learning wherein the neural networks mimic the neuronal network present in the human brain. The neural network involves several layers of neurons and translates input signal into output signal also known as the predictive value. The various applications of DL are clinical studies, cell imaging, genomic analyses, protein prediction, identification of end-stage hematopoietic lineage from microscope images, etc. [39]. A quality control study based on deep learning was performed on human pluripotent stem cells-derived cardiomyocytes employing CNN wherein the CNN was able to discriminate the abnormal cells within normal cell culture with mean force of 0.89 and speed of 2000 images per second. The CNN works better in ethics, speed, cost, and labor with improved accuracy, correctness, and efficient performance when associated to humans [40]. The knowledge of the topological structure and surface morphology of human bone marrow stromal

stem cells via DL neural network and laser topography displayed tissue fabrication, tissue structure, and cell signaling useful for predicting structural functionality, cell response, and cell behavior. The DL statistical probability tool developed 203 fluorescent images that assisted in revealing variations between donor cells like proliferation variation and percentage of non-responders to osteogenic differentiation and also enhanced the predictive capability of the model unlike photolithography that is time-consuming and costly [41]. Another DL-based cell motion analysis, quantitative model for identification and evaluation of cultured keratinocyte stem cell via the non-invasion method was studied in keratinocytes to address alterations. Further, Single Shot MultiBox Detector (SSD) deep learning model was applied to produce phase-contrast images of human epidermal keratinocytes wherein the velocity vector of single keratinocytes cells was observed by the quantitative estimation of behavior differences of keratinocyte by varying culture conditions. Also, automated cell tracking and clonal analysis showed unique patterns of motion leading to the identification of the stem cell colonies with velocity information of cells and without labeling of human cells [42]. Similarly, a U-Net-based algorithm was used to measure the various types of parameters affecting the formation of cells, hiPSC colony, single cells, dead cells, and differentiated cells and other parameters like shape, size, center of gravity attachments of other cells, etc. The automated cell analysis enables an average recording time of less than 1 min wherein the image provided displayed a total size of about 610 MP and each pixel denoting $1.69\mu\text{m}$. This method served hiPSCs for biomedicine applications in transplantation by assisting automated generation and cultivating high-quality hiPSCs [43]. Also, the identification of endothelial cells obtained from hiPSCs by utilizing the K-fold cross-validation based on four independent datasets was carried out by comparing with immunofluorescence staining for CD31 (marker). The blocks were inserted using phase-contrast images, and the input data was validated by network optimization using CNN leading to error analysis and improvement in performance and efficient formation of

endothelial cells (20%–35%). The data adjustment was carried out by input number of blocks (labeled and unlabeled cells), size of blocks, and fixing the ratio of targeted blocks followed by LeNet and AlexNet [44]. Furthermore, enhancement in accuracy up to 99% was observed in less than 20 min on using DL neural networks for the identification of differentiated cells from undifferentiated cells. Precision, recall, and F1 value of two CNN models (ResNet50-SA and DenseNet50-SA) were used wherein the differentiated and pluripotent stem cells were determined at various stages of the cell cycle. The CNN was also able to differentiate serum and leukemia inhibitory factor from the ESC wherein the primed biological markers FGF5, Oct6, Dnmt3A, and Otx2 were upregulated and pluripotency markers Klf4, Nanog, Esrrb, and Tbx3 were downregulated at the end of 48 h. The optimization of the algorithm was developed by using epoch also known as learning rate at each training cycle [45]. Another study reported the recognition of acute cellular rejection during lung transplant biopsies using digital pathology and AI technology. After 3349 annotations, the vascular component of acute cellular rejection was differentiated from normal alveolar lung tissue with high accuracy (95%). Therefore, the DL AI algorithm is also practiced in diagnosis and the detection of cellular rejection during transplantation [46]. Similarly, the assessment of cardiac allograft vasculopathy and progression conventionally performed by 3D OCT imaging and wall

layer quantification analysis was carried out by novel DL method for atherosclerosis. The DL CNN leave-20%-out approach was evaluated in OCT pullbacks assimilated at 1 and 12 months after heart transplantation in 116 patients wherein DL method displayed 86.3% correctness in images within 10 s when compared to manual method (1 h). The 3D bioprinting technique by using computer programs is used for gene expression in cancers, tissue engineering, as well as skin and vascular regeneration [47, 48, 49, 50] (Fig. 3).

Conclusions

The current article provides insights into various newer permutation methods in combination with stem cells to understand and mimic the mechanism of transplantation. The application of artificial intelligence with stem cell therapy provides the advantage for optimization of clinical trials, development of precise trajectories for transplantation, reduction of error, application of up-to-date technologies, and prediction of results. Integration of artificial intelligence with stem cells is foreseeable; however it is still considered a deficient technique in comparison with the conventional tools. With the growth in regenerative therapy in transplantation, innovative techniques such as XplOit, allogeneic hematopoietic stem cell transplantation, chimeric antigen receptor (CAR) T-cell therapy, bioprint, etc. proved to be effective in combination with algorithm performance. With

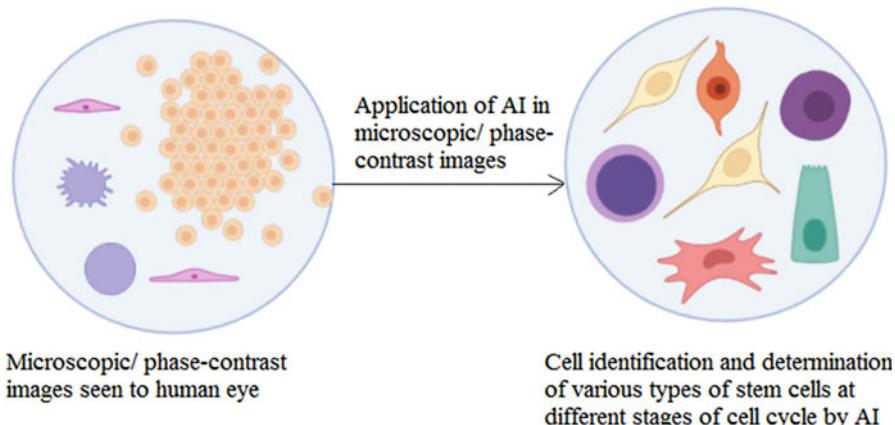

Fig. 3 Difference between microscopic images seen to human eye and via using AI

the application of the algorithm technique, stem cell therapy will be possibly able to modify the conventional transplantation therapies. Although the application of artificial intelligence in the field of stem cell transplantation acts as an alternative for the risky conventional method, predictive analysis remains a concern. Though the application of stem cells has helped to overcome such obstacles, the efficiency and safety regarding the transplantation with the help of artificial intelligence will be resolute in the near future.

Abstract

While the analysis of high-dimensional gene expression data by means of artificial intelligence (AI) has become an integral part of basic biomedical and immunological research, the great potential of this approach to substantially advance clinical diagnosis as well as medical routines has not become a reality yet. Significant advancements in both RNA-sequencing technologies and in the development of suitable algorithms for high-dimensional data, however, enabled a plethora of clinically oriented research that proposes promising concepts for systems-oriented and individualized medicine based on transcriptomic data. The blood transcriptome is of particular interest, as it is easily accessible and has proven to be a good predictor of blood and non-blood-based diseases thus making it a prime candidate to develop new powerful diagnostic approaches. The addition of concepts to the medical armamentarium, however, implicates ethical, legal, and technical aspects of data governance, which are a prerequisite to successfully integrate data-driven AI technologies into clinical routines.

RNA-seq · Transcriptomics · Artificial intelligence · Machine learning · Diagnosis · Systems medicine

Introduction

The emergence of high-throughput technologies allowing to measure vast amounts of clinically relevant data at increasingly high speed and low

cost has scientists facing data so high in dimensionality that finding patterns and relationships among the data points exceeds the capabilities of the human brain. Meanwhile, harvesting the wealth of information contained in this data is presumed to offer new opportunities in preventing, diagnosing, and treating diseases and therefore improving the efficiency of health care and promoting the concept of precision medicine. One such data source is the human transcriptome, the whole of all transcribed RNA molecules which can be accessed by different technologies (Fig. 1a). The transcriptome has been shown to be a feature space that is well suited for Artificial Intelligence (AI)-based algorithms, and especially the blood transcriptome, which has the advantage of being relatively easily accessible, turned out to be a good predictor not only for blood-based diseases such as leukemia [1, 2], but also of other diseases, infectious [3] and noninfectious, such as cancer, [4] or neuroimmunological diseases [5, 6]. AI algorithms have the potential to detect and extract the essential information from the transcriptomic feature space, a task that is too complex to be executed by a human given that it relies on high-dimensional datasets, but also too exhaustive to be phrased in the form of classical algorithms with explicitly defined rules. Instead, AI models can quickly comprehend and process a great wealth of information from high-dimensional transcriptomic data, granting substantial advantages in time-sensitive procedures such as prediction of disease course and outcome [7–10], detecting disease subtypes [11], or guide adequate medication of a patient [10, 12, 13]. Furthermore, AI algorithms have the potential to evolve based on the data they are presented and can, in

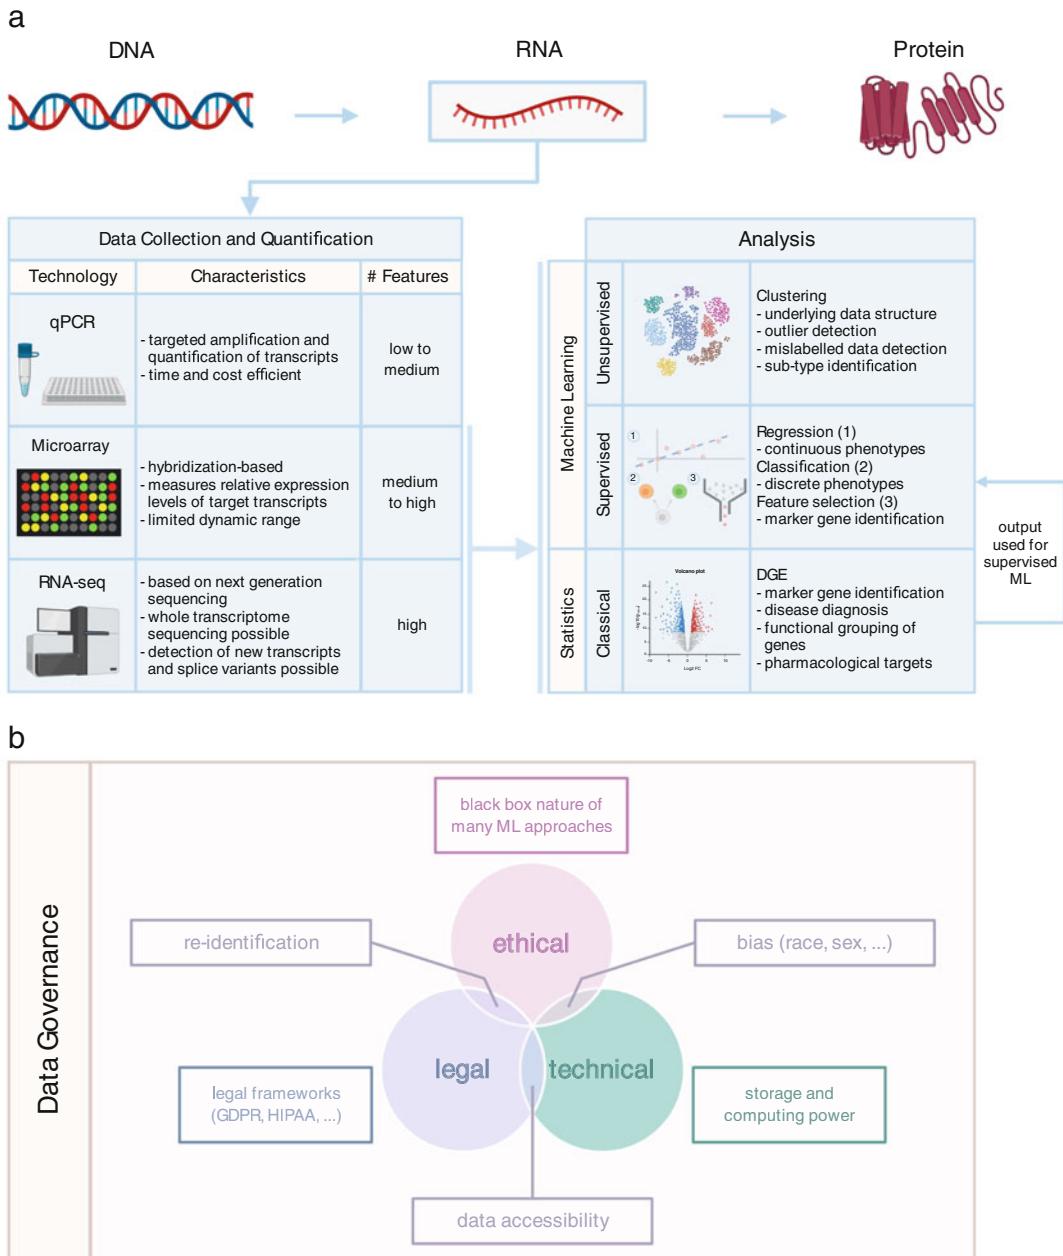

Fig. 1 Collection, analysis, and aspects for data governance of transcriptomic data. (a) Transcriptomic data represents the abundance of RNA molecules of either a selected panel of transcripts or of the whole transcriptome. The measured RNA molecules typically undergo a series of preprocessing steps (not shown) that are specific to the used protocol. Quantification is commonly conducted using qPCR, microarrays or RNA-seq methods. The

collected data is analyzed using a variety of techniques from classical statistics to machine learning. (b) Shown is a number of common issues that arise from storing and sharing transcriptomics data. Technical difficulties are mainly caused by the size of the data and the computing power required by the analytical methods. Ethical and legal issues arise due to the personal, and therefore sensitive, nature of the data

principle, continuously update and improve their predictions [13]. The speed of AI algorithms, which is unmatched by a human, could lower the costs of health care and therefore increase the amount of financial resources and medical staff available for patients in need of intensive care [13].

However, the full potential of AI-based transcriptomics to truly enhance clinical diagnosis as well as disease monitoring on a large scale is not yet translated into clinical practice and molecular diagnostics. Reasons for this include technical and infrastructure requirements that must be met at hospitals to build, train, and run models, as well as complex ethical and legal considerations (Fig. 1b).

In this chapter, we will discuss current technologies and their potential for clinical application (section “[Blood Transcriptomics in Clinics: Methods, Features, Pitfalls](#)”), different algorithms suitable for high-dimensional transcriptomic data (section “[Background on Artificial Intelligence in Biology](#)”), research development towards clinical applications (section “[Research Development Towards Clinical Applications](#)”), and important considerations in terms of data security, potential biases, and data management (section “[Ethical Considerations, Data Security and Federated Learning](#)”).

Blood Transcriptomics in Clinics: Methods, Features, Pitfalls

When translating research on transcriptomic data into AI-based clinical applications, several technical and analytical aspects need to be considered. First, the measurable feature space varies across technologies and the right method to choose is dependent on the analytical question that is being addressed. Second, downstream processing, e.g., of high-throughput RNA-sequencing data is not trivial, and standardized clinical usage of that data requires highly streamlined and reproducible pre-processing workflows which prepare the data prior to the actual prediction by AI-based methods.

Regarding the RNA features which are measured, a fundamental difference between technologies is that between a targeted approach, where a defined set of features is measured, and that of “whole transcriptome” approaches, which do not

require a priori knowledge of the features of interest (Fig. 1a).

A large body of transcriptome studies which contributed to a better understanding of disease biology are based on microarray data, which is a targeted approach to transcriptomics. Here, all RNA molecules are being converted to cDNA and labeled with fluorochrome dyes. DNA sequences complementary to the target cDNA molecules are bound to a microarray chip, to which the cDNA hybridizes. The fluorescence of the hybridized target transcripts on the chip is then measured and used as a surrogate of the transcript abundance of each target transcript. Initially, quality concerns were raised on microarray data concerning reliability and consistency [14], which led to the establishment of microarray standards, quality measures [15], and a consensus of data analysis for the development and validation of predictive models [16]. Consequently, the usage of microarray data in clinical application has been proposed for disease prediction [17–19], subtype discovery [20, 21], and subtype prediction [22]. However, the use of microarrays for accessing the transcriptome did not translate into clinics yet at a larger scale, whereas genetic microarrays to screen for chromosomal aberrations [23] and single-nucleotide polymorphisms (SNPs) [24] in patients with unspecified genetic disorders and primary immunodeficiency have become a cost-efficient standard tool.

Following more recent technological developments, microarray-based transcriptome technologies have largely been replaced by next-generation RNA sequencing (RNA-seq) protocols, which have the great advantage that they not only quantify known transcripts, but can also detect unannotated transcripts, identify alternatively spliced genes or detect allele-specific expression [25]. Compared to microarrays, RNA-seq also has a wider dynamic range of detecting transcripts, which makes it the method of choice for recent clinical transcriptomic studies. Also, with the introduction of single-cell sequencing techniques [26] it has become possible to study gene expression of individual cells, which is particularly interesting for understanding disease biology at a cellular level [27] and developing disease- and cell-type-specific predictive signatures [28].

RNA-seq protocols are manifold and can differ in the RNA species they detect. While most protocols aim at detecting polyadenylated messenger RNA (mRNA), it is also possible to investigate nonpolyadenylated RNA species, such as microRNAs, certain long noncoding RNAs, or pre-mRNA. In a nutshell, RNA is extracted and specific RNA species are being selected mostly by either enrichment of polyA-containing transcripts or the depletion of highly abundant ribosomal RNA [29]. Then, the selected RNA is fragmented, converted into cDNA, sequencing adapters are added, and the cDNA is amplified in order to construct a library for sequencing. In the case of Illumina sequencing, libraries are then loaded on a flow cell, where the cDNA molecules bind to oligonucleotides that are complementary to the sequencing adapter. Sequencing by synthesis [30] is performed with the primary sequencing output being per-cycle binary base call (BCL) files which store base calls and quality for each sequencing cycle. These are then translated into per-read FASTQ files that contain the base sequences of the library fragments, which correspond to the transcribed RNA molecules of the original specimen as well as the corresponding quality scores. In order to retain gene expression information from those fragments of sequences, they need to be mapped to a reference genome or transcriptome, depending on the application (for a detailed review see [31]). Then the relative expression level of each target feature (transcript or gene) is quantified, which results in a matrix of expression counts.

A promising alternative to next-generation sequencing protocols that use sequencing by synthesis are long-read sequencing protocols [32–34] that produce reads, e.g., in the range of 5 to 15 kb for SMRT sequencing or even ultralong (100 kb or more) nanopore reads [35]. In contrast, the maximum read length of Illumina NovaSeq 6000 is paired-end 250 bps [36]. Long read sequencing is of particular interest for applications that rely on isoform identification, for targeted sequencing of complex genomic and paralogous regions and also in particular for de novo assembly approaches [32]. This clearly illustrates that the technologies used to determine transcriptomes will have an enormous impact on further

downstream data preprocessing, data analysis, but also interpretation of the data and utility for machine learning.

Depending on the RNA-seq technology used, the amount and type of studied RNA features and based on the features that are considered during preprocessing, such count matrices can contain up to 200,000 features, which is roughly the number of annotated human transcripts, and even more if RNA-seq data is used for de novo assembly of unannotated transcripts [37]. Most current routine RNA-seq pipelines, however, aim at reducing background noise of low-expressed features before the actual biological analysis and, e.g., around 20,000 informative features are usually used for downstream analyses on the gene level of bulk RNA-seq data. Also, with decreasing costs of RNA-seq methods [38], whole-transcriptome protocols can be envisioned to become a standard tool in clinical diagnostics.

In contrast to RNA-seq and microarray application, which can both be used to generate high-dimensional datasets, quantitative reverse transcriptase PCR (qRT-PCR), a protocol which quantifies the expression of only a few target genes by amplification via the polymerase chain reaction (PCR), is considered the gold standard for the qualitative and quantitative detection of cellular mRNA, e.g., in the diagnosis of acute myeloid leukemia (AML) [39], miRNAs [40], and also genomic RNA from viruses [41, 42]. Also, RT-PCR kits are available for testing gastrointestinal, respiratory, or sexually transmitted infections. However, despite their great success in clinical applications, it has to be stated that the application of such highly sensitive but targeted protocols is by definition unsuited to detect unexpected results, with a recent example being the detection of mutations of SARS-CoV-2, which could not be detected without molecular surveillance of the viral genome [43].

Background on Artificial Intelligence in Biology

Given the magnitude and diversity of the research field, the definition of AI is oftentimes broad and unspecific. It is mostly described as a machine that

demonstrates behavior, which we would classify as intelligent, such as problem solving [44] or pattern recognition [13, 45]. A more precise distinction is that into strong and weak, also referred to as narrow, AI. Strong AI references a so-far-theoretical concept of an artificial intelligence that exhibits self-awareness and functions on the same cognitive level as the human mind. A strong AI would be able to learn autonomously and solve problems of previously unseen categories without human interference. Weak AI on the other hand is AI that specializes in mastering a specific type of task and requires a large amount of human input in the form of hyperparameter tuning and training set selection [46]. All currently existing machine learning models are of the weak type and are mostly adapted to perform tasks such as clustering of unlabelled data or pattern recognition for the use of classification and regression. The following section will specifically focus on weak AI in the context of transcriptomics.

AI Methods for Transcriptomics Analyses

Differential gene expression (DGE) is a common element in the analysis of transcriptomic data. It aims to identify groups of significantly up- or downregulated genes using statistical testing, which in the case of RNA-seq data is commonly based on a negative binomial distribution [47]. An issue that arises from the typical dimensions of RNA-seq experiments, comprising few samples but thousands of genes, is the multiple testing problem [48]. To identify differentially expressed genes, a test is conducted for each gene in the dataset, leading to a high number of expected false positives. To account for this typical issue arising from *small-n-large-p* problems, the p-values require adjustment. A common method here is the Benjamini-Hochberg procedure. The results of DGE analyses are often used as input to further statistical methods, such as testing for over- or underrepresentation of functional groups and the enrichment of gene sets or of transcription factor binding motifs. The insights are used for a vast majority of application purposes such as marker gene identification, disease diagnosis, and detection of functional gene groups or potential pharmacological targets. This classical

statistical analysis approach comes at the disadvantage of explicitly having to make assumptions with regard to the underlying data such that the correct model can be chosen. Making these assumptions is often erroneous or too simplistic and the knowledge base for the decision potentially incomplete. Among other reasons, particularly this difficulty to build an explicit model prompts the use of AI. The learning process that is involved in the construction of most AI tools is described as machine learning (ML), a model design concept that does not require explicit programming of decision rules but instead develops and improves these autonomously based on data it is provided [44]. The difference between machine learning and classical statistical approaches roots in the questions that are being asked when applying either one: While traditional statistical methods aim to find a model that explicitly describes the relationship between a set of variables, machine learning focuses on generating a model that allows for the accurate outcome prediction of previously unseen data, oftentimes without providing detailed information on the underlying model architecture itself [49].

However, classical statistical methods are by no means obsolete. They often serve as a pre-selective step to provide first subsets of genes used, for instance, in ML-based classification tasks.

The subsequently presented methods are machine learning techniques that have been recently applied in transcriptomics. These techniques can be broadly divided into supervised and unsupervised ML methods.

Supervised Learning

Supervised learning is used to build a model that receives a set of input data and based on that predicts a previously unknown output label or value. The model is initially confronted with a labelled training data set from the domain in which it is meant to predict an outcome later on. After applying the model to the data, the predicted outcome is compared to the true label of the data point. The level of discrepancy is then used to adjust the model, such that it performs better in the next iteration. This process is

repeated until convergence or until a preset prediction accuracy is reached. The final model can then be used on a data set it has not seen before to make predictions or to classify the data. If the training was successful, the model has generalized enough to accurately predict the unknown data [13].

Unsupervised Learning

Unlike supervised learning, unsupervised learning does not require training on a data set with known labels. Instead, unsupervised learning techniques attempt to group the presented, unlabeled data solely based on the data itself. The cluster labels that are assigned to the detected groups do not allow any insight into the characteristics of the data points. Unsupervised learning therefore enables the detection of patterns and outliers thereof. Since it does not rely on known labels, it allows for the detection of groups in the sample space that were not known a priori. These methods mainly differ in their definition of similarity and dissimilarity which underlie the clustering process of the sample space [50].

Feature selection

Some machine learning methods allow for the selection of a subset of features that is relevant to the task. Feature selection is especially useful in cases where not all the features are expected to be required to fulfil the machine learning task, or where the feature space is larger than the sample space, as it is the case with most high-dimensional transcriptomic datasets [51]. Here, feature selection is commonly used to address the dimensionality problems of transcriptomic data sets and to make the output human-readable and more insightful by providing a distinct set of markers that were included in the prediction or classification task [51]. Not only does this increase the amount of trust put into the model by specialists, it also allows further insight into the underlying mechanisms of the studied condition. Models that commonly do not allow the explicit extraction of features are deep learning-based models, the networks of which are too complex to pinpoint a distinct set of features used for the prediction and which are therefore often referred to as black

boxes. They are considered superior in tasks involving only very few negligible features, or where features are highly interdependent, and they therefore require a large amount of data such that the size of the sample space exceeds that of the feature space.

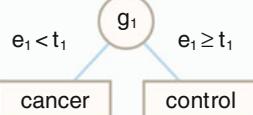

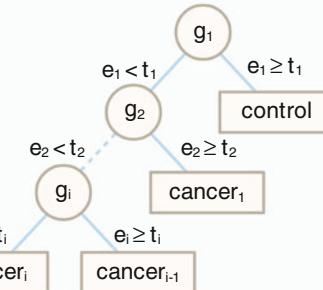

Random Forest

Random forest is a supervised machine learning technique often used for classification purposes. The name originates from the fact that the model consists of an ensemble of decision trees – a forest. A decision tree is built such that each branching point represents a decision – comprising one or several features present in the data – based on which a sample progresses along either of the two branches when traversing the tree.

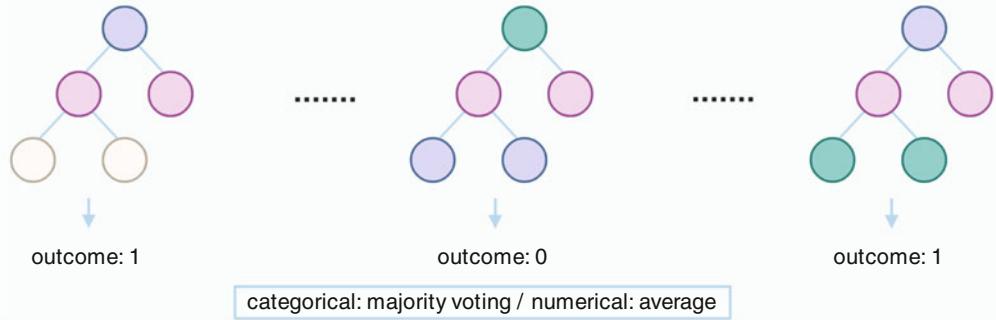

As an illustrative example consider the task of classifying a sample as belonging to either one of many specific cancer types or controls. For simplification purposes, imagine there existed a ubiquitous tumor suppressor gene g_1 where if the expression of g_1 drops below a threshold t_1 , the cell becomes tumorous without any further specification of the tumor. The expression level of g_1 could be utilized as a first branching point in a decision tree (Fig. 2a). Then, to distinguish between tumor types, imagine a distinctive marker gene g_i including a corresponding threshold t_i for each kind of tumor that would provide for further distinction along the tree (Fig. 2b).

In reality, genes that allow for such clear splits are rare and unknown, which makes the precise design of such an optimal decision tree impossible. Hence, the trees are built by randomly selecting the features for the next split, making one tree's prediction less reliable, a problem that is addressed by building an ensemble of trees. The ensemble utilizes the “wisdom of crowds” to reduce the classification error, following the idea that the majority of opinions is likely to be the correct one if the vote count is large enough. After collecting the outputs of all individual trees, the random forest classifies a given sample based on the majority of votes (Fig. 2c). In order for the ensemble to work, it is important that the single trees are as independent from another as possible. To ensure this, two techniques are typically used

Decision Trees

Fig. 2 Overview of selected machine learning methods. **Decision Trees.** (a) Example for an initial branching that separates the samples into “cancer” and “control,” given the expression level e_1 of a gene g_1 . (b) After the initial categorization, cancer samples are further classified based on the expression levels of cancer-type-specific genes. **Random Forest.** (c) Node colors represent features and each tree represents a different decision sequence. The ensemble of trees predicts the final outcome either by majority voting, in the case of categorical variables, or by

averaging, in the case of numerical variables. **Support Vector Machine.** (d) The hyperplane is found by maximizing the margin. In a two-dimensional plot, the hyperplane is represented by a line. Decreasing the slope in this case increases the margin from the left to the right. Final support vectors are indicated by a red border. (e) The data points cannot be optimally separated in the one-dimensional space (left). A polynomial kernel of degree 2 transforms the data into a higher dimensional space, where the linear separation becomes possible (right)

when building a random forest: Bagging (Bootstrap Aggregating) and feature randomness.

Bagging describes the process of creating a training set for each tree by sampling from the sample space while allowing elements to be chosen more than once (sampling with replacement). This results in a data set that only contains samples that were present in the original data set, but at different frequencies. The purpose of bagging is to expose the ensemble to versions of the data that incorporate small changes, making the model more robust towards aberrations in the input data.

Feature randomness refers to the construction of the decision trees. To avoid trees from looking too similar and therefore being strongly correlated, only a subset of random features is made available for each branching point, with the consequence that the trees represent different decision sequences.

Bagging and feature randomness attempt to make the trees as uncorrelated as possible and therefore reduce the error of the model [52].

Support Vector Machine

Support Vector Machines (SVMs) are a supervised machine learning method for classifying samples into two separate classes. In order to do so, the algorithm determines a hyperplane that divides the data points into the two classes such that the margin of that hyperplane is maximal. For data points with n-features which are therefore projected into an n-dimensional space, a hyperplane defines an $(n - 1)$ -dimensional subspace [53]. The margin of that hyperplane describes the minimum distance of a data point to the hyperplane. The margin is maximized if the hyperplane is in equal distance to the closest data point from each group (Fig. 2d). Once the hyperplane is found, it represents a decision boundary for new samples: The samples will be classified based on which side of the hyperplane they are located.

If the data points are arranged in a way such that no optimally separating hyperplane can be found in their original dimension, SVMs utilize kernel functions to project the data into a higher-dimensional space in which such a separation becomes possible (Fig. 2e). A kernel function

has the advantageous attribute of providing the dot product of two vectors – which is needed to determine the hyperplane – in higher dimensions, without explicitly having to map all of the data points to that dimension [54], which would come at great computational cost [55].

In the context of transcriptomics, SVMs can be utilized to classify a new sample as one or another biological group, e.g., “case” or “control.” The size of the feature space is defined by the genes considered for building the model. This can be either the unfiltered vector of genes that were quantified during the sequencing process or a subset acquired by a feature selection method. If n is the length of every sample’s expression vector, then the SVM would attempt to find an $(n - 1)$ -dimensional hyperplane that best segregates the samples into the two labelled groups within the N -dimensional feature space.

Support Vector Machines come with one distinct disadvantage, that is their restricted ability to only solve binary classification problems.

Lasso

The Least Absolute Shrinkage and Selection Operator (LASSO) is a variant of linear regression that addresses and solves the problem of overfitting inherent to the classical linear regression of ordinary least squares by adding a regularization term to the objective function. This regularization term is an L_1 -norm, the introduction of which imposes a minimization of the least absolute errors. The consequence of the regularization term in LASSO is that the coefficients of features with low predictive weight are shrunk to 0, which introduces sparsity into the feature space and therefore is accompanied by an explicit selection of features for the model [56]. In transcriptomics analyses of whole genome sequencing data, the analyst often faces expression values for several thousands of genes, all while a standard dataset only comprises a few hundred samples – and that would already be considered rather large. Here, LASSO is a helpful tool to extract a manageable number of genes to build a more comprehensive model. Consider a case in which the gene expression profiles of different cancer types are to be

analyzed with respect to finding a model that allows the prediction of the cancer type present in a sample. It is unlikely that all genes are involved in the cancer phenotype, but rather that there exists a subset of biomarkers that allow the discrimination between the different kinds and which are therefore represented by LASSO as features with nonzero weights [1].

K-Nearest Neighbors (KNN)

The k -nearest neighbors algorithm is a supervised machine learning algorithm that can be used for both classification and regression. The underlying assumption of the algorithm is that in a given feature space, those samples that have similar features are located in closer proximity to each other than samples with vastly different features. Given a labelled set of samples and a new, unlabelled sample the label of which is to be predicted, the distance of that unlabelled sample to every labelled sample is calculated based on a predefined distance measure (e.g., Euclidean distance, Manhattan distance, Minkowski distance). Subsequently, the k labelled samples with the smallest distance are selected. In the case of a classification task, the sample is assigned a label based on the label majority among its k -nearest neighbors, the output is hence discrete. In the case of regression, the sample is assigned the mean value of its k -nearest neighbors, the output is therefore real. Given that for every sample which is to be classified, all pairwise distances to the available labelled data points must be calculated, this algorithm quickly becomes infeasible with growing sample and feature space [57]. The growth in the feature space poses a particular issue when working with unfiltered transcriptomics data, since the number of dimensions of the feature space in which the samples are located equals the number of observed genes, therefore equating to a few thousands. Thus, to reduce the size of the feature space, a preselection of genes (feature selection) or their transformation into another, summarizing feature space (feature extraction) may be necessary depending on the available computing power.

Deep Neural Networks (DNNs)

Many supervised learning approaches use artificial neural networks (ANNs) or deep ANNs (DNNs). These comprise an input layer, which represents the data fed into the model, followed by one – or more in the case of DNNs – hidden layer and eventually an output layer representing the model's predictions [13]. Each layer consists of one or more neurons, the neurons of different layers are connected by weights. In the process of forward propagation, the input is transported from the input layer through the hidden layers and finally to the output layer. After comparing the predicted outcome to the true label, a reverse signal travels from the output layer back to the input layer, adjusting weights accordingly and improving the predictive power of the network. This process is called backpropagation. If the network only propagated the outputs from one layer to the other following the scheme above, the entire network would be linear and could therefore be condensed to a two-layer network – input and output layer only – that retrieves exactly the same results. Such a network would per definition not be a *deep* neural network. What actually characterizes a DNN and differentiates it from a regular ANN is nonlinearity. Nonlinearity is introduced by applying a nonlinear function to the output of each layer before forwarding that output to the next layer. The most common nonlinear function is ReLU (Rectified Linear Unit), which sets all negative outputs to zero [58, 59].

The application of DNNs to transcriptomics data has been the subject of research in recent years and is therefore a rather young topic. Different scenarios in which DNNs could provide insight into transcriptomics data are thinkable. In a straightforward approach, the input to the DNN could be directly provided as the gene expression vector of a given sample but also other representations that require a previous transformation, for instance, into an image format [60], have been discussed. For the output layer one could imagine a phenotype classification, functional assignment [60] or – in the case of bulk RNA-seq inputs – a deconvolution of cell types [61].
